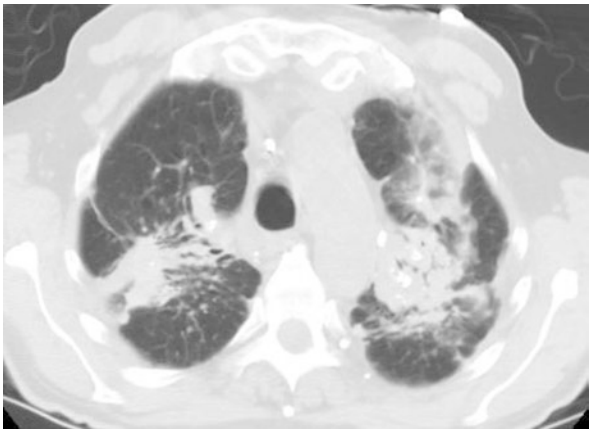
Silicosis. PA chest film demonstrates bilateral small nodules seen best over the lingual. [Goodman PC. Radiography and CT of occupational and environmental lung diseases. In: Huang Y-CT, Ghio AJ, Maier LA, editors. A clinical guide to occupational and environmental lung diseases [Internet]. Totowa, NJ: Humana Press; 2012 [cited 2015 Dec 22]. p. 59-92. Available from: http://link.springer.com/10.1007/978-1-62703-149-3_4] *Caption from original*

- Complicated silicosis occurs when the nodules grow or coalesce to greater than 1 cm in diameter. This usually is associated with significant fibrosis and usually leads to symptoms. As in CWP, these fibrotic nodules may become quite large and also lead to PMF and significant functional impairment and mortality. Once the process of fibrosis starts, it may continue even in the absence of continued exposure.



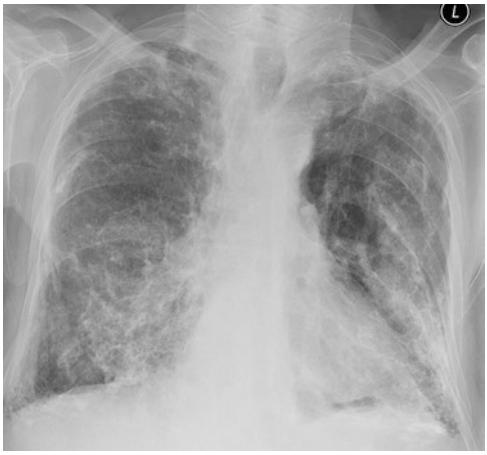
Silicosis. Single slice from a CT scan in lung windows demonstrates the typical upper posterior location of conglomerate opacities or progressive massive fibrosis in a patient with silicosis. Note the small clustered nodules posterior to the right-sided PMF as well as the bilateral hilar and mediastinal calcified lymph nodes. Also note that some calcified parenchymal nodules are incorporated in the PMF. [Goodman PC. Radiography and CT of occupational and environmental lung diseases. In: Huang Y-CT, Ghio AJ, Maier LA, editors. A clinical guide to occupational and environmental lung diseases [Internet]. Totowa, NJ: Humana Press; 2012 [cited 2015 Dec 22]. p. 59-92. Available from: http://link.springer.com/10.1007/978-1-62703-149-3_4] *Caption from original*

  - Acute silicosis is an uncommon syndrome that occurs after short-term exposure (about 1 year) to high concentrations of silica in confined spaces (e.g., from sandblasting or tunneling through rock with a high quartz content). It is manifest with progressive dyspnea and a chronic, usually nonproductive cough, although the patient occasionally may have gelatinous sputum, with low-grade fever and constitutional symptoms. CXR usually reveals a diffuse miliary pattern but may show diffuse alveolar opacities. HRCT shows a characteristic "crazy paving" pattern.

- Asbestos: *Asbestos* is a general term that refers to several mineral silicates. Silicate minerals are the predominant minerals in rock and make up 90 % of the earth's crust. These silicates differ from silica, which is silicon dioxide; rather, silicates have many different ratios of silicon to oxygen. Asbestos is characterized by being made up of long, thin, fiber-like crystals. Each visible fiber is composed of millions of microscopic "fibrils" that may be released by abrasion and other processes. Asbestos has been mined and used for millennia. It has excellent thermal, electrical, and acoustic insulating properties and is markedly fire resistant. Although synthetic materials largely have replaced asbestos use in developed nations, asbestos continues to be mined and used widely in developing countries. Asbestos predominantly affects the respiratory tract and causes pleural fibrosis, pulmonary fibrosis, cancers of the respiratory tract, and pleural and pulmonary mesothelioma. The development of asbestos-related diseases is

directly related to the extent and duration of exposure. In general, more than 10 years of exposure is necessary for any of these diseases to develop.

- *Asbestosis* is the term given to the pneumoconiosis associated with asbestos exposure. It is a diffuse, nodular, interstitial fibrosing disease of the lung. CXR usually shows the typical progression of disease, usually with pleural plaques as the initial finding. These plaques are observed as thickening or calcification of the parietal pleura, usually along the diaphragmatic border. Pleural plaques are a clue to significant asbestos exposure; they generally are asymptomatic and in isolation do not signify underlying pulmonary disease. Benign pleural effusions also may occur. As the disease progresses, CXR will show linear opacities in the lung bases that may become irregularly shaped and spread into the middle and upper lung zones. Severe disease may be associated with a diffuse ground-glass appearance and/or honeycombing on CXR. Once patients become symptomatic, they demonstrate restrictive pulmonary disease with decreased lung volumes and decreased diffusing capacity.



Asbestosis and asbestos-related pleural plaques. PA chest film demonstrates bibasilar heterogeneous irregular lung opacities (look at lung overlying both costophrenic angles) as well as calcified bilateral pleural plaques, many seen en face, which makes assessment of underlying lung disease difficult [Goodman PC. Radiography and CT of occupational and environmental lung diseases. In: Huang Y-CT, Ghio AJ, Maier LA, editors. A clinical guide to occupational and environmental lung diseases [Internet]. Totowa, NJ: Humana Press; 2012 [cited 2015 Dec 22]. p. 59-92. Available from: http://link.springer.com/10.1007/978-1-62703-149-3_4] *Caption from original*

- Other asbestos-related pulmonary disease:
  - Lung cancer is the most common cancer associated with asbestos exposure. It is directly related to the extent and duration of the exposure.

Smoking dramatically increases the risk of lung cancer in those exposed to asbestos. The risk is beyond what would be expected from just adding each risk (asbestos exposure and smoking) individually.

- Mesothelioma. Pleural and peritoneal mesothelioma is associated with asbestos exposure. It may occur with much less exposure and with prolonged latent periods (up to 40 years). Smoking does not appear to increase the risk of mesothelioma. Mesothelioma is much less common than lung cancer.

Presentation

Typical/"Classic"

- Pneumoconiosis may range from asymptomatic findings on imaging to severe, life-threatening restrictive pulmonary disease.
- Patients who develop symptoms usually will have slowly progressive shortness of breath and a dry cough.
- It usually is possible to obtain a history of occupational exposure to a known cause of pneumoconiosis.
- On examination, symptomatic patients usually have fine, inspiratory crackles.
- CXR and/or HRCT of the lungs usually show the typical changes of the inciting pneumoconiosis (see "Imaging").

Atypical

- Silicosis rarely may present more acutely, in patients who have been exposed to large amounts of silica dust in a small space (such as in tunneling and sandblasting). Acute silicosis may occur with short-term exposure (1 year or less). The presentation of acute silicosis is unlike that of usual silicosis (or other pneumoconioses), as it is not a restrictive disease. Although patients with acute silicosis have shortness of breath and cough, the cough may produce a copious amount of thick, white sputum. CXR may show diffuse, miliary nodules that subsequently develop into lobar consolidations. HRCT reveals the characteristic crazy-paving appearance of the lung parenchyma.

Primary Differential Considerations

- Pneumonia
- Acute exacerbation of COPD
- Pulmonary edema
- Acute exacerbation of asthma
- Lung cancer

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis often may be nearly confirmed by a history of prolonged occupational exposure to a known inciting agent.
- There are no pathognomic physical examination findings for pneumoconiosis. Patients often demonstrate the signs of restrictive lung disease, such as diffuse, fine inspiratory crackles. Later findings with more advanced disease may include digital clubbing and hypoxia.
- The aforementioned findings together with a confirmatory imaging study confirm the diagnosis.

Factors That Suggest Diagnosis

- A history of occupational exposure to a known inciting agent should suggest the diagnosis.
- Symptoms that occur, or worsen, only while the patient is at work strongly suggest an occupational cause.

Factors That Exclude Diagnosis

- The complete lack of any occupational/environmental/hobby exposure to any of the known inciting agents for pneumoconiosis should lead to evaluation for an alternative diagnosis.

Ancillary Studies

Pulmonary Function Studies

- Pulmonary function tests (PFTs) may be very helpful in the diagnosis of pneumoconiosis. PFTs should show a restrictive pattern, with diffusely decreased lung volumes (total lung capacity [TLC], functional residual capacity [FRC], residual volume [RV], and forced vital capacity [FVC]) and a decreased diffusing capacity for carbon monoxide (DLCO). As opposed to obstructive lung disease (asthma, COPD), airway resistance in restrictive lung disease is normal.

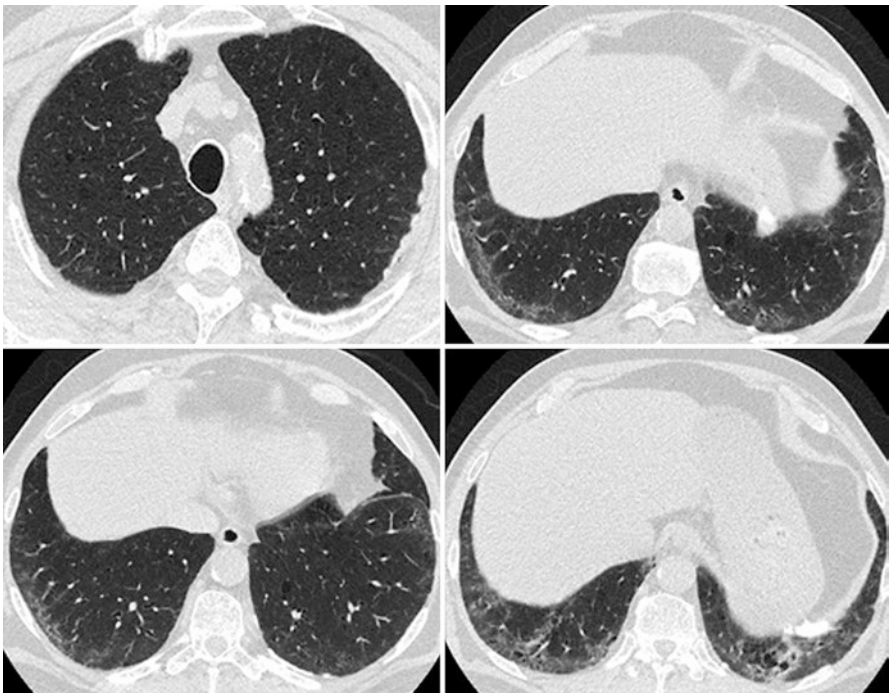
Laboratory

- There are no laboratory studies particularly helpful for the diagnosis or management of pneumoconiosis.

Imaging

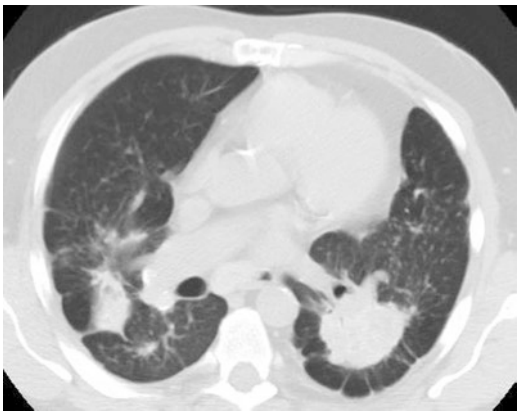
- CXR:
  - The plain CXR may be extremely useful in the diagnosis of pneumoconiosis.
  - In general, small round opacities in the upper lung zones are characteristic of both simple silicosis and simple CWP.
  - In both silicosis and CWP, the nodules may coalesce and grow to 1 cm or greater. Both diseases also progress to significant pulmonary fibrosis with larger areas of opacity as well as lung volume loss, usually noted in the upper lung zones. Sometimes these changes involve an entire lobe or even multiple lobes; this situation is termed progressive massive fibrosis.
  - About 20 % of patients with silicosis will develop calcification of the hilar lymph nodes, as seen on CXR; this is termed eggshell calcification and is characteristic of silicosis.
  - Asbestosis is characterized by pleural plaques (usually diaphragmatic) and small linear opacities in the lung bases. These opacities may spread to include all lung fields.
- HRCT of the lungs:

- HRCT is very helpful in the diagnosis and evaluation of all the ILDs.
- The changes associated with these diseases may be appreciated earlier and be more characteristic on HRCT as compared with CXR.
- HCRT has been shown to improve the detection and diagnosis of asbestosis compared with plain CXR.



HRCT scan of a 62 year old plumber with asbestosis showing linear opacities and subpleural nodular opacities (upper left), ground-glass attenuation, subpleural honeycombing, and calcified plaques [Müller-Quernheim J, Zissel G, Kayser G, Prasse A. Chronic beryllium disease and other interstitial lung diseases of occupational origin. In: Cottin V, Cordier J-F, Richeldi L, editors. Orphan lung diseases [Internet]. London: Springer; 2015 [cited 2015 Dec 22]. p. 473-91. Available from: http://link.springer.com/10.1007/978-1-4471-2401-6_30] *Caption from original*

- HRCT may lead to consideration of alternative ILDs in the differential diagnosis.
- HRCT may demonstrate the crazy-paving pattern typical of acute silicosis.



Coal worker's pneumoconiosis. Single slice of a CT scan demonstrates progressive massive fibrosis as represented by the larger opacities posterior to midline in the upper lobes. Just adjacent to the masses are very small nodular opacities which represent the earlier changes of coal worker's pneumoconiosis. As these small nodules coalesce, the large opacities are formed. As the masses migrate centrally, areas of emphysema are formed in the lung periphery as seen here bilaterally [Goodman PC. Radiography and CT of occupational and environmental lung diseases. In: Huang Y-CT, Ghio AJ, Maier LA, editors. A clinical guide to occupational and environmental lung diseases [Internet]. Totowa, NJ: Humana Press; 2012 [cited 2015 Dec 22]. p. 59-92. Available from: http://link.springer.com/10.1007/978-1-62703-149-3_4] *Caption adapted from original*

Special Populations

Age

- Given the decades-long latency between exposure and disease, these are diseases of middle-aged to older adults.

Co-morbidities

- There are multiple comorbidities of importance. Many of these patients also have risk factors for other pulmonary diseases, such as COPD, from other exposures and smoking, making the diagnosis and management more difficult.

- In many patients, the etiology of their pulmonary disease is multifactorial and includes occupational, environmental (smoking, air pollution), and genetic factors.
- Any cause of chronic dyspnea and cough (COPD, CHF, another ILD) may coexist with a pneumoconiosis.
- Patients with silicosis have decreased alveolar macrophage numbers and function, because silica is cytotoxic to these macrophages. These patients then have an increased risk and incidence of pulmonary infections associated with decreased macrophage function, primarily tuberculosis, atypical mycobacterial pneumonia, and fungal pneumonia.
- Silicosis (and to a lesser extent, CWP) also is associated with an increased incidence of autoimmune connective tissue diseases, such as rheumatoid arthritis (both silicosis and CWP) and scleroderma (silicosis only). Seropositive rheumatoid arthritis associated with findings of simple silicosis or simple CWP on CXR has been called Caplan's syndrome.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critical to obtain a complete occupational, environmental, and hobby history to be able to ascertain any significant exposures the patient may have sustained.
- If supported by the history, and the diagnosis is being considered, it is critical to perform appropriate imaging (CXR, HRCT) and PFTs to secure the diagnosis.

Mimics

- Many different diseases may present similarly to pneumoconiosis (with dyspnea and cough), including all the ILDs, COPD, asthma, and CHF.
- With an appropriate history, examination, imaging, and PFTs, the mimics include other restrictive lung diseases, such as other ILDs.

Time-Dependent Interventions

- These disorders tend to be chronic and slowly progressive, so there are no significant time-dependent interventions.

- If a patient presents with hypoxia, oxygen should be administered.
- If a patient is having ventilatory difficulty, ventilation should be supported. Patients with ventilatory difficulty generally have advanced disease, and the approach to managing ventilatory emergencies would ideally have been discussed with the patient and family and decisions made before the acute event.

Overall Principles of Treatment

- There is no specific treatment for any pneumoconiosis.
- Treatment tends to be supportive and should proceed as for most restrictive lung diseases.
- Patients with hypoxia require oxygen.
- Patients with silicosis should be monitored for atypical lung infections, such as tuberculosis.
- All patients should receive routine care as appropriate for any patient with chronic lung disease, including appropriate vaccinations (influenza, pneumococcus).
- Patients who smoke tobacco should be offered all assistance needed to stop.
- Patients still working in an occupation with risk for continued exposure should stop or be moved to a position with no exposure risk.
- These patients may be at increased risk for lung cancer and may need periodic monitoring.

Disease Course

- These diseases are slowly progressive.
- The diseases may continue to progress even after the exposure has stopped.
- There is a large individual variation in the severity of disease. Although development of a pneumoconiosis is related to the extent and duration of exposure, severity of disease is less so.
- Many patients will remain asymptomatic, with only CXR findings, throughout their lives. Some patients may develop only minor symptoms; others may progress to life-altering and -shortening disease.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_58

Pneumococcal pneumonia, Chest radiograph of a black African man aged 19 years who presented with a 1-week history of cough, fever, and chest pain. Radiograph shows dense consolidation of the right upper lobe. Differential diagnosis included Klebsiella pneumonia. Sputum Gram stain and blood culture confirmed Streptococcus pneumoniae. The patient also had marked weight loss and oropharyngeal candidiasis. [Lalloo UG, Ambaram A, Vawda F. Pulmonary Complications. In: Mildvan D, editor. International Atlas of AIDS. 4e.: Current Medicine; 2008. 366 p. ISBN: 1-57340-270-2] *Caption adapted from original*

- Chest pain due to pneumonia tends to be pleuritic in nature.
- Pneumonia may be caused by any of a broad variety of infectious agents, including viruses, bacteria, fungi, rickettsiae, and parasites.
- Pneumonia is typically classed as community-acquired (community-acquired pneumonia or "CAP"), healthcare- (or hospital-) associated (HCAP or HAP), or ventilator-associated (VAP). Each of these classifications carries a largely predictable etiologic profile. Classification does not usually affect the chest pain presentation of pneumonia, although pneumococcal pneumonia and infections that cause pleural effusions or lung abscesses typically present with more severe pain.
- The bacterial pathogens that cause pneumonia may be "typical" (such as pneumococcal, *Hemophilus*, or staphylococcal) or "atypical" (such as *Mycoplasma* or *Chlamydophila*). Pathogen does not usually affect the chest pain presentation of pneumonia.

Pathogen	CAP	HAP/HCAP	Adults	Children
Bacteria				
S. pneumoniae	+++	+++	+++	+++
H. influenzae	++	++	++	++
M. pneumoniae	+++	+	++	+++
Chlamydia spp.	+		(+)	++
Klebsiella spp.	+	++		
Legionella spp.	++	+++		
S. aureus	++	+++	+++	+
P. aerugenosa	+	+++	+	
Acinetobacter spp.		++		
Viruses				
RSV	++		+	+++
Rhinovirus	++		(+)	++
Influenza virus	++	+	+	++
Parainfluenza virus	++		+	++
Fungi				
Candida spp.		++1		
Aspergillus spp.		++1		
P. jirovecii		+2		

+ indicates the relative importance of the pathogen and the frequency of isolation in adults or children. 1 of importance in immunocompromised hosts. 2 important opportunistic pathogen in HIV/AIDS patients. CAP, community-acquired pneumonia; HAP, hospital-acquired pneumonia; HCAP, health-care associated pneumonia. Based on collective data [2,5,6,15-18,23,252,253].

Important pathogens causing pneumonia. (See article for data sources.) [From article: Lung epithelium as a sentinel and effector system in pneumonia – molecular mechanisms of pathogen recognition and signal transduction. Respiratory Research. 2006 Jul 8;7(1):97. https://doi.org/10.1186/1465-9921-7-97, at http://link.springer.com/article/10.1186/1465-9921-7-97; by Stefan Hippenstiel, Bastian Opitz, Bernd Schmeck, Norbert Suttorp, © Hippenstiel et al. 2006; licensee BioMed Central Ltd.; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption adapted from original*

Differential Diagnosis

- The differential considerations for chest pain due to pneumonia are for the most part other primary lung diagnoses such as pulmonary embolism and pleurisy.
- As in all chest pain presentations, immediate life threats such as acute coronary syndrome and aortic dissection should always be considered.
- Less severe differential considerations include pneumothorax, which can cause pleuritic pain, as well as chest wall pain/costochondritis, and anxiety.
- Pericarditis may present similarly to pneumonia and may also be accompanied by fever.
- Acute chest syndrome in sickle cell disease is a differential consideration in at-risk patients.

Pathophysiology and Etiology

- The clinical manifestations of pneumonia result from a variable combination of actual infection, as well as the host's inflammatory response to the infection.
- The actual etiologic agents behind pneumonia would require an exceedingly long list. For purposes of considering pneumonia in the differential diagnosis of chest pain syndrome, pain is typically caused by inflammation of the pleura. Chest pain in pneumonia can also result from lung abscess, pleural effusion or empyema, myalgias associated with a more systemic infection, or chest wall pain from coughing.

Presentation

Typical/"Classic"

- The classic presentation of pneumonia includes:
  - Cough, which may or may not be productive.
  - Fever, which may be mild or high.
  - Shortness of breath, typically more evident with exertion.
  - Chills.

Atypical

- Especially with "atypical" etiologies, pneumonia may present with more prominent extrapulmonary symptoms, such as headache, myalgias, sore throat, gastroenteritis-type symptoms, or fatigue. Chest pain may or may not be a prominent feature at presentation.
- Elderly patients with pneumonia may present with altered mental status. Chest pain may or may not be a prominent feature at presentation.

Extra-pulmonary symptoms	Chills, nausea, vomiting, altered sensorium, diarrhea, delirium, worsening of a chronic confusion, fall to the ground
Pulmonary symptoms	Dyspnea, pleuritic chest pain
Signs of pneumonia	Fever, crackles, cough
Clinical features suggestive of aspiration pneumonia	Evident macroaspiration
	Reduced level of consciousness
	Dysphagia
	Mechanical or neurological dysfunction of the high gastrointestinal tract

Signs and symptoms most commonly associated with pneumonia in elderly patients. [Falcone M, Blasi F, Menichetti F, Pea F, Violi F. Pneumonia in frail older patients: an up to date. Internal and Emergency Medicine. 2012 Oct;7(5):415–24.] *Caption from original*

- *Mycoplasma* pneumonia may present with ear pain (from bullous myringitis) or with rashes (such as erythema multiforme). Chest pain may or may not be a prominent feature at presentation.

Characteristics	*M. pneumoniae*	*S. pneumoniae*	*p* value
Number	64	68

WBC mean (/μL)	7,400	13,800	<0.0001

*Data represent the numbers of patients, and numbers in parentheses are percentages.
**PSI, pneumonia severity index.

Clinical characteristics in patients with *Mycoplasma pneumoniae* pneumonia and *Streptococcus pneumoniae* pneumonia on admission* [From article: Radiographic features of *Mycoplasma pneumoniae* pneumonia: differential diagnosis and performance timing. BMC Medical Imaging. 2009;9(1):7. https://doi.org/10.1186/1471-2342-9-7, at http://link.springer.com/article/10.1186/1471-2342-9-7; by Naoyuki Miyashita, Tadaaki Sugiu, Yasuhiro Kawai, Keiko Oda, Tetsuya Yamaguchi, Kazunobu Ouchi, Yoshihiro Kobashi, Mikio Oka, © Miyashita et al; licensee BioMed Central Ltd. 2009; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

- *Chlamydophila* pneumonia may present with bronchospasm and wheezing even in nonasthmatics, but it should be noted that patients with underlying asthma or COPD who present with pneumonia are likely to be wheezing. Chest pain may or may not be a prominent feature at presentation.
- Patients with pneumonia may present with overwhelming sepsis, but chest pain is typically not the most prominent feature.

Primary Differential Considerations

- Early consideration should be given to bronchitis, acute exacerbation of COPD, foreign body aspiration, asthma, and ARDS.

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination cannot confirm the presence of pneumonia.

Factors That Suggest Diagnosis

- A history of fever, chills, and/or sputum production—especially hemoptysis—is suggestive of pneumonia in the patient with chest pain.
- Findings of consolidation of pulmonary exam—such as egophony and percussion dullness—are suggestive of pneumonia.

https://www.youtube.com/watch?v=48nzLXnEHvg
Percussion of the Chest (Stanford Medicine 25 video): Demonstrates percussion technique and surface anatomy

- Tachycardia and reduced pulse oximetry readings are suggestive of pneumonia in the patient with chest pain.
- Wheezing, rales, and pleural friction rub may all suggest pneumonia in the patient with chest pain.

Pleural Friction Rub

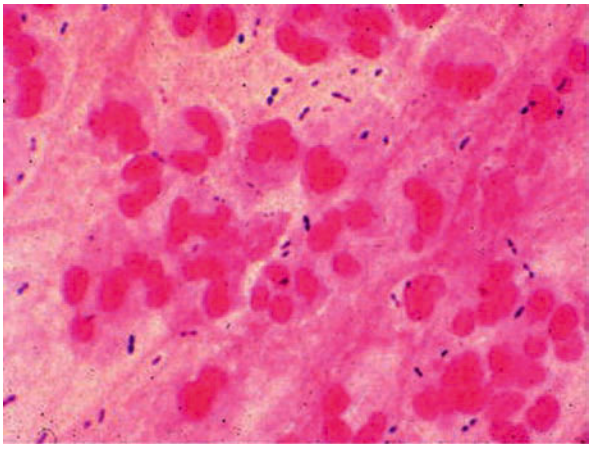
Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude pneumonia in the patient with chest pain.

Ancillary Studies

Laboratory

- Bacterial pneumonia is confirmed, not in real time, by the presence of a positive bacterial culture from sputum or blood.
- Various diagnostic tests performed on sputum, blood, or urine can provide confirmation of the etiology of a clinical pneumonia.
- Sputum Gram stain is a notoriously unreliable test for evaluating possible pneumonia.



Gram stain of sputum sample from patient with pneumococcal pneumonia. Note diploid organisms surrounded by polymorphonuclear cell infiltrate [Shelburne S, Musher DM. Management of Gram-Positive Bacterial Disease: Staphylococcus aureus, Streptococcal, Pneumococcal and Enterococcal Infections. In: Safdar A, editor. Principles and Practice of Cancer Infectious Diseases [Internet]. Totowa, NJ: Humana Press; 2011 [cited 2015 Jun 2]. p. 409–21. Available from: http://link.springer.com/10.1007/978-1-60761-644-3_35] *Caption from original*

- A CBC in pneumonia will typically show an elevated WBC count except in severely immunocompromised patients. This is also less likely in viral pneumonias.
- *Legionella* pneumonia is often associated with hyponatremia.

	Patients with Legionella that met IDSA/ATS criteria for Legionella testing	Patients with Legionella that did not meet IDSA/ATS criteria for Legionella testing	All patients with Legionella pneumonia
Male	15	9	24 (65%)
Recent travel	1	0	1 (3%)
History of alcohol abuse	6	0	6 (16%)

SD, standard deviation; TNF, tumor necrosis factor; COPD, chronic obstructive pulmonary disease; abnormal liver function test defined as above reference range; Crude mortality defined as in-hospital death or discharge to hospice care with impending death.

Characteristics of Adult Patients with *Legionella* Pneumonia, 2005-2009 [From article: How often is a work-up for *Legionella* pursued in patients with pneumonia? A retrospective study. BMC Infectious Diseases. 2011; 11(1):237. https://doi.org/10.1186/1471-2334-11-237, at http://link.springer.com/article/10.1186/1471-2334-11-237; by Brian Hollenbeck, Irene Dupont, Leonard A Mermel, © Hollenbeck et al; licensee BioMed Central Ltd. 2011; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

- Normal laboratory studies do not exclude pneumonia as a cause of chest pain.

Imaging

- Chest radiography can confirm the presence and location of pneumonia.

Hospital-acquired pneumonia. Chest radiograph of a patient with hospital-acquired pneumonia. This patient developed bilateral infiltrates after aspirating postoperatively. [Rumbak MJ. Nosocomial infections including pneumonia. In: Crapo JD, editor. Bone's Atlas of Pulmonary Medicine. 3rd edition. Philadelphia, PA: Current Medicine Group; 2005. 338 p. ISBN: 1-57340-211-7] *Caption adapted from original*

- Chest radiography can identify abscesses, cavities, and pleural involvement.

Chest radiograph of a patient with complicated lung abscess. [Ayed AK, Al-Rowayeh A. Lung resection in children for infectious pulmonary diseases. Pediatric Surgery International. 2005 Aug;21(8):604–8.] *Caption from original*

- Chest radiography can be used to follow the treatment success (or lack thereof) of pneumonia management.
- A normal chest radiograph does not exclude pneumonia, as patients who are immunocompromised, dehydrated, or very early in the disease process may not show an infiltrate. Chest CT may be helpful in patients suspected of having pneumonia but lacking diagnostic certainty on plain chest radiography.

Computed tomography (CT) findings of organizing pneumonia on admission. Multiple consolidations with sub-pleural distribution were detected in both lungs by CT scan. The lesions were accompanied by ground glass opacities. [Nakamura H, Kita J, Kawakami A, Yamasaki S, Ida H, Sakamoto N, Furusu A, Eguchi K. Multiple bone fracture due to Fanconi's syndrome in primary Sjögren's syndrome complicated with organizing pneumonia. Rheumatology International. 2009 Dec;30(2):265–7.] *Caption from original*

Special Populations

Age and Gender

- Pneumonia occurs in all age, ethnic, and socioeconomic groups. It occurs in both males and females.
- Pneumonia often has poorer outcomes at the extremes of age.
- In children, atypical pathogens predominate.
- In newborns and infants, viruses (including RSV), pneumococcus, and aspiration are important etiologic ocnsiderations.

- Current recommendations for the management of community-acquired pneumonia in children include:
  - Viral testing for infants less than 1 year.
  - Avoidance of routine chest radiographs.
  - Omission of blood work, including CBC's and blood cultures.
  - Use of amoxicillin in pre-school children.
  - Use of a macrolide in school-age children.

Co-morbidities

- Co-morbidities associated with the various types of pneumonia include but are not limited to:
  - congestive heart failure
  - cancer
  - chronic renal failure
  - COPD and chronic respiratory failure
  - chronic hepatic disease
  - alcoholism
  - diabetes mellitus
  - neurologic disease
  - immunosuppression, including HIV infection

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Except in significantly compromised patients, pneumonia is most often not a life-threatening diagnosis. Still, it is a cause of significant morbidity, loss of productivity, and cost. Even in immunocompetent patients, pneumonia can cause sepsis and death. It is therefore critical to at least consider the diagnosis in the patient with chest pain, and a chest radiograph often gives useful information.

Mimics

- The entire constellation of diagnoses that underlies chest pain syndrome, especially those often accompanied by dyspnea, can mimic the pain and overall presentation of pneumonia. Be especially cognizant of pulmonary embolism as a mimic, as PE has a higher case-mortality rate than pneumonia.
- Pericarditis may mimic pneumonia in presentation. Listen for a pericardial friction rub.

http://www.easyauscultation.com/acute-pericarditis

Acute Pericarditis Audio Recordings. [Acute Pericarditis; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

Time-Dependent Interventions

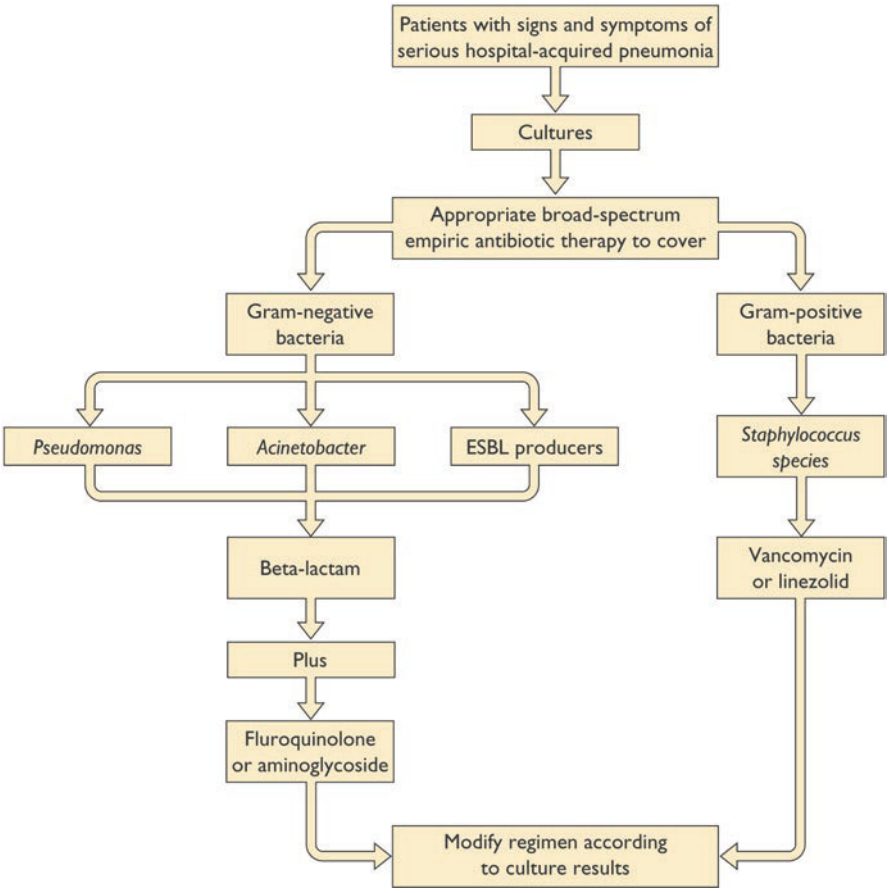
- Anti-infective therapy, usually at first with empiric antibiotic therapy, should be initiated when the diagnosis of pneumonia is strongly considered or confirmed. Consult your local antibiogram for guidance on choosing a specific agent.
- Choice of antimicrobial is also driven by the classification of the pneumonia (CAP vs HAP vs VAP).

Overall Principles of Treatment

- Anti-infective therapy is the mainstay of pneumonia treatment. Unfortunately, treatment is not always guided by positive microbiologic or virologic results.

Patient status	Treatment
Outpatient (previously healthy without history of antimicrobials in the last 3 months)	Macrolide or Doxycycline
Outpatient (comorbidities such as chronic heart, lung, liver or renal disease, diabetes, alcoholism, malignancy, asplenia, immunosuppressed, or history of antimicrobials in the last 3 months)	Respiratory fluoroquinolone or Beta lactam plus macrolide
Inpatient (non-ICU)	Respiratory fluoroquinolone or Beta lactam plus macrolide
Inpatient (ICU)	Beta lactam plus Either azithromycin or respiratory fluoroquinolone
Inpatient (with concern of *Pseudomonas*)	Antipneumococcal, antipseudomonal beta lactam (piperacillin–tazobactam, cefepime, imipenem, or meropenem) plus ciprofloxacin or levofloxacin or Above beta lactam plus either aminoglycoside or azithromycin or Above beta lactam plus azithromycin and aminoglycoside
Inpatient (with concern of methicillin-resistant *Staphylococcus aureus*)	Add vancomycin or linezolid to regimen

Recommendations for empiric treatment of community-acquired pneumonia. [Nguyen HH. Pneumonia. In: Mainous III AG, Pomeroy C, editors. Management of Antimicrobials in Infectious Diseases [Internet]. Totowa, NJ: Humana Press; 2010 [cited 2015 Jun 3]. p. 169–82. Available from: http://link.springer.com/10.1007/978-1-60327-239-1_9] *Caption from original*



Treatment of patients with ventilator-associated pneumonia (VAP). This algorithm suggests initial broad-spectrum antibiotics to cover gram- negative and gram-positive bacteria. Once the cultures are back from the laboratory, the antibiotics are tailored to the bacteria. "Beta-lactams" here include carbapenems and monolactems. ESBLS and *Acinetobacter* may respond best to carbapenems. ESBL—extended-spectrum β-lactams [Rumbak MJ.Nosocomial infections including pneumonia. In: Crapo JD, editor. Bone's Atlas of Pulmonary Medicine. 3rd edition. Philadelphia, PA: Current Medicine Group; 2005. 338 p. ISBN: 1-57340-211-7] *Caption from original*

- Chest pain associated with pneumonia usually improves quickly as the infection resolves. Non-steroidal anti-inflammatory drugs or narcotics can be given to patients with persistent or severe pain.

Disease Course

- The course pneumonia varies widely with mortality rates as high as 50% in some severely compromised patients, and as low as less than 1% in immunocompetent, nonsmoking adults with CAP.

Chapter 59
Pneumothorax (Simple)

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Simple pneumothorax; dropped lung; ruptured lung; ruptured bleb

Incidence/Epidemiology

- Because simple pneumothorax may be largely or completely asymptomatic, the incidence is clearly underestimated. It ranges from 2–60 per 100,000 people per year, depending on gender and associated lung disease.
- Primary spontaneous pneumothorax is more common in men than in women, and is more common in smokers than in nonsmokers.
- Primary spontaneous pneumothorax occurs most commonly in the third decade of life and is rare after the fifth decade.
- Secondary spontaneous pneumothorax tends to occur in older patients because of the prevalence of underlying lung disease in those patients.
- Traumatic pneumothorax can occur at any age and may result from accidental or iatrogenic trauma.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_59

Differential Diagnosis

- The differential considerations for pneumothorax are primarily driven by the size of the pneumothorax and the extent of any underlying lung disease. Exacerbations of asthma and COPD may both precipitate and present similarly to simple pneumothorax. Other causes of dyspnea and pleuritic chest pain, alone or together, should also be considered, including pulmonary embolism, pneumonia, pleurisy, mediastinal disorders, and anxiety.

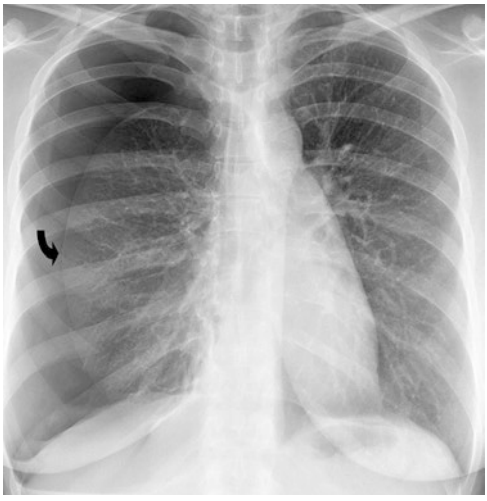
Pathophysiology and Etiology

- Pneumothorax is defined by the presence of air in the pleural space, which is the ordinarily tiny space between the visceral and parietal layers of the pleura.

Primary spontaneous (simple) pneumothorax
Secondary spontaneous (complicated) pneumothorax
Catamenial pneumothorax
Pneumothorax associated with drug abuse
Iatrogenic pneumothorax
Pneumothorax associated with mechanical ventilation
Traumatic pneumothorax
Tension pneumothorax

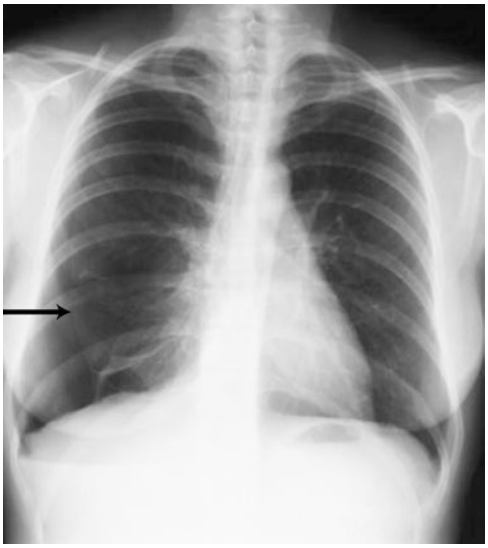
Types of pneumothorax. Primary spontaneous pneumothorax occurs in patients without underlying lung disease. It usually occurs in young, tall, slender male patients. Secondary pneumothoraces occur in those patients with underlying lung disease. Pneumothorax has also been associated with drug abuse and is believed to be related to the inhalational route of drug abuse, in which the abuser performs a Valsalva maneuver with generation of pressures greater than 200 cm H2O. Iatrogenic pneumothorax occurs most commonly during attempted central line placement, with the risk between 3% and 6% for subclavian placement and about 1% to 2% with internal jugular catheterization. Traumatic pneumothorax may be caused by blunt or penetrating trauma and may have associated hemopneumothorax and other vascular injuries. [Szokol J, Vender J. Respiratory emergencies (pulmonary aspiration of gastric contents, acute epiglottis, anterior mediastinal mass). In: Tremper KK, editor. Principles of anesthetic techniques and anesthetic emergencies. Philadelphia: Current Medicine; 1998. 195 p. (Miller RD, editor. Atlas of anesthesia; vol. 4). ISBN: 0-443-07903-X] *Caption from original*

- Simple pneumothorax may be small and asymptomatic or larger, resulting in dyspnea. Depending on the size of the pneumothorax, the adjacent lung may be deformed or compressed, or totally collapsed. Simple pneumothorax is differentiated from the more obvious, more symptomatic, and life-threatening "tension pneumothorax" by the fact that in the latter, the pressure in the pleural space is positive throughout the respiratory cycle, resulting in forced deviation of the mediastinum to the contralateral side.



Tension pneumothorax. Portable chest radiograph demonstrates large right-sided tension pneumothorax (curved arrow) with mediastinal shift to the left side [Carter BW, Muse VV. Imaging of Nontraumatic Mediastinal and Pulmonary Processes. In: Singh A, editor. Emergency Radiology [Internet]. New York, NY: Springer New York; 2013 [cited 2015 Aug 31]. p. 321–32. Available from: http://link.springer.com/10.1007/978-1-4419-9592-6_23] *Caption from original*

- Simple pneumothorax may be spontaneous (primary or secondary) or traumatic:
  - Primary spontaneous pneumothorax is usually the result of rupture of an apical pleural bleb or bulla, a small cystic space lying just under the visceral pleura. The designation "primary" is meant to imply the absence of underlying lung disease, but primary spontaneous pneumothorax occurs more commonly in smokers than in nonsmokers, indicating the likely presence of subclinical lung pathology. The "primary" also signifies the absence of a known inciting event, such as trauma. A special case is so-called "catamenial" pneumothorax, which typically occurs in women age 30–40, presents within 48 hours of menses onset, and may be recurrent.



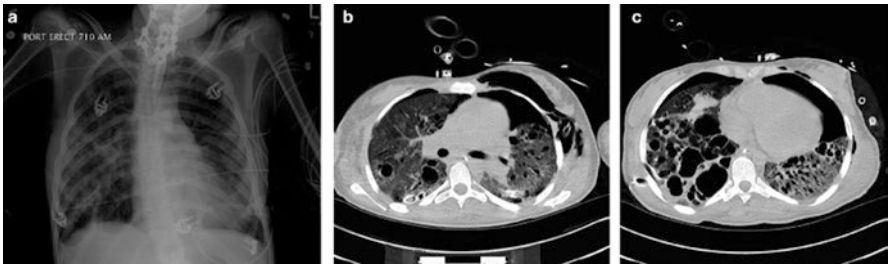
Catamenial pneumothorax. Chest radiograph of a 31-year-old nonsmoking woman with multiple spontaneous right-sided pneumothoraces who presented with acute onset of pleuritic chest pain and dyspnea. There is a large right-sided pneumothorax; the arrow signifies the 1 mm visceral pleural line. [Huggins J, Sahn S. Pleural disease. In: Crapo J, editor. Bone's atlas of pulmonary and critical care medicine. Philadelphia: Current Medicine; 2005. Chapter 25. ISBN: 1-57340-211-7] *Caption adapted from original*

  - Secondary spontaneous pneumothorax has been reported with virtually all lung diseases, but is most common with COPD. Air enters the pleural space through distended or damaged alveoli.
  - Traumatic pneumothorax occurs as a result of physical disruption of the pleura, either from blunt force pressure or from puncture. Puncture may be accidental, as in blunt trauma with rib fracture, or iatrogenic, as in puncture of the pleura during placement of a central venous catheter.

- Primary spontaneous pneumothorax is more likely to occur in tall, thin individuals. There is an association with Marfan's syndrome. It is much more common in smokers than in nonsmokers. There seems to be a familial tendency to develop primary spontaneous pneumothorax. It is also more common during pregnancy.

Clinical features. Many of the typical features of Marfan's syndrome are seen in this patient, including arm length greater than height, increased lower to upper extremity ratio, pectus excavatum, and pes planus. [Maricic M, Ko M. Diseases of bone and connective tissue. In: Hunder G, editor. Atlas of rheumatology. Philadelphia: Current Medicine; 2005. Chapter 6. ISBN: 1-57340-210-9] *Caption adapted from original*

- Secondary spontaneous pneumothorax is most common in patients with obstructive lung disease, such as COPD or asthma, in which intrathoracic pressures are higher. It is also more common in pneumonia (including necrotizing pneumonia, *Pneumocystis* pneumonia in AIDS, and tuberculosis), sarcoidosis and other connective tissue diseases, and lung neoplasms.
- Accidental traumatic pneumothorax may result from penetrating or nonpenetrating (blunt) injury. Iatrogenic traumatic pneumothorax has been reported with:
    - Central venous catheter insertion (subclavian or internal jugular)
    - Lung, pleural, or mediastinal biopsy
    - Intercostal nerve block
    - Chest compressions for CPR
    - Positive-end-expiratory pressure (PEEP) ventilation



AP chest radiograph (a) axial CT (b, c) confirms the presence of subcutaneous emphysema and bilateral pneumothorax in this ICU patient who developed barotrauma secondary to high levels of PEEP. There is evidence of acute respiratory distress syndrome (ARDS). [Boiselle PM, Dass C, Steiner RM. Radiologic Imaging in the Critically Ill Patient. In: Criner GJ, Barnette RE, D'Alonzo GE, editors. Critical Care Study Guide [Internet]. New York, NY: Springer New York; 2010 [cited 2015 Aug 31]. p. 181–207. Available from: http://link.springer.com/10.1007/978-0-387-77452-7_11] *Caption from original*

Presentation

Typical/"Classic"

- Pleuritic chest pain and shortness of breath are the most common findings in simple pneumothorax at presentation. Pain is often of sudden onset. With larger pneumothorax volumes, patients may manifest hypoxemia and have hemodynamic instability or mental status changes.
- The diagnosis of simple pneumothorax is made on chest radiography—typically a plain CSR, sometimes computed tomography. Ultrasound is occasionally used.
- Patients with traumatic pneumothorax usually offer a pertinent history.
- Patients with primary spontaneous pneumothorax are typically tall and thin and are often smokers.
- Patients presenting with secondary spontaneous pneumothorax often manifest signs and symptoms of their underlying lung disease.

Atypical

- Patients with pneumothorax of sufficient size to be diagnosed will have some dyspnea. Chest pain may not be the presenting complaint.
- There may be distractions to the presentation, as in catamenial pneumothorax, which occurs within 48 hours on onset of menses.

Primary Differential Considerations

- When evaluating a patient suspected of having a pneumothorax, early consideration should be given to these differential diagnoses:
  - Acute coronary syndrome
  - Asthma
  - Pneumonia
  - Pulmonary embolism
  - Rib fracture

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination are key to diagnosing simple pneumothorax, but the magnitude of those findings is dependent almost wholly on the side of the pneumothorax. With larger lesions, patients are quite dyspneic. With smaller lesions, the diagnosis may prove elusive. Chest radiography is diagnostic.

Factors That Suggest Diagnosis

- Pleuritic chest pain and dyspnea on history are suggestive but not confirmatory.
- Those same findings in smokers, asthmatics, Marfanoid body habitus, women within 48 hours of menses onset, recent sharp procedure above the diaphragm, or recent thoracic trauma should be suspected of having pneumothorax.
- Patients with larger pneumothoraces are likely to show signs of frank respiratory distress, including tachycardia, tachypnea, diaphoresis, and pallor or cyanosis. These patients are also more likely to manifest asymmetric breath sounds upon careful lung auscultation.
- The larger the pneumothorax, the more likely it is that the patient will have tracheal shift (classic for tension pneumothorax), hyperresonance upon percussion of the affected lung, or jugular venous distention.

Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude simple pneumothorax.

Ancillary Studies

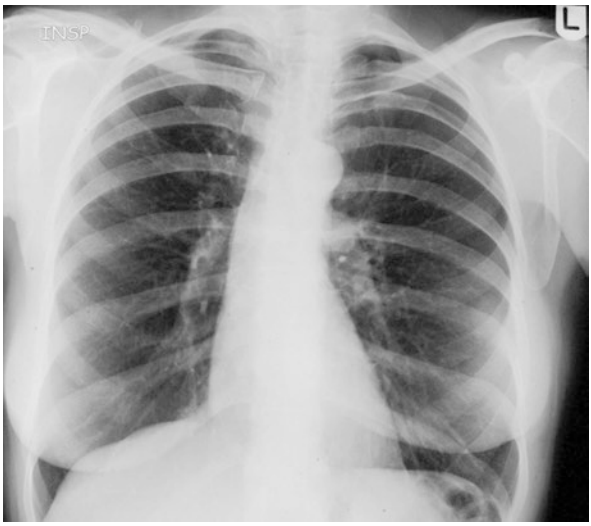
Laboratory

- There are no diagnostic laboratory studies for pneumothorax. Patients with secondary spontaneous pneumothorax should undergo laboratory screening pertinent to their underlying diagnosis.

Imaging

- The diagnosis of simple pneumothorax is confirmed on chest radiography. Small pneumothoraces may only be visible on computed tomography of the chest. Look for a thin line representing the pleura separate from the chest wall. The upright, inspiratory posteroanterior film offers the best opportunity of demonstrating a simple pneumothorax.

Poteroanterior upright chest X-ray shows large pneumothorax of the right lung [Kim S-H, Yoo W-H. Recurrent pneumothorax associated with pulmonary nodules after leflunomide therapy in rheumatoid arthritis: a case report and review of the literature. Rheumatology International. 2011 Jul;31(7):919–22.] *Caption from original*



CXR in inspiration showing left sided small pneumothorax [From article: Pneumothorax after a clinical breast fine-needle aspiration of a lump in a patient with Poland syndrome. International Seminars in Surgical Oncology. 2005 Aug 19;2(1):14. https://doi.org/10.1186/1477-7800-2-14, at http://link.springer.com/article/10.1186/1477-7800-2-14; by M Salhab, W Al Sarakbi, N Perry, K Mokbel, © Salhab et al; licensee BioMed Central Ltd. 2005; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

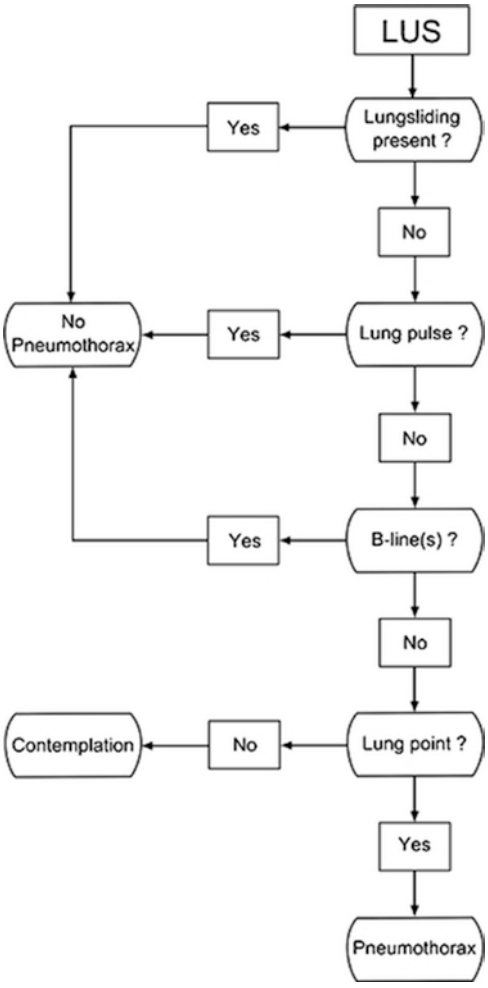
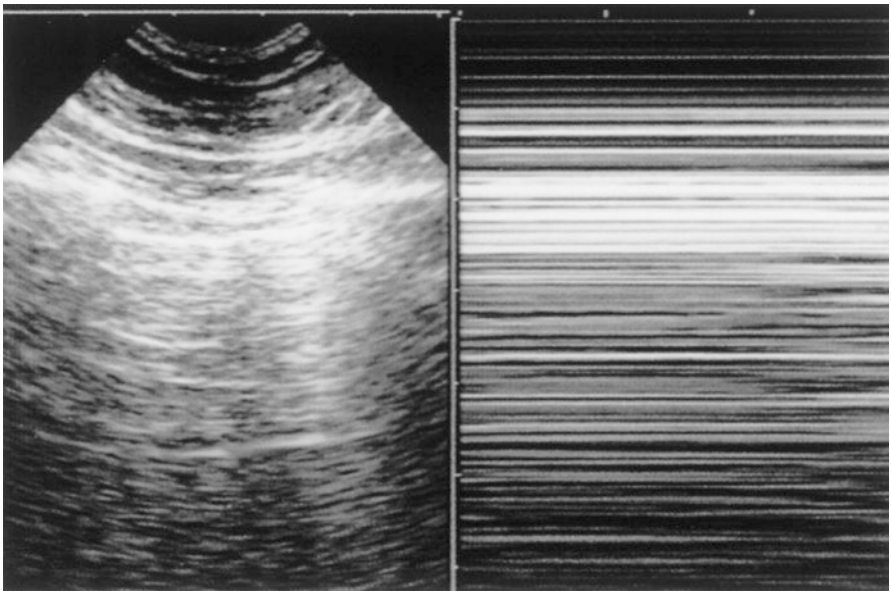
Spontaneous pneumothorax in a patient with dendriform pulmonary ossification: report of a case. Surgery Today. 2012 Sep;42(9):903–8.] *Caption from original*

- The lateral film may be especially helpful.
- The lateral decubitus film (affected side up) may better demonstrate a simple pneumothorax.

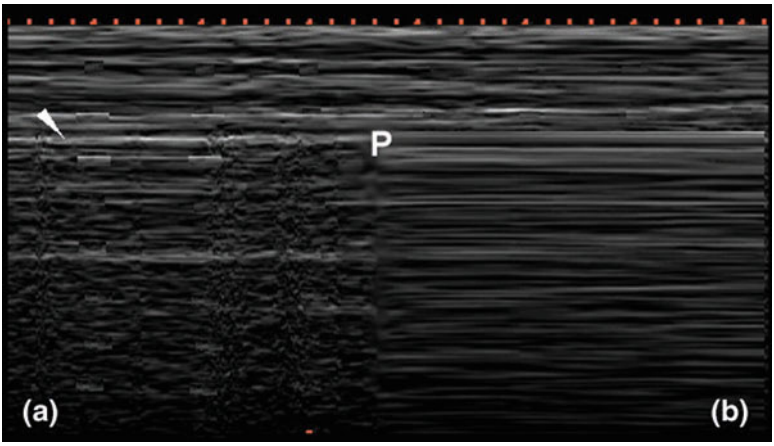
- Ultrasound may be useful in some cases. Look for the "sliding lung sign."



Algorithm for the diagnosis and exclusion of pneumothorax using LUS. Initially one should look for signs which rule out the presence of pneumothorax [lung sliding, lung pulse, B-line(s)] at the anterior surface of the chest. If none of these are present, then one should gradually move the transducer laterally and posterior on the surface of the chest and look for lung point in order to establish the diagnosis of pneumothorax. If neither sign is present, contemplation is needed since pneumothorax can neither be ruled in nor out. In young, previously healthy patients, such as most trauma patients, the absence of lung sliding alone is sufficient to diagnose pneumothorax. In such patients the absence of all signs will be consistent with pneumothorax. In comparison, patients with known lung diseases or previous chest surgery may have a variety of causes for the absence of lung sliding. In such patients the absence of all signs can neither be used to rule in nor to rule out a pneumothorax and further imaging should be performed in order to establish whether pneumothorax is present or absent [From article: Ultrasonography for clinical decision-making and intervention in airway management: from the mouth to the lungs and pleurae. Insights into Imaging. 2014 Apr;5(2):253–79. https://doi.org/10.1007/s13244-014-0309-5, at http://link.springer.com/article/10.1007/s13244-014-0309-5; by Michael S. Kristensen, Wendy H. Teoh, Ole Graumann, Christian B. Laursen, © The Author(s) 2014; licensed under Creative Commons Attribution License https://creativecommons.org/licenses/by/2.0/] *Caption from original*



Pneumothorax. *Left* Real-time. Lung sliding or pathological comet-tail artifacts are absent. In real time the pleural line appears completely motionless. *Right* Time motion. This mode objectifies the complete disappearance of lung sliding, without any visible “lung pulse” [Lichtenstein DA, Lascols N, Prin S, Mezière G. The”lung pulse”: an early ultrasound sign of complete atelectasis. Intensive Care Medicine. 2003 Dec 1;29(12):2187–92.] *Caption from original*



Time-motion mode lung ultrasound. (a) Normal lung and (b) pneumothorax patterns using time-motion mode lung ultrasound. In time motion mode, one must first locate the pleural line (white arrow) and, above it, the motionless parietal structures. Below the pleural line, lung sliding appears as a homogenous granular pattern (a). In the case of pneumothorax and absent lung sliding, horizontal lines only are visualised (b). In a patient examined in the supine position with partial pneumothorax, normal lung sliding and absence of lung sliding may coexist in lateral regions of the chest wall. In this boundary region, called the 'lung point' (P), lung sliding appears (granular pattern) and disappears (strictly horizontal lines) with inspiration when using the time-motion mode. [From article: Clinical review: Bedside lung ultrasound in critical care practice. Crit Care. 2007 Feb 16;11(1):1–9. https://doi.org/10.1186/cc5668, at http://link.springer.com/article/10.1186/cc5668; by Bélaïd Bouhemad, Mao Zhang, Qin Lu, Jean-Jacques Rouby, © BioMed Central Ltd 2007; licensed under Creative Commons Attribution License https://creativecommons.org/licenses/by/2.0/] *Caption from original*

Special Populations

Age and Gender

- Primary spontaneous simple pneumothorax occurs most often in tall, thin adults between the ages of 18 and 40 and is more common in smokers. It is more common in men than in women.
- Secondary spontaneous simple pneumothorax occurs in older patients, often with COPD. It is more common in men than in women.
- Catemenial pneumothorax occurs in menstruating females, most often in the fourth decade of life.
- In the pediatric population, the highest incidence of simple pneumothoraces occurs in the newborn period. In some studies, the incidence approaches 2 in 10,000 live births.

- In adolescents, the development of both pneumothorax and pneumomediastinum has been associated with smoking marijuana and crack cocaine.

Co-morbidities

- Asthma and COPD are common comorbidities.
- Marfan's syndrome and other connective tissue disorders predispose to simple pneumothorax.
- Tobacco use increases the incidence of simple pneumothorax.

Pitfalls in Diagnosis

Critical Steps Not to Miss

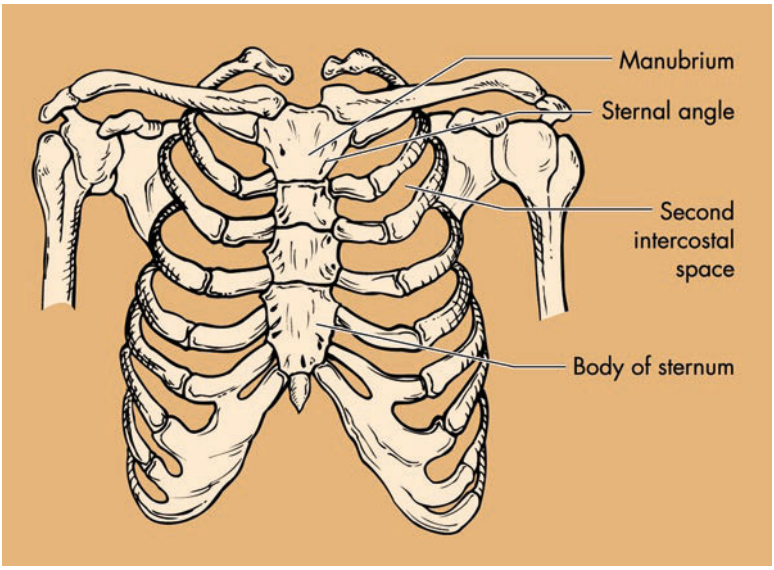
- Consideration of the diagnosis is the first critical step. Chest radiography is required to confirm the diagnosis.

Mimics

- The entire constellation of diagnoses that underlies chest pain syndrome, especially those often accompanied by dyspnea, can mimic the pain and overall presentation of simple pneumothorax.

Time-Dependent Interventions

- There are usually no time-dependent interventions in the management of simple pneumothorax. In this way the diagnosis differs sharply from tension pneumothorax, which is immediately life-threatening.
- Patients with significant underlying pulmonary disease may be intolerant of the hypoxemia that may result from simple pneumothorax, even without tension. For those patients, decompression of the pneumothorax (with needle, catheter, or tube thoracostomy) should be performed immediately.



Needle thoracostomy. The occurrence of a pneumothorax in the patient receiving positive pressure ventilation necessitates the placement of a chest tube. If the patient has evidence of a tension pneumothorax and exhibits hemodynamic or respiratory instability, a needle thoracostomy should be undertaken immediately. The procedure involves using a 14-gauge angiocatheter and inserting it into the second intercostal space in the midclavicular line of the side of the pneumothorax. The needle is "walked off" the superior portion of the third rib into the second intercostal space. This is done to prevent laceration of the intercostal vessels. If the tension is not released then a tube thoracostomy should be done in the same location. Once a tension pneumothorax is decompressed, a chest tube must be inserted to prevent reaccumulation of air. The angiocatheter, once it has released the tension in the chest, should not be removed until a chest tube is in place.[Szokol J, Vender J. Respiratory emergencies (pulmonary aspiration of gastric contents, acute epiglottis, anterior mediastinal mass). In: Tremper KK, editor. Principles of anesthetic techniques and anesthetic emergencies. Philadelphia: Current Medicine; 1998. 195 p. (Miller RD, editor. Atlas of anesthesia; vol. 4). Tube thoracostomy. Tube thoracostomy is indicated to remove air or fluid (including blood) from the pleural space. Preferred sites are the fourth or fifth intercostal space in the anterior axillary line (A) or the second interspace in the midclavicular line (pneumothorax alone) (B). Local anesthetic is infiltrated into the skin, subcutaneous tissue, intercostal muscles, periosteum, and pleura (C). A 2-cm incision is made below the selected rib (D) and a subcutaneous tunnel formed with a Kelly clamp (E). The clamp is then inserted into the pleural space over the superior margin of the upper rib (F and G), followed by insertion of a gloved finger to confirm thoracic penetration (H). The tip of the thoracostomy tube is grasped by the Kelly clamp and inserted posteriorly and superiorly into the pleural space (I). The tube is then connected to a collection-suction apparatus with high-volume flow, adjustable suction, and underwater seal and is sutured to the skin. [Yeston N. Chapter 12. In: Kirby R, editor. Critical Care. Philadelphia: Current Medicine; 1997. (Miller RD, editor. Atlas of anesthesia; vol. 1). ISBN: 0-443-07906-4] *Caption from original*

Overall Principles of Treatment

- Treatment of simple pneumothorax involves evacuation of the air collection between the pleural layers. This should be done for all cases of simple pneumothorax except those that are shown to be very small on chest radiograph and are not causing symptoms; such lesions may be treated with supplemental oxygen and observation. Percutaneous management options include simple aspiration, chest tube placement, one-way valve insertion, and tube thoracostomy with continuous suction.

- Intensity of treatment is driven by size of the pneumothorax, degree of respiratory distress, severity of underlying lung disease, and risk of recurrence. Sometimes pharmacologic agents are instilled into the pleural space in an effort to prevent recurrence.

Disease Course

- It typically takes about 10 days for a simple pneumothorax to completely resolve, although symptoms typically improve much more quickly. Recurrence rates are 25–35 % for primary spontaneous simple pneumothorax and 40–50 % for patients with severe underlying lung disease.

Chapter 60
Pneumothorax (Tension)

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Tension Pneumothorax, Dropped Lung

Incidence/Epidemiology

- The incidence of tension pneumothorax is clearly underestimated. Because it results in such dramatic ventilatory and hemodynamic compromise, it often is treated rapidly, before the diagnosis is confirmed. Needle thoracostomy, for example, may relieve tension pneumothorax, but if the presumed diagnosis is incorrect, it creates a simple pneumothorax.
- Tension pneumothorax is a rare complication of primary spontaneous pneumothorax. In the 1800s, the most common underlying cause of tension pneumothorax was pulmonary tuberculosis.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_60

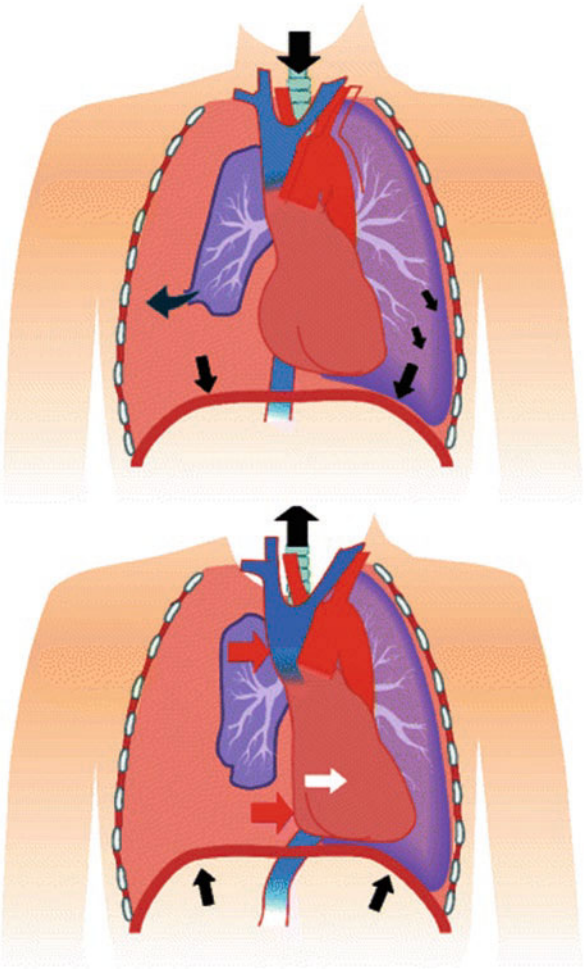
- Probably the most common cause of tension pneumothorax in the community is blunt chest trauma. It may occur in the hospital as a complication of mechanical ventilation with positive end-expiratory pressure (PEEP), which may or may not be associated with a sharp procedure (such as central line placement). Rupture of blebs during PEEP ventilation is an important cause of significant pneumothorax.

Differential Diagnosis

- The differential considerations for tension pneumothorax are quite limited. Given the dramatic presentation with tracheal shift and extraordinary hemodynamic and ventilatory compromise, the diagnosis is usually straightforward. This is important because emergency treatment is required.
- If the tracheal deviation and unilateral hyperresonance described below are not readily apparent, other dramatic diagnoses, such as overwhelming pulmonary embolism or cardiac rupture, may be considered.

Pathophysiology and Etiology

- Pneumothorax is defined by the presence of air in the pleural space, which is the usually tiny space between the visceral and parietal layers of the pleura.
- Tension pneumothorax occurs when the abnormal gas-filled space become so large that the ipsilateral lung completely collapses and the pressure in the pleural space is positive throughout the respiratory cycle. The expanding gas eventually extends across the mediastinum and affects the volume and function of the contralateral lung.



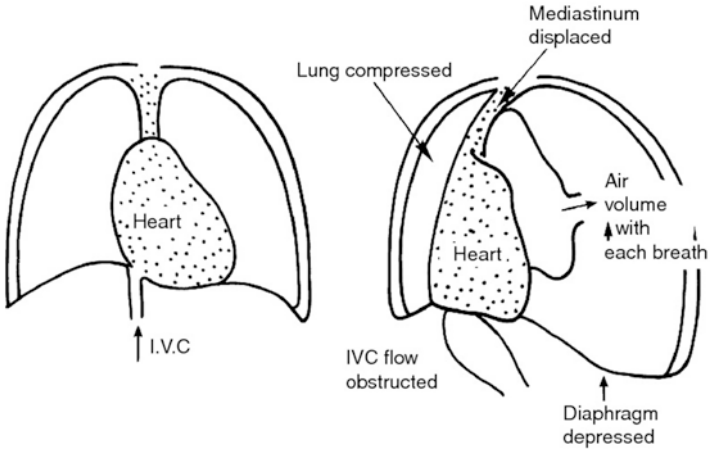
Tension pneumothorax, a feared and immediately life-threatening complication of pneumothorax. At the site of the lung injury, a valve mechanism occurs so that air leaks out but not back in. In a closed pneumothorax (intact chest wall) this leads to an increase of intrapleural pressure. The mediastinum is pushed toward the unaffected side, leading to ventilatory insufficiency on that side. The most threatening consequence of this condition is the pressure on the large chest veins with impairment of the refilling of the heart, which can lead to a rapidly progressing circulatory collapse. Immediate normalization of the pressure with needle thoracotomy is a prerequisite for survival [Lennquist S. Medical response to major incidents and disasters. Berlin Heidelberg: Springer; 2012. Chapter 7, Incidents caused by physical trauma; p. 111–96. Book https://doi.org/10.1007/978-3-642-21895-8; Chapter: 7; Chapter https://doi.org/10.1007/978-3-642-21895-8_7; Published: 2012-01-01] *Caption from original*

- The ventilatory compromise associated with tension pneumothorax results from the burden of trying to overcome consistent positive intrathoracic pressure combined with the loss of functional lung volume.
- The circulatory compromise associated with tension pneumothorax results in part from the impact of continuous positive pressure on the mediastinum, which reduces both venous return to the heart and cardiac output.
- Tension pneumothorax may be diagnosed as a complication in patients in whom simple pneumothorax has already been recognized, or it may present *de novo*.
- Tension pneumothorax in the outpatient setting is often the result of trauma, which is more commonly blunt (nonpenetrating) than penetrating. In the hospital, iatrogenic trauma may result from sharp procedures that violate the pleura (central line placement, lymph node or lung biopsy, etc.) or from positive-pressure ventilation, especially in patients with blebs.
- Tension pneumothorax in nontraumatic settings is most often the result of a severe infection process, such as necrotizing pneumonia. Pneumothorax is more common in smokers than nonsmokers, and is more common in patients with Marfan's syndrome and other connective tissue disorders associated with a tall, thin body type.

Presentation

Typical/"Classic"

- Tension pneumothorax presents dramatically—with a hypotensive patient who cannot ventilate effectively.
- Classically, the trachea is deviated out of the midline away from the collapsed lung.
- The ipsilateral hemithorax is hyperresonant (because it is filled with gas and the lung is collapsed) and may be visibly distended. Breath sounds are absent on that side.
- If the patient is on mechanical ventilation, airway pressure alarms will sound.
- The patient is hypotensive and tachycardic.



The effect of tension pneumothorax on ventilation and venous return [Hutson JM, Beasley SW. The Surgical Examination of Children, 2e. Berlin Heidelberg: Springer; 2013. Chapter 12, Trauma; p. 151–83. Book https://doi.org/10.1007/978-3-642-29814-1] *Caption from original*

- Jugular venous distension is present.
- Although chest radiography is diagnostic, it is often said that tension pneumothorax should never be diagnosed by x-ray, because delays in obtaining imaging may lead to further deterioration and death of the patient. If the diagnosis is suspected, treatment with decompressive needle thoracostomy should begin immediately.

Atypical

- Given the underlying pathophysiology of tension pneuomothorax, presentation is almost always "typical" (see above). The presentation may be slightly less dramatic very early and slightly obscured in the ICU when the patient is on a ventilator.
- Bilateral pneumothoraces with tension may present without tracheal deviation, but other cardinal features, especially hemodynamic collapse, will be present.

Primary Differential Considerations

- Because the clinical presentation of tension pneumothorax is so dramatic, there are few immediate differential considerations. In fact, pausing to consider other possibilities is dangerous to the patient. The only other immediate considerations might be severe shock or acute respiratory distress syndrome.

History and Physical Exam

Findings That Confirm Diagnosis

- Tension pneumothorax is a clinical diagnosis. Whether or not the patient has been injured, whether in the hospital or in the community, the findings of severe cardiopulmonary distress and volume/pressure shift in the chest are suggestive enough of the diagnosis that treatment should be empirically undertaken.

Factors That Suggest Diagnosis

- Each of the cardinal findings—respiratory distress, cardiovascular compromise, tracheal shift, asymmetry of sound and appearance in the two sides of the chest—points to the diagnosis.
- Appreciation of trauma or the presence and extent of underlying pulmonary disease may be helpful.

Factors That Exclude Diagnosis

- Tension pneumothorax results from the impact of persistently positive intrapleural pressure. Even finding a concomitant diagnosis (pulmonary embolism, pneumonia) not associated with this pressure shift does not exclude tension pneumothorax.

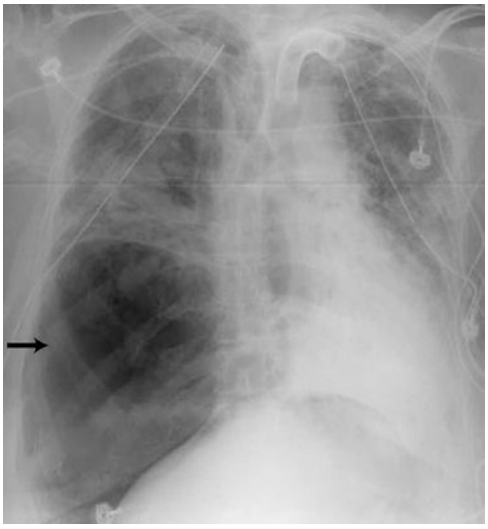
Ancillary Studies

Laboratory

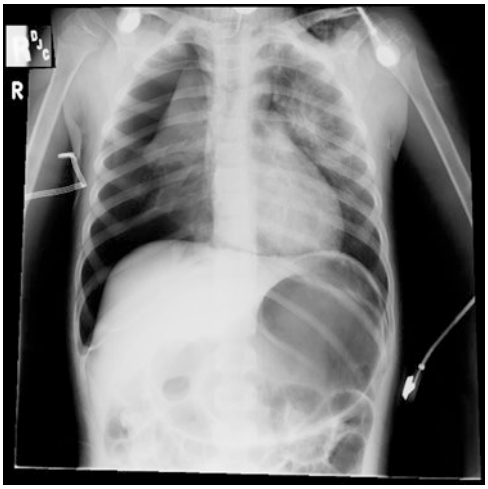
- There are no diagnostic laboratory studies for tension pneumothorax. Obtaining "resuscitation labs" is appropriate but must not delay treatment with decompressive needle thoracostomy.

Imaging

- Tension pneumothorax is readily identified on chest radiograph. However, it is often said that tension pneumothorax should never be diagnosed by x-ray, because delays in obtaining imaging may lead to further deterioration and death of the patient. If the diagnosis is suspected, treatment with decompressive needle thoracostomy should begin immediately.



Tension pneumothorax. A, Chest radiograph of a critically ill patient with a deep sulcus sign on the left (arrow), consistent with the diagnosis of a pneumothorax. B. Chest radiograph of a critically ill patient on mechanical ventilation with the presence of a right loculated tension pneumothorax (arrow). Note the increase in volume of the right hemithorax, depression of the right hemidiaphragm, and contralateral mediastinal shift. [Huggins J, Sahn S. Pleural disease. In: Crapo J, editor. Bone's atlas of pulmonary and critical care medicine. Philadelphia: Current Medicine; 2005. Chapter 25. ISBN: 1-57340-211-7; Published: 2005-01-14] *Caption from original*



Chest radiograph of the chest showing tension pneumothorax on the right side [Parray T, Siddiqui SM, Hughes M, Shah S. Tension pneumothorax and subcutaneous emphysema during retrieval of an ingested lithium button battery. J Anesth. 2010 Jun;24(3):469–71. https://doi.org/10.1007/s00540-010-0908-3; Published: 2010-06-10] *Caption from original*

- There is no role for CT or ultrasound imaging in patients with tension pneumothorax.

Special Populations

Age and Gender

- Because the potential etiologies of tension pneumothorax are so varied, there are limited age and gender predilections. Patients with chronic obstructive pulmonary disease (COPD; who are more likely older males) have more blebs, the rupture of which may eventually lead to tension pneumothorax, especially in the setting of positive pressure ventilation.
- Because tension pneumothorax may be a complication of untreated or extensive simple pneumothorax, the age and gender considerations discussed for the former may be applicable.
- It cannot be stressed enough that consideration of differential diagnoses, special populations, etc. must not result in delay in recognition and immediate treatment of tension pneumothorax.
- Within the pediatric population, both simple and tension pneumothoraces are rarely encountered.

- There are, however, well recognized associated pediatric conditions that may present with pneumothoraces, such as cystic fibrosis, reactive airway disease, Marfan's syndrome, and Ehlers-Danlos syndrome.

Co-morbidities

- Asthma and COPD are common comorbidities. Pneumonia may be associated with either simple or tension pneumothorax.
- Marfan's syndrome and other connective tissue disorders predispose to pneumothorax.

Clinical features of Marfan syndrome. Clinical features. Many of the typical features of Marfan's syndrome are seen in this patient, including arm length greater than height, increased lower to upper extremity ratio, pectus excavatum, and pes planus. Marfan's syndrome is characterized by autosomal dominant inheritance and has a prevalence of one in 20,000. A disorder of fibrillin, a glycoprotein abundant in the aortic media, skin, and ciliary zones, has recently been implicated as the most likely cause of this disorder. Musculoskeletal features include limbs disproportionately long for trunk size (dolichostenomelia), arachnodactyly, pectus excavatum or

carinatum, scoliosis, pes planus, and joint hypermobility. Serious extraskeletal features include dilation of the aortic root (leading to aortic dissection) and upward subluxation of the lens. [Maricic M, Ko M. Diseases of bone and connective tissue. In: Hunder G, editor. Atlas of rheumatology. Philadelphia: Current Medicine; 2005. Chapter 6. ISBN: 1-57340-210-9; Published: 2005-01-18] *Caption from original*

- Tobacco use increases the incidence of pneumothorax.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis in the acutely compromised patient is the first critical step.

Mimics

- There are no real mimics of the dramatic presentation of tension pneumothorax. In the absence of tracheal deviation, one might consider large pulmonary embolism, cardiac rupture, or other intrathoracic catastrophe.

Time-Dependent Interventions

- Immediate release of the positive intrapleural pressure is required. Needle thoracostomy is the fastest means of relieving the tension.

Overall Principles of Treatment

- Treatment of tension pneumothorax is best provided by simple needle thoracostomy. The needle is usually inserted into the second or third intercostal space, in the midclavicular line, of the ipsilateral side. A rush of air through the needle confirms the diagnosis. The patient should then undergo formal tube thoracostomy while other hemodynamic support measures, as needed, are taken.

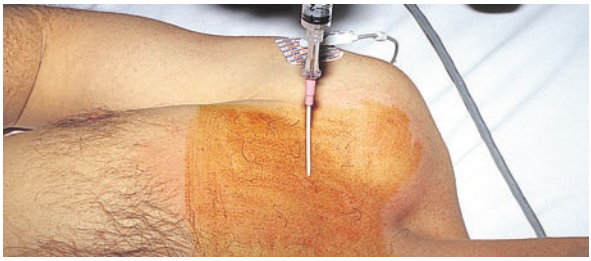
https://www.youtube.com/watch?v=UvHJ4pjNh2Q



Needling the chest for tension pneumothorax. This procedure is performed with readily available equipment and can be accomplished rapidly before a chest tube is obtained and inserted. A, A 12- or 14-gauge intravenous cannula is inserted in the second intercostal space in the midclavicular line. The cannula is inserted on the side of the pneumothorax, if known, or it can be inserted bilaterally, if the side is not evident clinically or if bilateral pneumothoraxes are suspected. [Woodcock B. Hemodynamic emergencies. In: Tremper K, Miller R, editors. Atlas of anesthesia. Philadelphia: Current Medicine; 1998. Chapter 11. ISBN: 0-443-07903-X; Published: 2002-01-22] *Caption from original*

B, Entry into a tension pneumothorax is confirmed by air rushing rapidly through the needle. There is risk of causing pulmonary damage with needle insertion if a pneumothorax is not present, and this technique should be reserved for the patient who is rapidly deteriorating and cannot tolerate any delay for chest radiography. [Woodcock B. Hemodynamic emergencies. In: Tremper K, Miller R, editors. Atlas of anesthesia. Philadelphia: Current Medicine; 1998. Chapter 11. ISBN: 0-443-07903-X; Published: 2002-01-22] *Caption from original*

Chest radiograph obtained after decompression showing resolution of tension pneumothorax with a small apical crescent of residual right pneumothorax. [Wachsman AM, Hoffer EK, Forauer AR, Silas AM, Gemery JM. Tension pneumothorax after placement of a tunneled pleural drainage catheter in a patient with recurrent malignant pleural effusions. Cardiovasc Intervent Radiol. 2007 May;30(3):531–3. https://doi.org/10.1007/s00270-006-0073-0; Published: 2007-06-01] *Caption from original*

Disease Course

- Tension pneumothorax is fatal if untreated. Ultimate recovery after initial treatment depends on a variety of factors, including comorbidity burden and extent of other injuries.

Chapter 61
Pulmonary Embolism

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Pulmonary embolism (PE); venous thromboembolism

Incidence/Epidemiology

- Pulmonary embolism is relatively common and is clearly underreported, as it is the most common cause of in-hospital death, and autopsies are not always performed on these patients.

C. V. Pollack, Jr. (✉)
Department of Emergency Medicine, Thomas Jefferson University, Philadelphia, PA, USA

R. M. Cantor

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_61

Autopsy specimen demonstrating pulmonary embolism. The patient subsequently suffered a cardiac arrest and died 3 days later despite maximal resuscitative efforts. At autopsy, the right main pulmonary artery, seen in cross-section, was filled with thrombus of varying age. [Goldhaber SZ, Piazza G. Interventional cardiology. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption adapted from original*

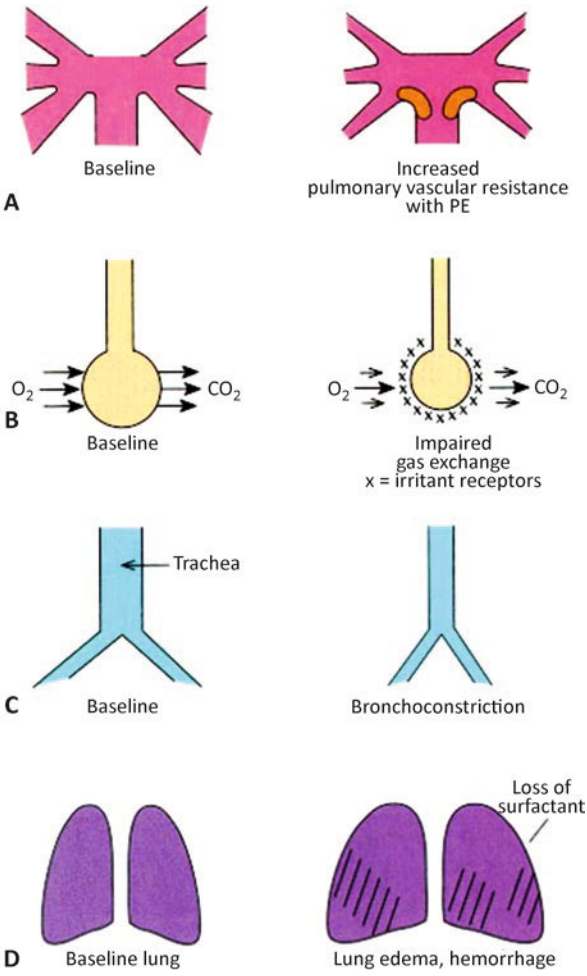
- On the other hand, PE is likely diagnosed now more than in previous times because of the ubiquitous availability of computed tomographic (CT) pulmonary angiography.
- The estimated incidence of PE in the US is about 1 case per 1,000 persons per year.
- The incidence of venous thromboembolism (PE plus deep venous thrombosis, or DVT) is increasing as the population ages and as obesity, cancer, and longer lifespans with debilitating disease all become more common.

Differential Diagnosis

- The differential considerations for chest pain due to PE includes acute coronary syndrome and aortic dissection, both of which—like PE—are potentially life-threatening.
- Less severe differential considerations include pleurisy, pneumonia, pneumothorax, chest wall pain, and anxiety.
- With significant hypoxemia patients may present with syncope, near-syncope, or seizure, so the differential considerations for those entities also must be entertained.
- Acute chest syndrome in sickle cell disease is a differential consideration in at-risk patients.

Pathophysiology and Etiology

- As the name implies, PE is an embolic phenomenon. The usual embolus is a thrombus that originates in a deep vein, typically in the lower extremities or pelvis, or occasionally from the upper extremities or other sources.



Pathophysiology of pulmonary embolism (PE). A, Increased pulmonary vascular resistance due to vascular obstruction, vasoconstriction by neurohumoral agents, vasoconstriction because of baroreceptors in the pulmonary arteries (which sense pressure exerted against the wall of the pulmonary artery by blood flowing past an obstructing blood clot), or increased pulmonary artery pressure. Baroreceptors may induce reflex pulmonary vasoconstriction. B, Impaired gas exchange due to irritant

receptors, increased alveolar dead space (from vascular obstruction), hypoxemia (from alveolar hypoventilation), and right-to-left shunting; impaired carbon monoxide transfer due to loss of gas exchange surface also occurs. C, Increased airway resistance due to bronchoconstriction. D, Decreased pulmonary compliance due to lung edema and hemorrhage as well as loss of surfactant. [Chapter 3 in: Braunwald E, Goldhaber S, editors. Cardiopulmonary Diseases and Cardiac Tumors. Atlas of Heart Diseases. 1st edition. Philadelphia: Current Medicine; 1995. ISBN: 1-878132-23-7.] *Caption from original*

- The thrombus fragments and detaches (or may detach in its entirety), passes through the right atrium, tricuspid valve, and right ventricle, and into the pulmonary vasculature. It lodges in a vessel either proximally or distally, depending on its size and pulmonary flow dynamics. Infarction of pulmonary tissue occurs when obstruction is complete and there is no collateral blood flow to that tissue.
- The result of pulmonary infarction is pain and hypoxemia (the extent of which relates to the volume of tissue infarcted). In some cases, the infarction will cause bleeding or sloughing of bloody tissue into the alveolar space, and hemoptysis may ensue.
- Even in the absence of frank infarction, PE results in pain, dyspnea, increased alveolar dead space and ventilation : perfusion (V:Q) mismatch.

Presentation

Typical/"Classic"

- The classic PE presentation is characterized by the combination of dyspnea, pleuritic chest pain, hypoxemia, and hemoptysis. Of these, hemoptysis is the least consistent.
- An even more "classic" presentation would include a known history of, or evidence of, DVT. Recall, however, that pelvic vein DVTs do not always cause significant findings on physical examination, and also that DVT from any source may *completely* embolize, leaving no clinical or ultrasonographic evidence behind.

Atypical

- The classic presentation is not typical. The most consistent finding in acute PE is dyspnea. The presentation of dyspnea and tachycardia together should always prompt consideration of PE.
- Patients with PE may present with syncope, seizure, or with sudden death.
- Patients with massive PE may present with hemodynamic collapse.

- Depending on the area of lung involved, presenting pain in PE may be in the flank or abdomen.
- Patients with PE may present with wheezing and may be confused with asthma or COPD.
- The coincidence of fever and chest pain in PE may mimic pneumonia.

Primary Differential Considerations

- Pulmonary embolism carries an immediate life threat and as such should be considered at the top of the list of differential considerations that present with the signs and symptoms described above. Other diagnostic considerations that are potentially immediately life-threatening include:
  - acute coronary syndrome
  - aortic dissection
  - tension pneumothorax
  - shock
- Other less acute but important differential diagnoses to consider include:
  - simple pneumothorax
  - pneumonia
  - pleurisy

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination are not diagnostic for PE.

Factors That Suggest Diagnosis

- History and physical findings are dependent upon the size of the PE. PE is typically classed as:
  - Massive, implying hemodynamic compromise, or
  - Submassive, implying clear symptoms but with intact hemodynamics
- Known DVT, risk for DVT, or swollen extremity suggestive of DVT is suggestive. A prior history of PE puts the patient at increased life-long risk for another episode.

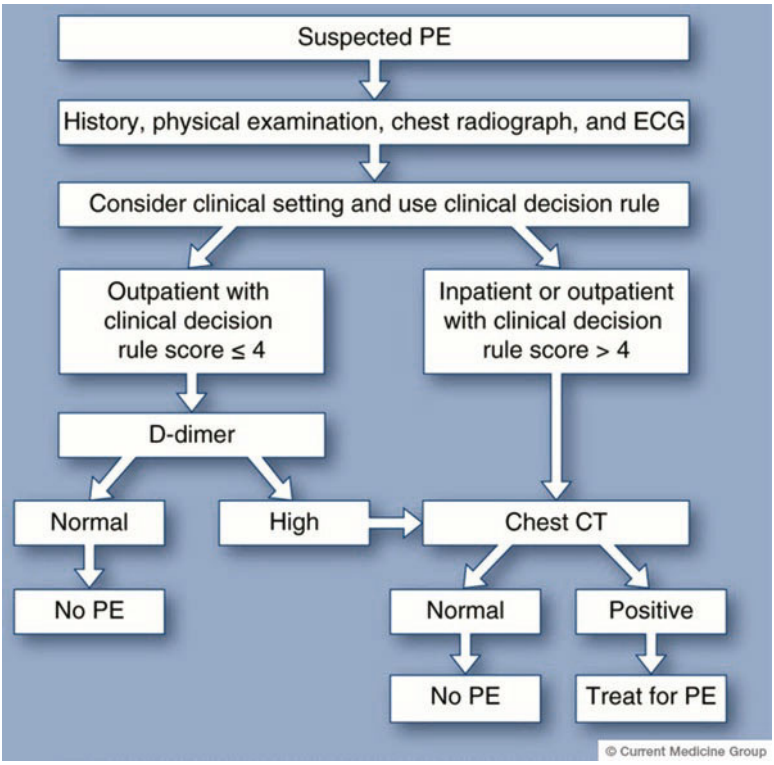
  - Findings of two or more of the cardinal symptoms (dyspnea, pleuritic chest pain, hypoxemia, and hemoptysis) should prompt serious consideration of PE.
  - Local wheezes in the affected area are commonly heard.
- There are predictive scores, such as that published by Wells, which may be useful.

Criteria	Points
1. Suspected PE	3.0
2. An alternative diagnosis is less likely than PE	3.0
3. Heart rate > 100 beats/min	1.5
4. Immobilization or surgery in previous 4 weeks	1.5
5. Previous DVT/PE	1.5
6. Hemoptysis	1.0
7. Malignancy (on treatment or treated within past 6 months)	1.0

Score	Mean probability of PE	% of Patients with this score	Risk
<2	3.6	40	low
2–6	20.5%	53	medium
>6	66.7%	7	high

Wells criteria for assessment of pre-test probability of pulmonary embolism (Data from Wells et al., 2000)[McIntyre LK, Langdale LA. Pulmonary Embolism. In: Bland, KI, Sarr, MG, Büchler, MW, Csendes, A, Garden, OJ, Wong, J (Eds.), editors. General Surgery [Internet]. Springer London; 2009 [cited 2016 May 27]. p. 263–72. Available from: http://link.springer.com/referenceworkentry/10.1007/978-1-84628-833-3_25] *Caption from original*

  - The Geneva Score is another such predictive tool. Many authorities hold, however, that clinical gestalt (that is, the evaluator's clinical impression) is superior—or at least noninferior—to any validated scoring systems.



Algorithm for diagnosis of pulmonary embolism. An integrated approach. [Goldhaber SZ, Piazza G. Interventional cardiology. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption adapted from original*

Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude PE.

Ancillary Studies

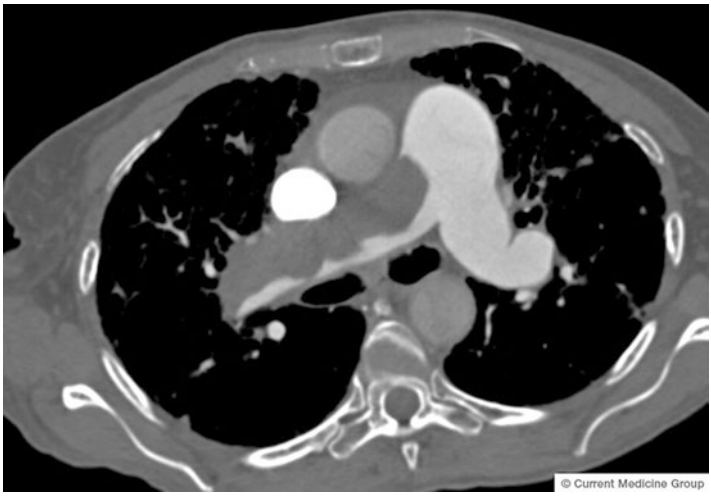
Laboratory

- There are no diagnostic laboratory studies for PE.
- Arterial blood gases may be used to calculate an arterial-alveolar oxygen gradient or to quantify hypoxemia, although in most cases transcutaneous pulse oximetry is sufficient.

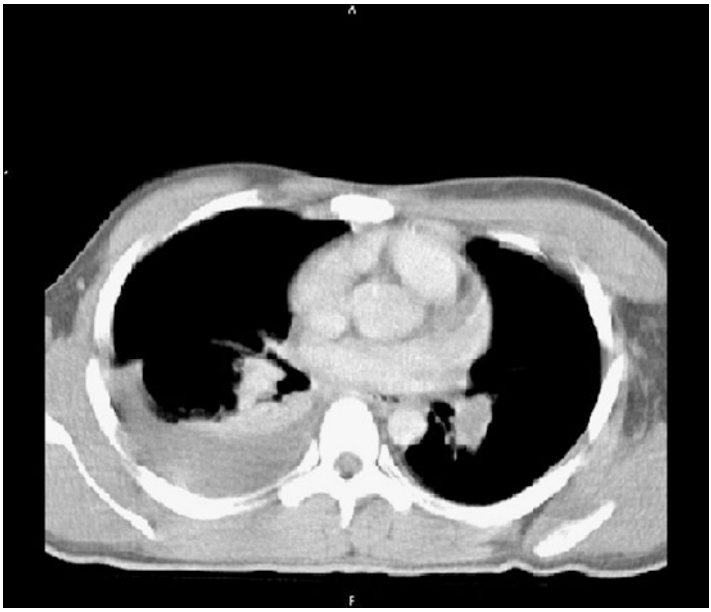
- A D-dimer assay (D-dimer is a byproduct of fibrin degradation, and can be found in the body when there is active or chronic clotting) is very sensitive for VTE but is not particularly specific. It should therefore be used to reassure providers that there is *not* a PE. In the setting of low clinical probability, a negative D-dimer is very helpful. If the D-dimer is positive, it should not be assumed that PE (or underlying DVT) is present, but further evaluation (usually by imaging) should ordinarily then be performed.

Imaging

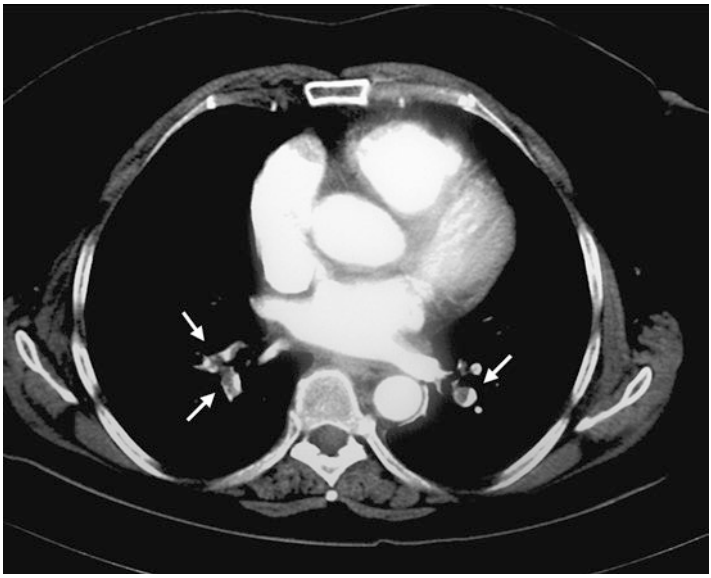
- The usual means of confirming the diagnosis of PE is with contrast-enhanced computed tomography of the thorax (called a computed tomographic pulmonary angiogram, or CTPA). This test is very sensitive for detecting PE down to the subsegmental pulmonary artery level.



Chest computed tomography in pulmonary embolism. Diagnosis of acute pulmonary embolism (PE) by CT of the chest. This image is from a 59-year-old woman with advanced sarcoidosis who underwent chest CT as part of an evaluation before lung transplantation. The CT demonstrated a previously unsuspected PE indicated by the large filling defect in the right main pulmonary artery. [Goldhaber SZ, Piazza G. Interventional cardiology. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption from original*

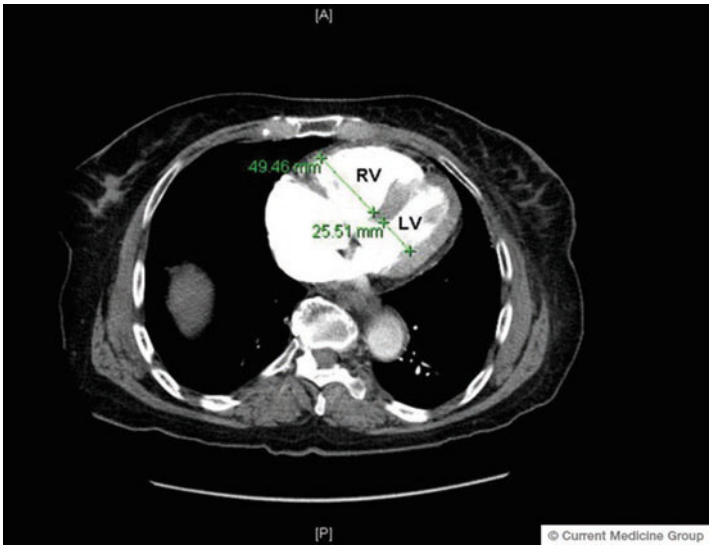


Acute pulmonary embolism. CECT chest showing thrombus in left pulmonary artery with right pleural effusion. [Vikram S, Jacob P, Nair CG, Vaidyanathan S. Gastric Carcinoma—A Rare Presentation. Indian Journal of Surgical Oncology. 2010 Dec;1(4):346–8.] *Caption from original*



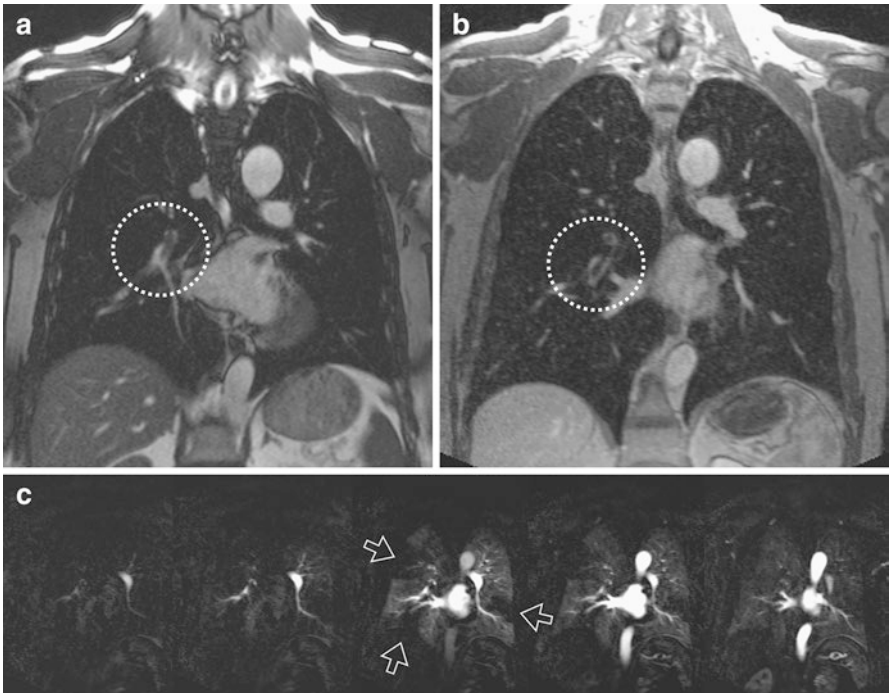
Visualization of a filling defect in the lumen of a vessel. *Arrows* indicate multiple filling defects in segmental branches of both pulmonary arteries diagnostic of bilateral pulmonary embolism. [Garcia-Bolado A, Del Cura JL. CT venography vs ultrasound in the diagnosis of thromboembolic disease in patients with clinical suspicion of pulmonary embolism. Emergency Radiology. 2007 Nov;14(6):403–9.] *Caption adapted from original*

- Because contrast material is required, CTPA may not be feasible in patients with renal insufficiency and should not be performed in pregnant patients.
- CT may also reveal suggestive right ventricular enlargement in PE.



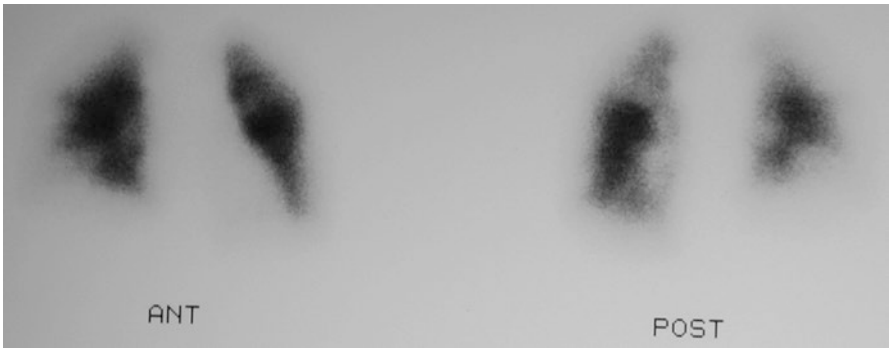
Chest computed tomography (CT) demonstrating right ventricular (RV) enlargement. This chest CT image demonstrates RV enlargement with a ratio of RV dimension to left ventricular (LV) dimension of 1.9. [Goldhaber SZ, Piazza G. Interventional cardiology. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption adapted from original*

- MRI of the chest can be used to evaluate for PE in patients who cannot undergo CT imaging.



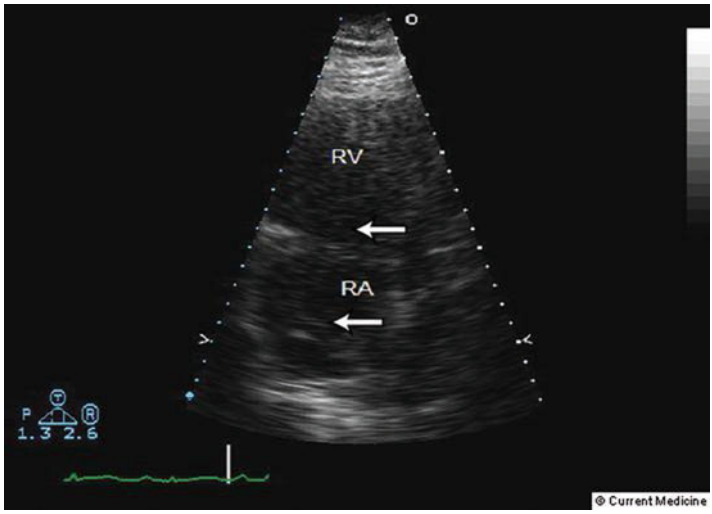
MRI of acute pulmonary embolism. A 55-year-old patient with acute pulmonary embolism. Coronal steady-state free precession images acquired during free breathing (a) and contrast-enhanced coronal 3d flash angiogram acquired in breathhold (b; embolus inside the right lower lobe artery circled); c series of subtracted images from the first pass perfusion study, perfusion deficits marked with open arrows at the image obtained at peak lung enhancement; 1.5-T MRI scanner [Biederer J, Mirsadraee S, Beer M, Molinari F, Hintze C, Bauman G, Both M, Van Beek EJR, Wild J, Puderbach M. MRI of the lung (3/3)—current applications and future perspectives. Insights into Imaging. 2012 Aug;3(4):373–86.] *Caption adapted from original*

- Ventilation-perfusion imaging (V/Q scan) is a nuclear medicine study that can demonstrate mismatches between ventilation and perfusion of the lungs and therefore indirectly identify PE. The test is more difficult to interpret than CT or MRI and is notably compromised in patients with existing lung disease such as COPD. It is still sometimes used when patients cannot receive contrast for CTPA.



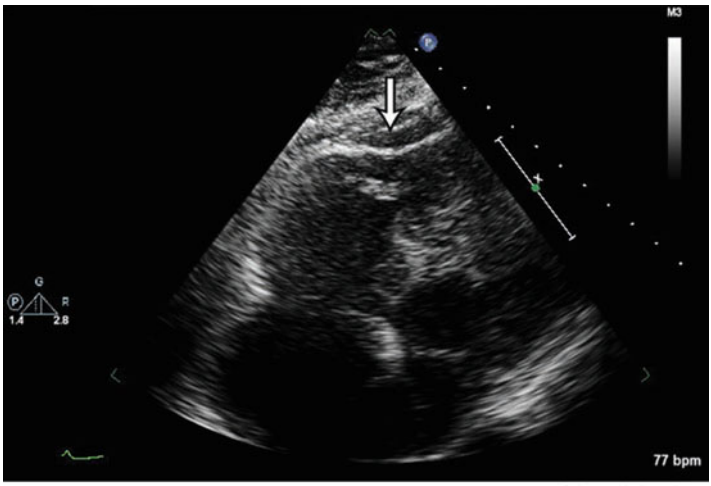
Ventilation-perfusion scan was interpreted as a high probability for pulmonary embolism involving the right lung and left upper lung. Patient was diagnosed as having deep venous thrombosis and pulmonary embolism. [Kawaguchi Y, Mine T, Kawana I, Umemura S. Protein-losing enteropathy, deep venous thrombosis and pulmonary embolism in a patient with generalized inflammatory polyposis in remission stage of ulcerative colitis. Clinical Journal of Gastroenterology. 2009 Jun;2(3):156–60.] *Caption adapted from original*

- An echocardiogram will typically demonstrate right ventricular strain with larger PEs and may occasionally show the thrombus.

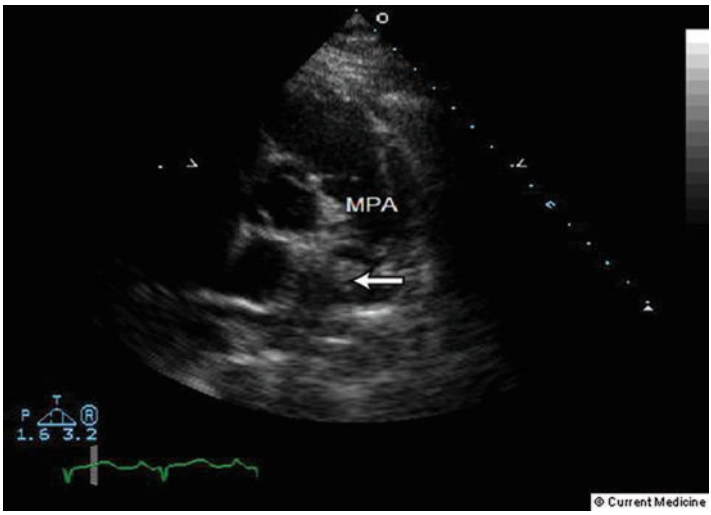


Echocardiogram of pulmonary embolism with thrombus in transit. Pulmonary embolism, thrombus in transit. Apical four-chamber view, demonstrating large mobile thrombi (arrows) within a dilated and hypokinetic RA and RV, which is consistent with acute pulmonary emboli. The appearance of thrombus in transit has been described as similar to "sausage links." Because most pulmonary emboli originate from the deep veins in the legs, it is hypothesized that the valves within the

deep veins create indentations in the thrombus, which contribute to the "sausage link" appearance. [Mangion J, Solomon S. Chapter 15. In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, Braunwald E, editors. Atlas of Echocardiography. 1e. Philadelphia, PA: Current Medicine Group; 2005. 312 p. ISBN: 1-57340-217-6] *Caption from original*

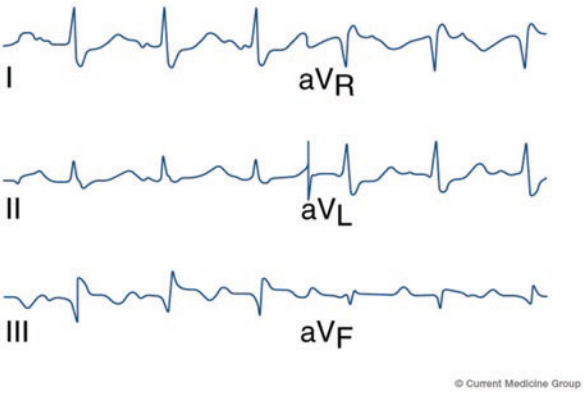


Echocardiographic assessment of pulmonary embolism. Pulmonary embolism. Apical four-chamber view, demonstrating right ventricular (RV) dilatation, hypokinesis, as well as McConnell's sign (arrow), which are markers of acute pulmonary embolism. [Mangion J, Solomon S. Echocardiography. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption adapted from original*



Echocardiogram of pulmonary embolism with right pulmonary artery thrombus Pulmonary embolism, thrombus within the right pulmonary artery (*arrow*). Main pulmonary artery and bifurcation view. Although echocardiography is often used in the setting of pulmonary embolism, it is not recommended as a routine imaging test for the diagnosis of pulmonary embolism because most patients with pulmonary embolism will have a "normal" echo. In patients with known pulmonary emboli, or with strong clinical suspicion for pulmonary emboli, it is important to visualize the pulmonary artery and branches, as in this case example. MPA—main pulmonary artery. [Mangion J, Solomon S. Echocardiography. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption from original*

- Ultrasound of the extremities can identify DVT as a potential source of PE. Keep in mind that an entire DVT focus can embolize, creating PE and leaving behind no clot to be detected in the extremities.
- Electrocardiographic manifestations of PE are inconsistent, but the "classic" S1Q3T3 pattern is occasionally seen. Tachycardia is the most common finding on ECG in PE patients.



Electrocardiogram in pulmonary embolism. Electrocardiogram of a 64-year-old woman who was hospitalized with "atypical chest pain" and subsequently diagnosed with pulmonary embolism (PE). This patient's electrocardiogram shows sinus tachycardia, incomplete right bundle branch block, an S wave in lead I, Q wave in lead III, and T-wave inversion in lead III. This so-called S1Q3T3 pattern along with the new incomplete right bundle branch block is indicative of right ventricular strain in the setting of pressure overload from PE. [Goldhaber SZ, Piazza G. Interventional cardiology. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption adapted from original*

Special Populations

Age and Gender

- The risk of PE increases with age.
- In general, the risk of PE is higher in men (perhaps owing to higher rates of cigarette smoking, cancer, and obesity), but women have higher risk when pregnant, in the post-partum period, and when taking hormone therapy (both oral contraceptives and replacement therapy).
- Blacks have higher rates of PE than whites in the US, and also have higher mortality with PE.
- The incidence of PE in children has risen sharply during the past decade, as a result of either more sensitive testing methods or greater survival from serious diseases (e.g., malignancies).
- The vast majority of PE in children is associated with the presence of central venous catheters, usually for the provision of chemotherapy or total parenteral nutrition (TPN).
- Within the adolescent population, adult risk factors apply.

Co-morbidities

- Hereditary thrombophilia (such as Protein C deficiency, antithrombin deficiency, Factor V Leiden) increases the risk of thromboembolism.
- Any state associated with increased levels of female hormones (including both pregnancy and prescribed therapy) increases the risk of thromboembolism.
- COPD is associated with PE, but that may derive from tobacco exposure more than from structural lung disease.
- Post-operative DVT and PE are common, owing primarily to post-op immobility, especially without prophylaxis such as low-molecular weight heparins.
- Prior VTE is a life-long risk factor for recurrent disease.
- Both malignancy and most forms of cancer treatment (surgery, chemotherapy, hormonal therapy) increase the risk of thromboembolism.
- Obesity increases the risk of thromboembolism.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. Therapeutic anticoagulation may be initiated while awaiting formal confirmation of the diagnosis.

Mimics

- The entire constellation of diagnoses that underlies chest pain syndrome, especially those often accompanied by dyspnea, can mimic the pain and overall presentation of PE.
- Sudden cardiac death may mimic or be a presentation of PE.
- Syncope or near-syncope may mimic or be a presentation of PE.

Time-Dependent Interventions

- Pulmonary embolism can be rapidly fatal.
- Parenteral anticoagulation therapy should be initiated upon high suspicion or confirmation of PE.
- Patients with PE and hemodynamic compromise (inability to support blood pressure or oxygenation) should be immediately evaluated for suitability for thrombolytic therapy.

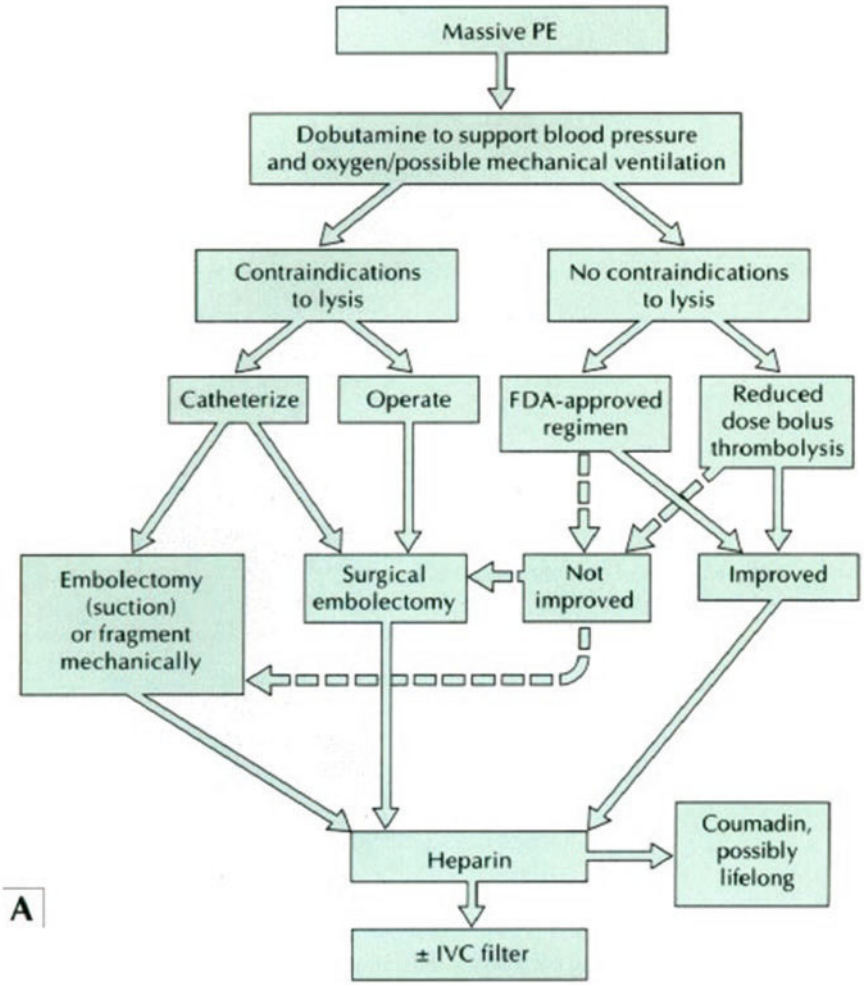
PRINCIPAL INCLUSION CRITERIA	MAJOR EXCLUSION CRITERIA
Massive pulmonary embolism	Intracranial disease
Anatomically small or moderate size pulmonary embolism with hemodynamic instability (*eg*, prior cardiopulmonary disease)	Recent major trauma or surgery
Hemodynamically stable, but right ventricular dysfunction detected on baseline echocardiogram	Active bleeding, known bleeding diathesis, or unexplained anemia
Normal echocardiogram and moderate size pulmonary embolism associated with massive pelvic or leg vein thrombosis	Uncontrolled hypertension

Inclusion and exclusion criteria for thrombolysis. The greatest challenge of thrombolysis for pulmonary embolism is gaining a thorough familiarity of when it should be utilized and, conversely, when it should be withheld. [Chapter 3 in: Braunwald E, Goldhaber S, editors. Cardiopulmonary Diseases and Cardiac Tumors. Atlas of Heart Diseases. 1st edition. Philadelphia: Current Medicine; 1995. ISBN: 1-878132-23-7.] *Caption from original*

Overall Principles of Treatment

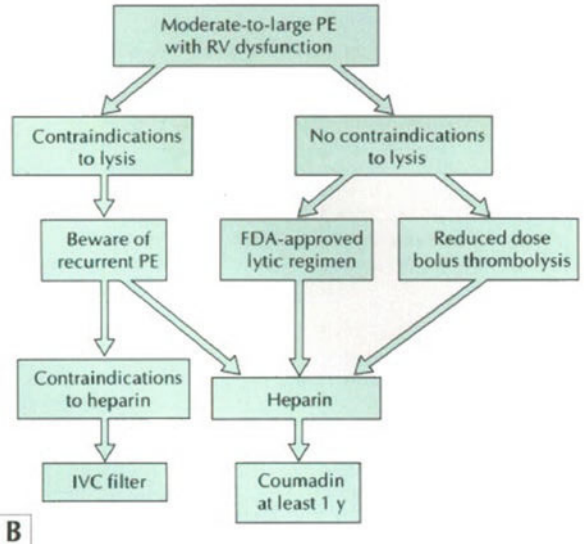
- Treatment of PE is with anticoagulation. Anticoagulants prevent clot progression while the body's native thrombolytic defenses gradually break down the clot and while collateral perfusion channels develop around the occluded vessel.

- Anticoagulation is recommended for at least 3 months after PE, but may be extended to 6 or 12 months or even longer based on the patient's thrombotic risk and the bleeding risk while on anticoagulants.

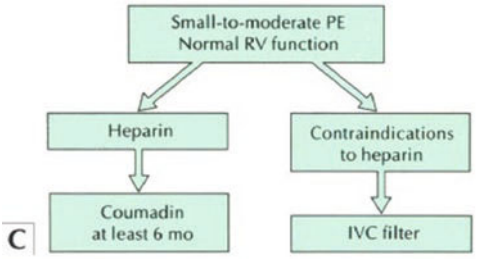


Protocols for treating different types of pulmonary embolism (PE). The optimal duration of Coumadin has not been studied in patients with pulmonary embolism. A, The patient who is hemodynamically compromised can receive an array of pharmacologic or mechanical interventions designed to lyse, remove, and dissipate the embolism while maintaining adequate right ventricular function. Consideration should be given to placement of a filter in the inferior vena cava (IVC) to prevent

recurrent embolism that may be fatal in a patient with persistently compromised cardiopulmonary status. [Chapter 3 in: Braunwald E, Goldhaber S, editors. Cardiopulmonary Diseases and Cardiac Tumors. Atlas of Heart Diseases. 1st edition. Philadelphia: Current Medicine; 1995. ISBN: 1-878132-23-7.] *Caption from original*



B, Moderate to large pulmonary embolism with associated right ventricular dysfunction. Although they are normotensive, these patients may benefit from thrombolytic therapy or suction catheter embolectomy not only to reverse right ventricular dysfunction rapidly and hasten pulmonary reperfusion but also to reduce the frequency of such adverse clinical events as recurrent embolism [Chapter 3 in: Braunwald E, Goldhaber S, editors. Cardiopulmonary Diseases and Cardiac Tumors. Atlas of Heart Diseases. 1st edition. Philadelphia: Current Medicine; 1995. ISBN: 1-878132-23-7.] *Caption adapted from original*



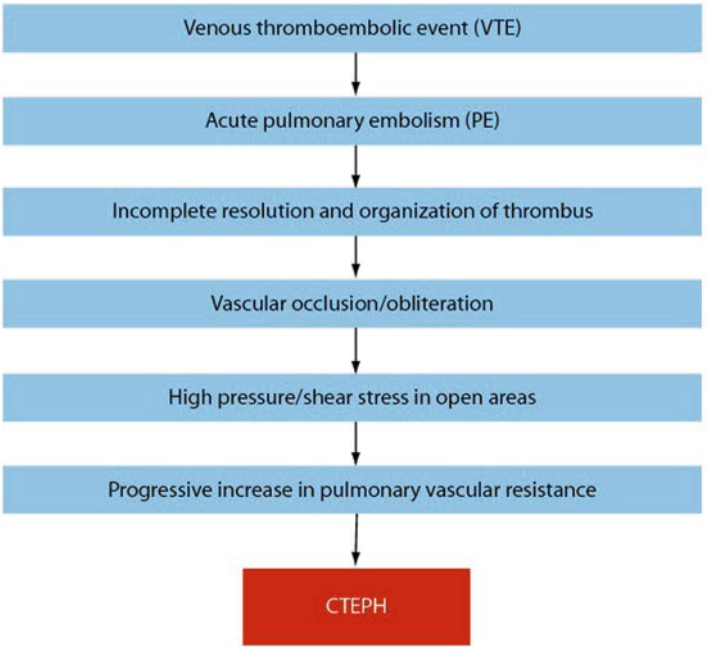
C, Small to moderate pulmonary embolism with normal right ventricular function. The prognosis of these patients is usually good with anticoagulation therapy alone. [Chapter 3 in: Braunwald E, Goldhaber S, editors. Cardiopulmonary Diseases and

Cardiac Tumors. Atlas of Heart Diseases. 1st edition. Philadelphia: Current Medicine; 1995. ISBN: 1-878132-23-7.] *Caption from original*

- Hemodynamically unstable PE is likely to benefit from thrombolytic therapy if contraindications do not exist.
- Remove or ameliorate risk as possible (e.g., stop smoking, lose weight if obese, discontinue birth control pills, etc).

Disease Course

- PE can be fatal. The true case mortality rate is not known owing to minor PEs that may not even be diagnosed on one end of the disease spectrum, and lack of autopsy data on the other end.
- Repeated PE may result in a serious disease called chronic thromboembolic pulmonary hypertension, or CTEPH.



Embolic hypothesis of CTEPH. [Humbert M, Lang IM, Mayer E. Chronic thromboembolic pulmonary hypertension (CTEPH): specific disease characteristics and similarities to idiopathic pulmonary arterial hypertension. Clinical Research in Cardiology Supplements. 2010 Sep;5(S2):12–5.] *Caption from original*

- Most patients with first submassive PE, treated with early anticoagulation, have full recovery.

Chapter 62
Pulmonary Fibrosis

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, Victoria G. Riese, and Jaime Friel Blanck

Name and Synonyms

Pulmonary Fibrosis

- Synonyms:
  - Chronic interstitial pneumonitis
  - Hamman–Rich syndrome
  - Diffuse fibrosing alveolitis

Incidence/Epidemiology

- Idiopathic pulmonary fibrosis affects about 128,100 people in the United States
  - 48,000 new cases diagnosed annually
  - 40,000 people die each year

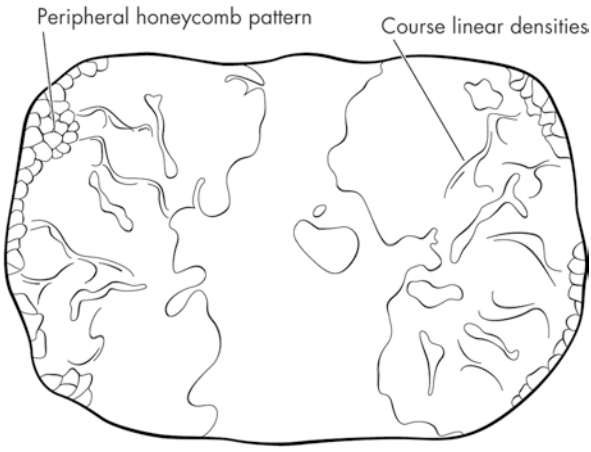
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_62

Differential Diagnosis

- The differential diagnosis is broad and includes acute and chronic lung infections, pneumoconioses, collagen vascular diseases, and hypersensitivity syndromes.
  - Usually a diagnosis of exclusion
  - Sarcoidosis
  - Histiocytosis X
  - Collagen vascular disease
  - Drug-induced pulmonary toxicity
  - Eosinophilic pneumonia
  - Farmer's lung
  - Histoplasmosis
  - Pneumonia (aspiration, bacterial, fungal, viral)
  - Pneumonitis (interstitial)
  - Pulmonary edema
  - Restrictive lung disease
  - Silicosis
  - Tobacco worker's lung

Pathophysiology and Etiology

- Scarring throughout the lungs results in impaired gas exchange.



Pathophysiology of idiopathic pulmonary fibrosis. Schematic representation of chest computed tomography in IPF, showing coarse linear densities and a peripheral honeycomb pattern. [Smith M, Grichnik K. Anesthetic considerations for lung transplant and thoracic aortic surgery. In: Reves JG, editor. Cardiothoracic

anesthesia. Philadelphia: Current Medicine; 1999. (Miller RD, editor. Atlas of anesthesia; vol. 8). ISBN: 0-443-07974-9] *Caption adapted from original*

- Associated with many conditions, including:
  - Infection
  - Pneumoconiosis (asbestos, silica)
  - Radiation exposure
  - Lupus, rheumatoid arthritis
  - Certain medications, including amiodarone
  - Granulomatous processes such as pulmonary sarcoidosis and Wegener's granulomatosis
  - Idiopathic: fibrosis develops without an identifiable cause
    - Most common form

Presentation

Typical/"Classic"

- Onset usually is gradual as symptoms worsen from a dry cough through dyspnea on exertion to dyspnea at rest.

Shortness of breath, exercise limitation
Cough
Age > 50 years
Crackles on physical examination (>80%)
Clubbing on physical examination (>20–50%)
Restrictive defect (reduced lung volumes) on pulmonary function tests
Hypoxemia (at rest or with exercise)
Characteristic HRCT scan

Clinical features of idiopathic pulmonary fibrosis [Lynch JP, Belperio JA. Idiopathic pulmonary fibrosis. In: Baughman RP, du Bois RM, editors. Diffuse lung disease [Internet]. New York, NY: Springer; 2012 [cited 2015 Sep 9]. p. 171–94. Available from: http://link.springer.com/10.1007/978-1-4419-9771-5_10] Caption from original

Atypical

- Occasionally seen as Hamman–Rich syndrome, in which symptoms and deterioration progress rapidly.

Primary Differential Considerations

Patients with signs and symptoms consistent with pulmonary fibrosis also may need to be evaluated for other lung and cardiopulmonary diseases, including:

- Pneumoconiosis
- Pneumonia
- Congestive heart failure
- Drug-induced lung toxicity
- Radiation pneumonitis
- Sarcoidosis
- Restrictive lung disease

History and Physical Exam

Findings That Confirm Diagnosis

Imaging (and often lung biopsy) is required to confirm the diagnosis of pulmonary fibrosis

Factors That Suggest Diagnosis

- History of occupational exposure
- History of connective tissue disease, inflammatory bowel disease, or malignancy
- Medication history
- Smoking history
- Prior irradiation
- Physical exam findings are nonspecific
  - Crackles may be present
  - Clubbing of the digits may occur

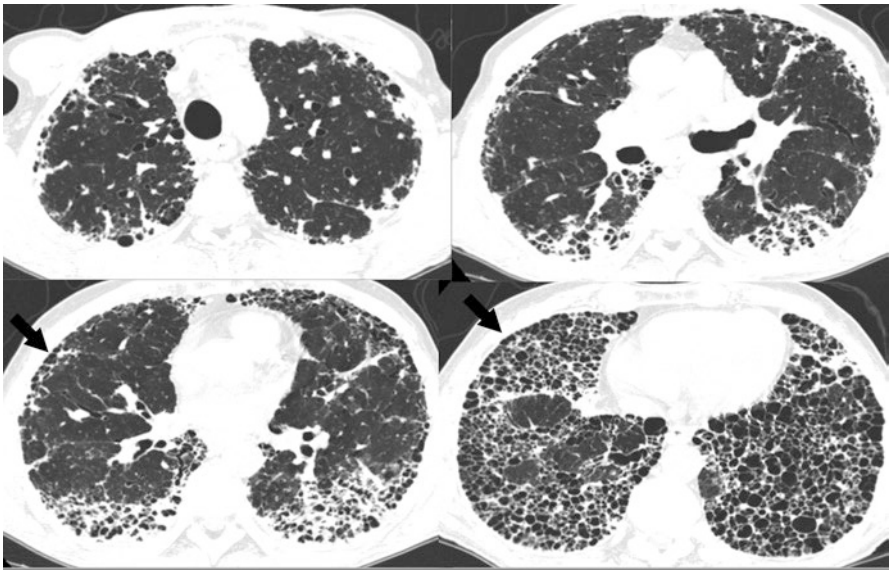
Factors That Exclude Diagnosis

- A productive cough is unusual.
- Wheezing and chest pain are uncommon signs.

Ancillary Studies

Imaging

- Plain chest radiography typically shows reticulonodular opacities and sometimes a "ground glass" appearance of the lung fields.
  - This is nonspecific, and advanced imaging is required in the evaluation.
- Chest CT reveals "honeycomb lung" with cysts that grow larger as the disease advances.



Multiple axial HRCT images show basilar- and peripheral-predominant pulmonary fibrosis characterized by reticulation, traction bronchiolectasis, and subpleural honeycombing (arrows), diagnostic of UIP [Chung JH, Kanne JP. Imaging of idiopathic pulmonary fibrosis. In: Meyer KC, Nathan SD, editors. Idiopathic pulmonary fibrosis [Internet]. Totowa, NJ: Humana Press; 2014 [cited 2015 Sep 9]. p. 55–75. Available from: http://link.springer.com/10.1007/978-1-62703-682-5_4] *Caption from original*

Special Populations

- Those with certain occupational, medication, or tobacco exposure are at increased risk.

Pediatric Considerations

- Pulmonary fibrosis generally is not a pediatric disease.
- As in the adult, it may be associated with certain medications, if taken by the child.
- At the extremes of chronicity (i.e. bronchopulmonary dysplasia, bronchiolitis, cystic fibrosis), it may develop.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Diagnosis needs a complete, thorough history and physical including occupation, drug exposures, and family history to exclude other diagnoses.

Mimics

- Many symptoms may be shared with a variety of pulmonary and cardiac diseases.

Time-Dependent Interventions

- Fibrosis is a chronic disease; unless the patient presents with acute ventilatory failure, there are no time-critical interventions.

Overall Principles of Treatment

- The course typically is inexorably downhill, with no consistently effective pharmacotherapy.
  - In some cases, corticosteroid therapy may be beneficial.
- Lung transplantation is reserved for very advanced cases.

Disease Course

- Scarring is permanent once it has developed.
- As the disease progresses, it may lead to pulmonary hypertension, cor pulmonale, respiratory failure, and increased risk of lung cancer.

Chapter 63
Pulmonary Hypertension

Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Pulmonary Hypertension; Idiopathic Pulmonary Hypertension; Pulmonary Arterial Hypertension; Primary Pulmonary Hypertension

Incidence/Epidemiology

- The incidence and prevalence of pulmonary hypertension is difficult to ascertain, as the disease has 5 general classes as defined by The World Health Organization (see Pathophysiology and Etiology section below), all with multiple etiologies.
- Pulmonary hypertension affects all age groups, races, and both sexes.
- The incidence varies among the different groups and etiologies.
- Group 1 (pulmonary arterial hypertension) is rare, with an estimated incidence of about 10 cases per one million adults. Group 1 affects adults younger than those in the other groups.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_63

Differential Diagnosis

- The differential diagnosis of pulmonary hypertension is broad, as the presenting symptoms of pulmonary hypertension are nonspecific.
- The most common initial symptom is dyspnea on exertion, and the differential diagnosis of this complaint is broad and includes a large spectrum of pulmonary, cardiac, and metabolic diseases.
- Initial symptoms often include dyspnea on exertion (the most common initial symptom), atypical chest pain, and exertional syncope. These symptoms are slowly progressive and often long-standing when the patient presents for care.
- It is important to consider pulmonary hypertension in the differential of patients being evaluated for any of these complaints.
- As the presenting symptoms are nonspecific, the diagnosis of pulmonary hypertension is often delayed for months to years after symptoms begin.

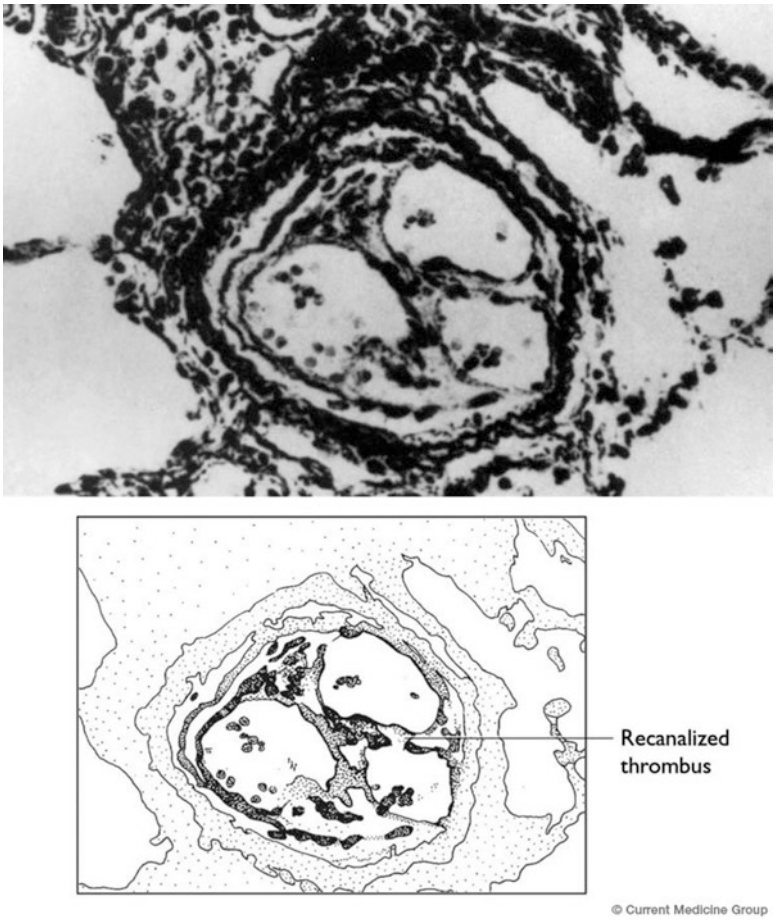
Pathophysiology and Etiology

- Pulmonary hypertension refers to elevated pulmonary arterial pressure. It is defined as a mean pulmonary arterial pressure of greater than or equal to 25 mm Hg at rest, usually measured during right heart catheterization.
- It can occur as a primary condition, with hypertension only within the pulmonary system; or, it can occur has a secondary condition in the context of pressure elevation within the pulmonary venous system. Primary pulmonary hypertension (outdated term) is now referred to as idiopathic pulmonary arterial hypertension (IPAH), and secondary pulmonary hypertension is referred to as pulmonary hypertension (PH). When referring to the group of disorders collectively, pulmonary hypertension is the appropriate term.
- IPAH has no identifiable cause, whereas PH generally has an identifiable cause, such as heart disease, thromboembolic pulmonary disease, and chronic lung disease.
- The World Health Organization has recently re-classified pulmonary hypertension into five broad groups based upon etiology.
    - Group 1: Pulmonary arterial hypertension (PAH). This group includes idiopathic PH (IPAH), familial (heritable) PAH, and PAH due to diseases that share the common pathologic basis of involvement of the small pulmonary muscular arterioles. This includes PAH caused by drugs and toxins, PAH secondary to connective tissue diseases, HIV infection, portal hypertension, congenital heart disease, and schistosomiasis.
    - Group 2: This is PH due to left heart disease.
    - Group 3: PH secondary to chronic lung disease and/or hypoxemia.
    - Group 4: PH secondary to chronic thromboembolic pulmonary disease. Often referred to as chronic thromboembolic pulmonary hypertension (CTEPH).

- Group 5: PH due to unclear multifactorial mechanisms.

- Group 1. Patients with idiopathic and familial PAH are pathologically and clinically nearly identical. The distinction can only be made when and if a patient with PAH is found to have a genetic defect known to cause PAH. It is estimated that up to 10 % of patients in Group 1 have familial PAH. The mutation BMPR2 is the most common mutation to cause familial PAH. It may account for up to 80 % of all cases of familial PAH. Other causes of Group 1 PAH include:
  - Drugs and toxins. Several drugs are known to induce PAH. These include appetite suppressants (fenfluramine, dexfenfluramine, aminorex, and diethylpropion), toxic rapeseed oil, and benfluorex. Other drugs that are considered to be possible causes of PAH include: amphetamines, L-tryptophan, methamphetamines, cocaine, phenylpropolamine, St. John's Wort, dasatinib, and interferon.
  - Connective tissue diseases. Systemic sclerosis (scleroderma), Rheumatoid arthritis, and systemic lupus erythematous (SLE) can cause PAH. The mechanism is unknown.
  - HIV. PAH occurs in about 0.5 % of patients with HIV. The cause is unknown.
  - Portal hypertension associated with chronic liver disease can lead to PAH. When portal hypertension and pulmonary hypertension are present together it is called portopulmonary hypertension.
  - Congenital heart disease. PAH can develop in patients with large left-to-right intracardiac shunts due to congenital heart disease such as atrial septal defects and ventricular septal defects. PAH can also develop in patients with left-to-right shunts from great artery defects. PAH develops due to increased pulmonary blood volume and subsequent pressure overload.
  - Schistosomiasis. Schistosomiasis is rare in the United States and other developed nations, but it is the most prevalent cause of PAH worldwide.

- Group 2. Pulmonary hypertension from left heart disease. Characterized by elevated left atrial and pulmonary venous pressures. Left atrial hypertension is most commonly caused by left ventricular systolic or diastolic dysfunction and mitral or aortic valvular disease. Other, less common, causes include: restrictive cardiomyopathies, constrictive pericarditis, left atrial myxoma, and congenital cardiomyopathies.
- Group 3. Group 3 PH is PH caused by underlying lung diseases and/or hypoxemia. This includes: chronic obstructive pulmonary disease (COPD), interstitial lung diseases (ILD), and obstructive sleep apnea (OSA), especially in the presence of obesity hypoventilation syndrome and hypoxemia.
- Group 4. Group 4 PH is PH caused by thromboembolic disease. Chronic thromboembolic pulmonary hypertension (CTEPH) occurs from chronic, small pulmonary emboli with occlusion of the pulmonary vasculature. This leads to pulmonary hypertension and vascular remodeling.
- Group 5. Pulmonary hypertension from unclear and multifactorial mechanisms. Examples include PH due to sickle cell anemia and other hemolytic anemias.



Vascular pathology in idiopathic pulmonary arterial hypertension. Thrombotic arteriopathy in a pathologic specimen from a patient with idiopathic pulmonary arterial hypertension. Evidence of thrombosis with recanalization can be observed in pathologic specimens from patients with idiopathic pulmonary arterial hypertension. [Goldhaber SZ, Piazza G. Interventional cardiology. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p. ISBN: 978-1-57340-309-2] *Caption from original*

Presentation

Typical/"Classic"

- The symptoms of pulmonary hypertension are non-specific. In retrospect, patients are often found to have complained of dyspnea on exertion and fatigue. These are not uncommonly attributed to other causes, such as age, deconditioning, or a coexisting and/or alternative medical condition.

- These early symptoms are caused by the inability to adequately increase cardiac output to match demand during exertion.
- Because the initial symptoms of PH can be very vague and nonspecific, patients are often not correctly diagnosed for several years after the development of symptoms.
- As PH is a chronic and progressive disease, the diagnosis is often not considered until the patient develops severe symptoms. These include exertional chest pain, exertional syncope, and signs of right heart failure such as peripheral edema.
- PH is frequently only considered and identified during the evaluation and work-up for an alternative diagnostic consideration.

Atypical

- It is difficult to define an atypical presentation of a process with such vague symptoms and signs.
- Ortner's Syndrome is one such defined atypical presentation of PH. It is marked by cough, hoarseness, and hemoptysis secondary to compression of the recurrent laryngeal nerve by a dilated main pulmonary artery.

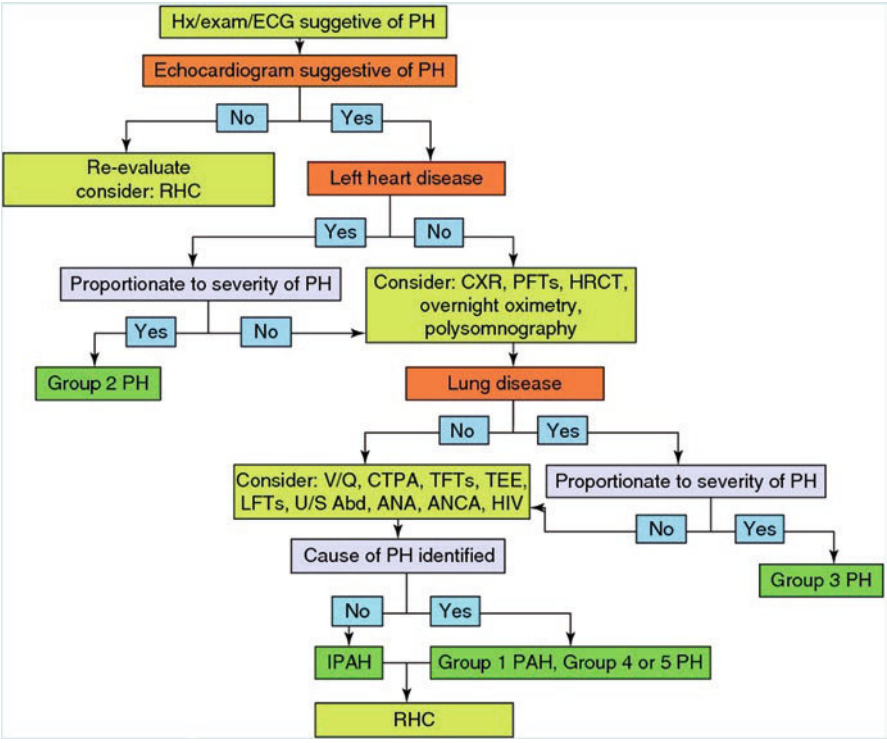
Primary Differential Considerations

- Patients with signs and symptoms referable to pulmonary hypertension should also be evaluated early on for other potentially accurate diagnoses, such as:
  - dilated cardiomyopathy
  - pulmonic valve stenosis
  - mitral valve stenosis

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination findings that are pathognomic for pulmonary hypertension.
- The diagnosis is only confirmed by diagnostic testing. Right heart catheterization is currently the standard test for confirmation of the diagnosis.



Suggested algorithm for evaluation of suspected pulmonary hypertension. Hx clinical history, Exam clinical examination, ECG electrocardiogram, PH pulmonary hypertension, CXR chest radiograph, PFTs pulmonary function tests, V/Q ventilation/perfusion scintigraphy, CTPA computed tomography pulmonary angiography, TFTs thyroid function tests, TEE transesophageal echocardiogram, LFTs liver function tests, U/S abd ultrasound of the abdomen, ANA antinuclear antibody, ANCA anti-neutrophil cytoplasmic antibody, HIV human immunodeficiency virus serology, IPAH idiopathic pulmonary arterial hypertension, RHC right heart catheterization [Judge EP, O'Callaghan D, Gaine SP. Pulmonary Vascular Disease. In: Rosendorff C, editor. Essential Cardiology [Internet]. New York, NY: Springer New York; 2013 [cited 2015 Sep 29]. p. 603–25. Available from: http://link.springer.com/10.1007/978-1-4614-6705-2_35] *Caption from original*

Factors That Suggest Diagnosis

- The diagnosis should be considered in any patient (especially a patient with any of the associated diseases and exposures as detailed in the Etiology section) with complaints of progressive dyspnea on exertion.

- The work-up and evaluation of a patient with dyspnea on exertion is broad, and should include studies (such as a chest x-ray, echocardiogram, or CT chest) that may give clues to the presence of PH.
- Physical exam findings in PH are also nonspecific, especially early in the disease course.
- Early in the course of PH, before right heart failure develops, patients may have a loud pulmonic component to the second heart sound, and the second heart sound may be narrowly split or single.
- As right heart failure develops, patients may develop the physical signs as described in the section on cor pulmonale.

Findings	Patients, %
Increase in P_2	93
Tricuspid regurgitation murmur	40
Right-sided S_4	38
Peripheral edema	32
Right-sided S_3	23
Cyanosis	20
Pulmonic insufficiency murmur	13

Physical findings in patients with idiopathic pulmonary arterial hypertension. The physical examination is nonspecific, revealing signs of pulmonary hypertension and right ventricular failure. In the NIH study, the presence of an S3 gallop and tricuspid regurgitation were associated with an increase in right atrial pressure and a decrease in cardiac index; the finding of pulmonic valve insufficiency was associated with a higher mean pulmonary artery pressure. The physical examination helps exclude secondary causes of pulmonary hypertension by an absence of crackles, wheezes, and clubbing. (Data from Rich S, Dantzker DR, Ayres SM, et al. Primary pulmonary hypertension: a national prospective study. Ann Intern Med. 1987; 107:216 -223.) [Singh J, Tapson V, Markewitz B, Elliott GC, Michael J. Chapter 18. In: Crapo J, editor. Bone's atlas of pulmonary and critical care medicine. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7] Caption adapted from original

Factors That Exclude Diagnosis

- There are no reliable historical or physical findings that exclude PH from the differential.

Ancillary Studies

- Extensive diagnostic testing is usually performed on patients thought to have PH, with three common goals:
  - to confirm the diagnosis
  - to attempt to identify an underlying cause
  - to evaluate the severity of the physiologic derangement
- Evaluation often begins with an echocardiogram, and includes multiple other tests as determined by the clinical scenario and symptoms. The diagnosis is usually confirmed by right heart catheterization.

Echocardiography

- Transthoracic echocardiography (TTE) is often the first step in the evaluation and diagnosis of pulmonary hypertension. TTE is used to estimate the pulmonary artery pressure, right ventricular size thickness and function, and right atrial size and function.
- TTE can also be used to assess left heart function, valve function, and any congenital heart anomalies, all three of which are necessary steps in the evaluation of PH.
- As PH progresses, patients will develop findings of right ventricular pressure overload, such as:
  - Paradoxical bulging of the septum into the left ventricle during systole
  - Hypertrophy of the right ventricle
- Echocardiographic findings of right ventricular failure/cor pulmonale are described in the chapter on cor pulmonale.

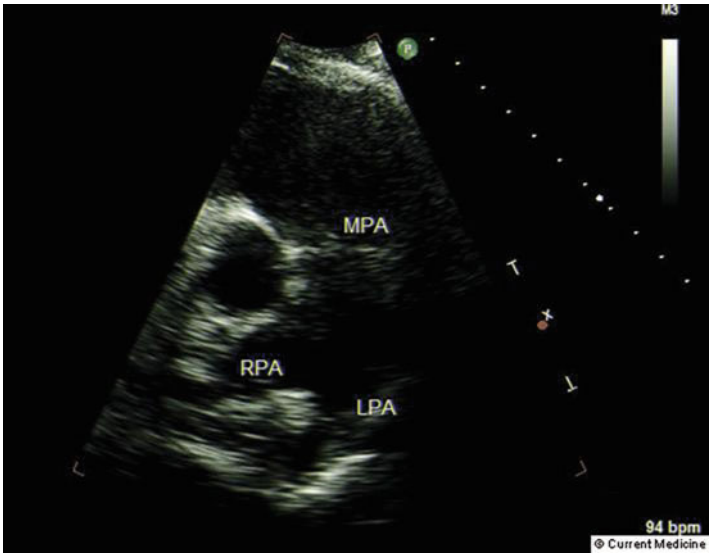
https://www.youtube.com/watch?v=3yOdNyTH07g
Video of Echocardiographic findings in PH.



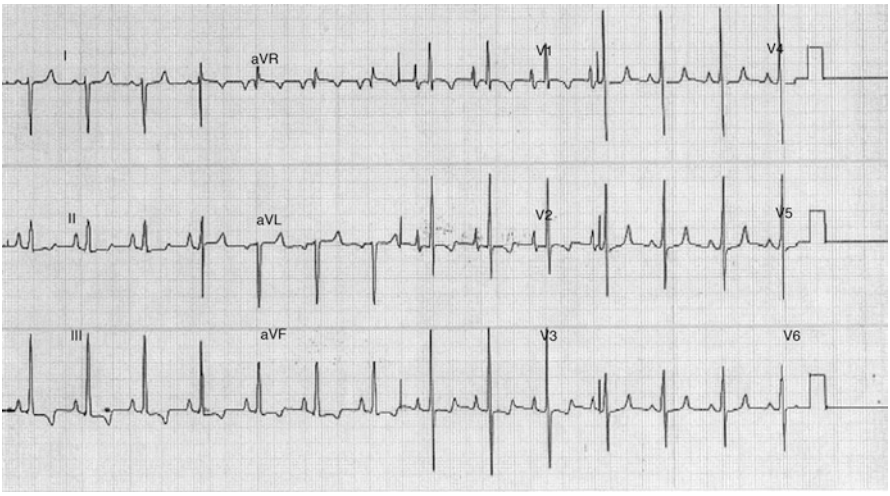
Echocardiogram of severely dilated main pulmonary artery in pulmonary hypertension. Main pulmonary artery (MPA) and bifurcation view, demonstrating severely dilated MPA and branches in a patient with severe pulmonary hypertension. LPA: left pulmonary artery; RPA: right pulmonary artery. [Mangion J, Solomon S. Chapter 15. In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, Braunwald E, editors. Atlas of Echocardiography. 1e. Philadelphia, PA: Current Medicine Group; 2005. 312 p. ISBN: 1-57340-217-6] *Caption from original*

Laboratory

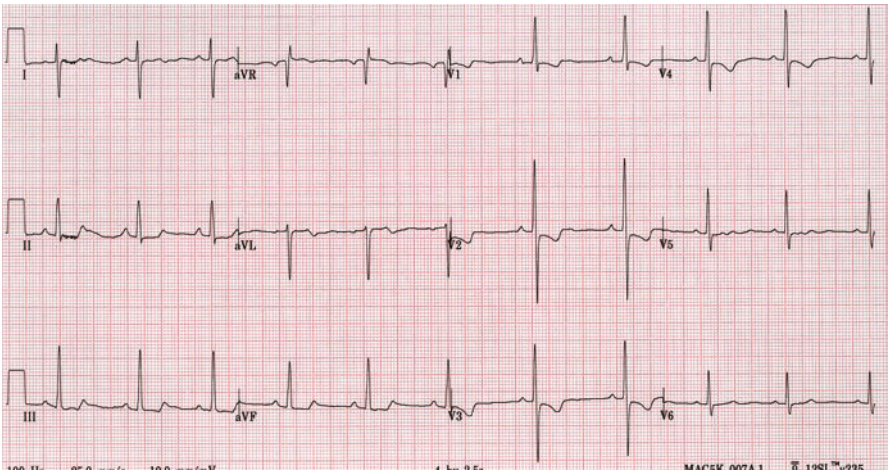
- Typical laboratory tests performed in the evaluation include evaluation for anemia with a complete blood count, and a complete metabolic panel to evaluate electrolytes, renal function, and liver function.
- In the appropriate clinical setting, HIV serology should be checked to screen for HIV-associated PH.
- An antinuclear antibody (ANA) should be sent to evaluate for connective tissue as the cause for PH. Further, more specific connective tissue disease testing can be performed as indicated.
- In areas of increased prevalence, screening for hemolytic anemia such as sickle cell anemia, and screening for Schistosomiasis should be considered.
- Brain natriuretic peptide (BNP) and its precursor, N-terminal pro-brain natriuretic peptide (NT-proBNP), are peptides that are released by myocardial cells when stretched. They are elevated in both right and left heart failure, and are not helpful in distinguishing between the two. Patients with known PH who have elevated levels of either have a worse prognosis than those with normal levels.

Electrocardiography

- The ECG in PH can show a right axis deviation, right ventricular hypertrophy (an R wave/S wave ratio greater than one in lead V1), right atrial enlargement (p pulmonale, an increase P wave amplitude in lead II), and an incomplete or complete right bundle branch block. These ECG changes are almost always present in pulmonary hypertension especially as the disease progresses, but can also be present in many other disease states (they are specific but not sensitive).



A 12-lead ECG strip of a 31-year-old male patient with pulmonary hypertension (p-pulmonale, right-axis deviation, and right ventricular hypertophy) [Stübgen J-P. Rigid Spine Syndrome: A Noninvasive Cardiac Evaluation. Pediatric Cardiology. 2008 Jan;29(1):45–9.] *Caption from original*



An ECG taken in a patient with idiopathic pulmonary arterial hypertension. Note the signs of right ventricular hypertrophy with a rightward mean frontal QRS axis. [Simon J, Gibbs R, Stefanidis A, Li W. Pulmonary Hypertension Clinical Echocardiography. In: Nihoyannopoulos P, Kisslo J, editors. Echocardiography [Internet]. London: Springer London; 2009 [cited 2015 Sep 3]. p. 229–49. Available from: http://link.springer.com/10.1007/978-1-84882-293-1_10] *Caption from original*

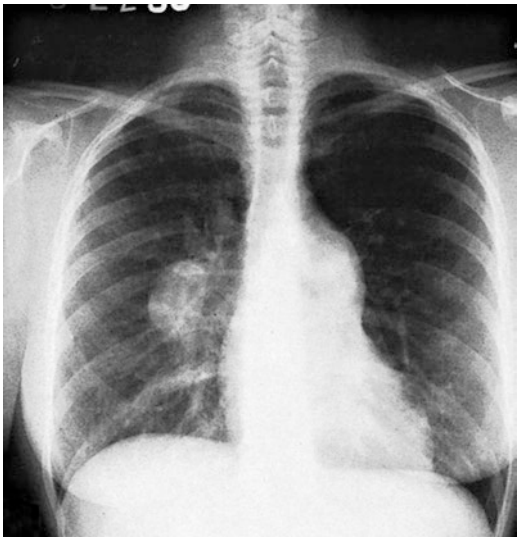
Pulmonary hypertension with severe right atrial and ventricular overload in a young woman. The ECG shows signs of right atrial and ventricular enlargement, the latter manifested by qR complexes in V1-V3 and ST-segment depression. The electrical axis is also deviated to the right. [Romanò M. The Electrocardiogram in Disorders of the Pulmonary Circulation. Text Atlas of Practical Electrocardiography [Internet]. Milano: Springer Milan; 2015 [cited 2015 Sep 3]. p. 213–5. Available from: http://link.springer.com/10.1007/978-88-470-5741-8_14] *Caption from original*

Imaging

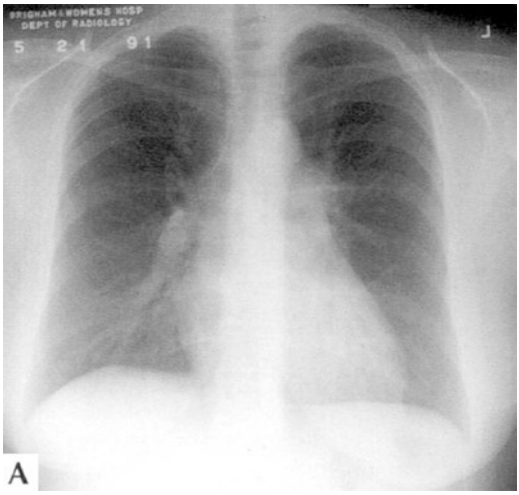
Chest X-ray

- Pulmonary hypertension often leads to enlargement of the central pulmonary arteries, i.e., the main pulmonary artery, the hilar vessels, and the descending right pulmonary artery, associated with gradual diminution in the peripheral vessels, leading to hyperlucent peripheral lung fields (oligemia). Other findings on CXR can include:
  - right ventricular enlargement (noted as loss of the retrosternal airspace on a lateral view)
  - right atrial dilatation (noted as a prominent right heart border)
- The chest x-ray can also occasionally help in giving clues to any underlying diseases that may be complicating PA, such as COPD, interstitial lung disease, and congestive heart failure.

https://www.youtube.com/watch?v=9y-PDoJoL2M
Video explaining radiographic findings in PH.



Pulmonary hypertension. A, An injection drug user aged 32 years presented with progressive shortness of breath. Marked dilatation of both pulmonary arteries is shown. For unknown reasons, the incidence of primary pulmonary hypertension is increased in patients with HIV infection. [Lalloo UG, Ambaram A, Vawda F. Pulmonary Complications. In: Mildvan D, editor. International Atlas of AIDS. 4e.: Current Medicine; 2008. 366 p. ISBN: 1-57340-270-2] *Caption adapted from original*

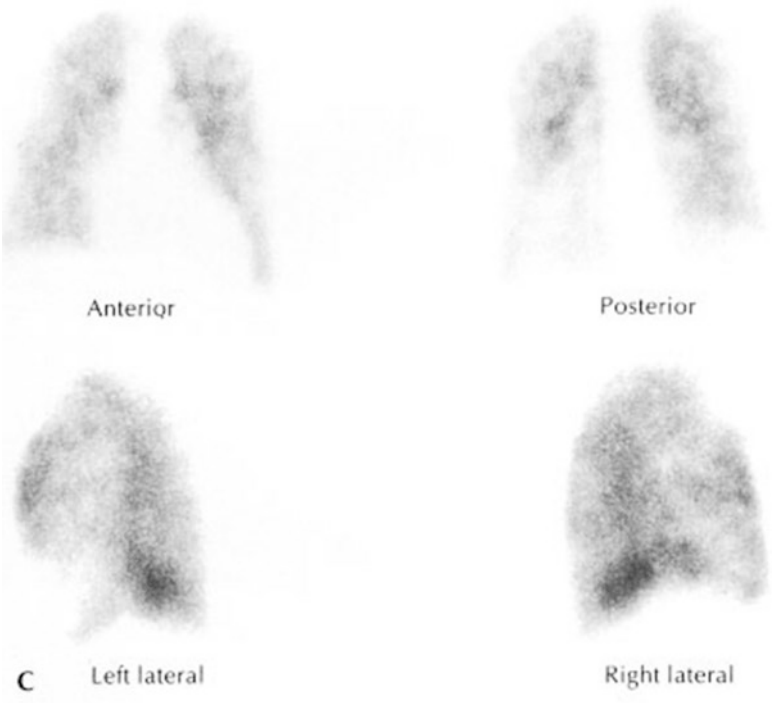


Typical radiograph of a patient with primary pulmonary hypertension and cor pulmonale. Note the peripheral oligemia of the pulmonary vessels with mild bilateral enlargement of the main pulmonary arteries. [Loh E. Chapter 01. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption adapted from original*

Ventilation/Perfusion Scanning (V/Q scan)

- V/Q scan is the imaging of choice in the evaluation of patients for CTEPH (Group 4 PH).
- A normal V/Q scan can nearly exclude chronic thromboembolic disease as the cause for PAH.
- If the V/Q suggests the presence of chronic thromboembolic disease, an angiogram or a CT angiogram should be performed to confirm the diagnosis.

Perfusion lung scan in chronic thromboembolic pulmonary hypertension. B, Perfusion lung scan in a patient with CTEPH. Ventilation scan was normal. [Fedullo P, Auger W, Channick R, Jamieson S, Moser K. Chapter 07. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption adapted from original*



C, Perfusion lung scan in primary pulmonary hypertension. Ventilation-perfusion lung scanning provides an excellent, low-risk, noninvasive means of distinguishing between pulmonary hypertension due to potentially operable CTEPH and obliterative, small-vessel pulmonary hypertension. In chronic thromboembolic disease, at least one (and, more commonly, several) segmental or larger mismatched defect is present. In primary pulmonary hypertension, the perfusion scan is either normal or has a mottled appearance consisting of patchy, subsegmental abnormalities. Although the ventilation-perfusion lung scan can suggest the diagnosis of CTEPH, it is incapable of confirming the diagnosis or establishing surgical feasibility. Any process that occludes major pulmonary arteries, either through external compression (fibrosing mediastinitis, mediastinal tumors) or intraluminal obstruction (thrombus, tumor), will result in similar defects. [Fedullo P, Auger W, Channick R, Jamieson S, Moser K. Chapter 07. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption adapted from original*

CT Scan/MRI

- CT scans of the lungs can be helpful in the evaluation and diagnosis of causes of PH, such as ILD, COPD, CTEPH.

- Cardiac magnetic resonance imaging (MRI), if available, is superior to transthoracic echocardiography in the evaluation of right ventricular structure and function.

Other

- Right heart catheterization is considered the best diagnostic test for confirming the diagnosis of pulmonary hypertension and evaluating the severity of the disease. Pulmonary hypertension is defined as a pulmonary artery (PA) pressure greater than 25 mmHg, and no evidence of left heart disease, as evidenced by either a normal (less than 15 mmHg) left ventricular end-diastolic pressure. All chamber dimensions and pressures can be directly measured.
  - Measuring *only* the pulmonary capillary wedge pressure (PCWP) is insufficient to distinguish PH alone from PH due to left heart disease, as the PCWP may be falsely elevated in all cases of PH due to dilatation of the main pulmonary artery, which prevents accurate measurement of the PCWP.
- Vasoreactivity test. Patients with Group 1 PAH should have a vasoreactivity performed prior to the initiation of any PAH-specific therapy. A small subset of patients with IPAH, hereditable PAH, and drug-induced PAH will have significant hemodynamic and symptomatic improvement with the use of calcium channel blockers. Vasoreactivity testing involves administering a short-acting vasodilator (such as inhaled nitric oxide, or infusions of adenosine or epoprostenol) during right heart catheterization and then measuring the response of the mean pulmonary artery pressure. Patients with a positive vasoreactivity test (decrease in mean PA pressure of at least 10 mm Hg to at least 40 mmHg, an increased or unchanged cardiac output, and insignificant change in systemic blood pressure) should have therapy with a calcium channel blocker started.
- Pulmonary function tests are used to evaluate for underlying lung disease such as interstitial lung disease (ILD) and chronic obstructive pulmonary disease (COPD) as the underlying causes for PH.
- Sleep studies (polysomnography) are used to diagnose obstructive sleep apnea as the underlying cause for PH when the clinical suspicion is high.
- Exercise testing (most commonly the 6-minute walk test) is often performed during the evaluation of or after the diagnosis of PH is established. Exercise testing helps to establish a clinical baseline to guide therapy and measure the response to therapy.

Special Populations

Age

- Pulmonary hypertension is mostly a disease of middle-aged to older adults.
- Group one PAH typically affects younger adults, and is slightly more common in women.
- There is a subset of Group 1 PH (Group 1″) known as persistent pulmonary hypertension of the newborn (PPHN). This is a rare disease of late preterm or term infants with abnormal development of the pulmonary vasculature.
- PH may complicate and be caused by diseases of childhood, congenital heart disease, sickle cell anemia, and cystic fibrosis. However, the development of PH in patients with these disorders is usually a late complication, developing in young adulthood.

Co-morbidities

- Many co-morbid conditions can worsen the prognosis and make the diagnosis of PH difficult. These include but are not limited to, cardiac diseases, other pulmonary diseases, liver disease, and kidney disease.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is important to keep PH on your differential diagnosis in the evaluation of patients with exertional dyspnea and fatigue, as the symptoms and exam findings are nonspecific. It is important to diagnose this disorder as early into the clinical course as possible, as this improves the ability to treat the disease and improves the overall prognosis.
- It is important to perform a detailed and specific evaluation for alternative diagnoses and causative factors for PH.
- It is also important to consider all alternative diagnoses that may cause worsening or acute dyspnea in patients with chronic pulmonary and heart disease. This list includes, but is not limited to, pneumonia, CHF, pulmonary embolism, pneumothorax, significant pleural effusion, and acute metabolic issues that can cause dyspnea.

Mimics

- Many diseases can present with exertional dyspnea and fatigue. This includes, but is not limited to, lung diseases such as COPD and ILD, coronary artery disease, valvular heart disease, congenital heart disease, chronic anemia, metabolic diseases, neuromuscular diseases, etc.

Time-Dependent Interventions

- It is important to make the diagnosis as early as possible into the disease course to improve treatments and outcomes.

Overall Principles of Treatment

- Early diagnosis and treatment is important, as less advanced disease responds better to treatment, and outcomes are better.
- Treatment is generally classified as primary therapy, which is treatment directed at the underlying cause of the PH, and advanced therapy, which is therapy directed at PH.
- Certain treatments need to be considered in all patients with PH. These include:
    - Anticoagulation. PH increases the risk for pulmonary thromboembolism through multiple mechanisms. As such, chronic anticoagulation is indicated in all patients with PH, but especially those with Groups 1 (especially IPAH, hereditary PAH, and drug-induced PAH) and 4 PH.
    - Diuretics. Diuretics are useful to reduce fluid retention and associated edema.
    - Oxygen. All patients with hypoxemia should be given oxygen.
    - Pulmonary rehab/exercise therapy. Pulmonary rehabilitation improves patients' exercise tolerance, daily function, and quality of life.
    - Digoxin. Digoxin is positively inotropic, meaning that it can increase the mechanical contractile strength of the heart. Digoxin's therapeutic window is narrow, however, and it has significant toxicities associated with its use. Patients receiving digoxin need to be closely monitored.
- Primary therapy.
    - Group 1 PAH. There are limited therapeutic options for Group 1 PAH patients. Management of the primary disease should be maximized for patients with an identified underlying cause (such as HIV, congenital heart disease, Schistosomiasis). However, this often does not improve symptoms of PAH once they develop and these patients often require advanced therapy for PAH.
    - Group 2. Therapy for the underlying heart disease must be maximized for patients with Group 2 PH.

- Group 3. These patients need to have their underlying lung disease treated, and they require oxygen therapy if hypoxemic.
- Group 4. Anticoagulation is the most important treatment for patients with group 4 PH. Some selected patients may benefit from surgical thromboendarterectomy.
- Group 5. Patients with group 5 PH should have their underlying diseases treated.

- Advanced Therapy. Patients requiring advanced therapy for PH should be referred to and managed by a center with significant experience managing these disorders. All patients should have a complete diagnostic evaluation (which includes right heart catheterization and vasoreactivity test) and functional class staging WHO functional class) prior to initiating advanced therapies.
- WHO Functional Classes for PH.
  - Group 1. Advanced therapy for PH by a specialized center is the treatment of choice for most patients with Group 1 PAH. Patients with a positive vasoreactivitiy test should have a trial of treatment with a either a dihydropyridine calcium channel blocker (e.g., amlodipine and others that end in *–ipine*) or diltiazem. If patients have a negative vasoreactivity test or are non-responders they need to have an alternative advanced therapy agent started. The choice of agent is complex and multifactorial, and best managed by a specialized center.
- Treatment with advanced agents is often guided by WHO functional class, and includes:
  - WHO functional class II or III (oral therapy preferred):
    - Oral endothelin receptor antagonists (ambrisentan, bosentan, macitentan)
    - Oral phosphodiesterase inhibitors (sildenafil, tadalafil)
    - Oral guanylate cyclase stimulants (riociguat)
  - Some patients with WHO functional class III disease may benefit from other parenteral agents such as intravenous epoprostenol, inhaled iloprost, or intravenous trepostinil.
  - WHO functional class IV. Intravenous epoprostenol.
- Patients with refractory disease may be considered for combination drug therapy or surgical therapy.
  - Surgical therapy includes: creation of a right-to-left intracardiac shunt (atrial septostomy, or a Potts shunt, a shunt between the left pulmonary artery and the descending aorta); and bilateral lung or bilateral lung and heart-lung transplantation. These therapies are reserved for refractory cases and should be considered only at highly specialized centers.

Disease Course

- Patients on therapy should be seen at least every three months. Patients on no therapy should also be followed at least every three-to-six months for reevaluation.
- PH is a chronic, progressive, and frequently fatal disease, especially if untreated.
- The course of disease progression and mortality is highly variable and dependent upon the type of PH and the disease severity at diagnosis.
- In general, Group 1 PAH tends to have a more rapid course and worse survival than the other types of PH. Recently reported data from the REVEAL registry (Registry to Evaluate Early and Long-term PAH Disease Management) shows survival rates one, three, five, and seven years from the time of right heart catheterization of 85, 68, 57, and 49 percent, respectively, for Group 1 PAH.
- There is early data that advanced therapy can improve survival in Group 1 PAH.
- The following factors are associated with a poorer prognosis in Group 1 PAH.
    - Age > 45
    - Male
    - WHO functional class III or IV
    - Failure to improve clinically with advanced therapy
    - Evidence of right heart failure on echocardiogram (large right atrial size, elevated right atrial pressure, septal shift during diastole, presence of a pericardial effusion, low right ventricular ejection fraction)
    - Increased NT-pro-BNP or BNP levels
    - Prolonged QRS duration
    - Hypocapnia
    - Certain comorbid conditions (especially interstitial lung disease, COPD, diabetes)
    - Persistent supraventricular arrhythmias (atrial fibrillation or flutter)
    - Long-term use of selective serotonin reuptake inhibitors
- The overall course and prognosis in other types of PH varies greatly and is mostly related to the course of the underlying disease.
- Patients with PH (especially those with PAH) are at increased risk for complications and death from any surgical procedure, use of general anesthesia, or mechanical ventilation.

Chapter 64
Radiation Pneumonitis

Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Radiation Pneumonitis; Radiation-induced Lung Injury (RILI); Radiation Fibrosis

Incidence/Epidemiology

- The incidence of radiation pneumonitis varies widely depending upon the regimen/modality of radiation used, and the size/volume of tissue treated.
- Radiographic changes of pneumonitis are much more common than symptomatic disease.
- Across all cancers, about 50% of patients who receive radiation therapy to the chest, lungs, or mediastinum will develop some radiographic findings of pneumonitis, but only about 10–15 % will develop symptoms.
- About 65 % of all patients with cancer will undergo therapeutic radiation therapy at some point during their cancer treatment. This leads to a large number of people being "at risk" for the development of radiation pneumonitis.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_64

Differential Diagnosis

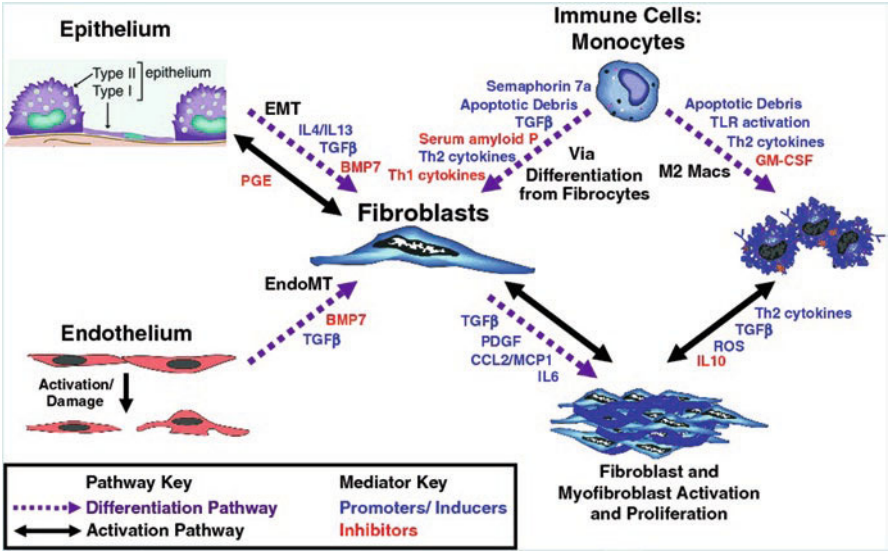
- The differential diagnosis can be broad, and includes all causes of dyspnea and cough, especially in a cancer patient.
- The differential can often be focused to include those processes that have a similar radiographic appearance to radiation pneumonitis. These include:
  - Infection, such as pneumonia, tracheobronchitis, and empyema. Infections can be bacterial, viral, atypical, or fungal.
  - Lymphangitic spread of tumor.
  - Pulmonary embolism (especially if dyspnea is the prominent complaint).
  - Drug reaction.
  - Congestive heart failure (especially in patients who have received chemotherapeutic agents such as doxorubicin).
  - Hypersensitivity pneumonitis-like reaction. This is a less common reaction to radiation that is distinguished from radiation pneumonitis by including areas of the lung outside those that received radiation. It is often bilateral, even if the radiation was only delivered to one lung. It follows a similar time course to early radiation pneumonitis.

Pathophysiology and Etiology

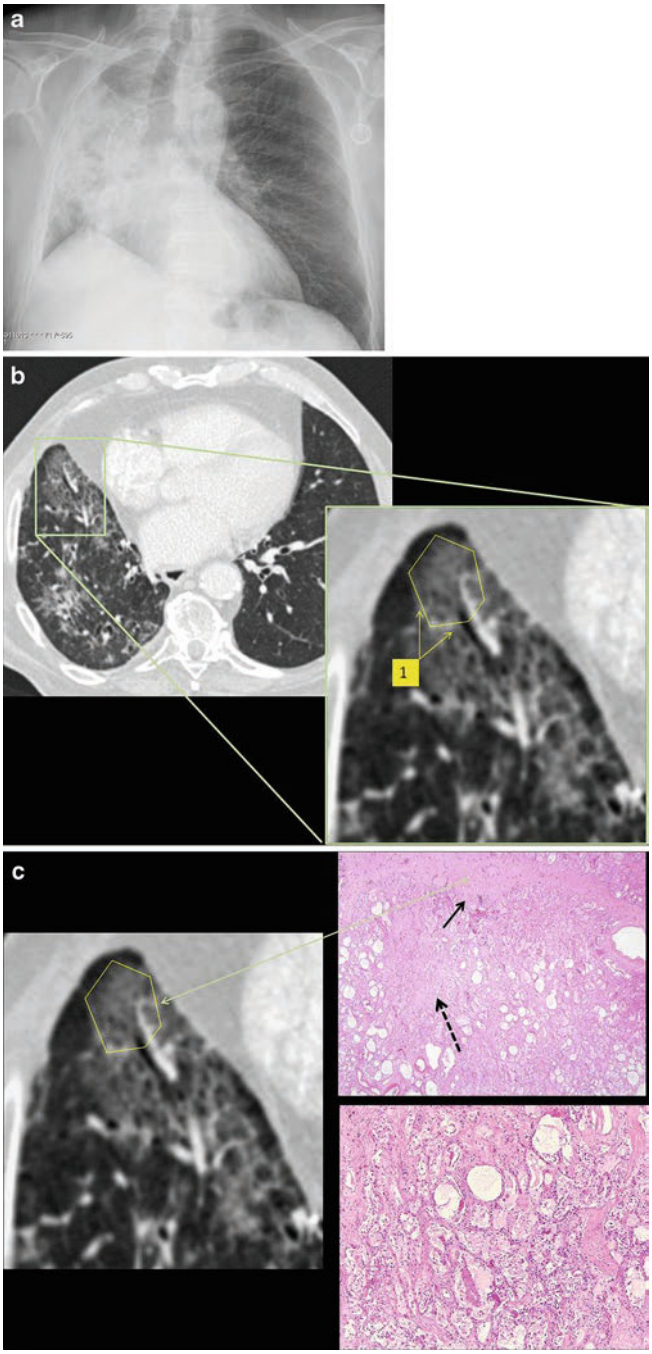
- Ionizing radiation passing through tissue causes the release of large amounts of energy, which can lead to the production of reactive free radicals in the tissue. As water is plentiful, the majority of free radicals include reactive oxygen and hydrogen ions. Other important free radical species include reactive nitrogen species. These free radicals react with and damage other cellular molecules such as DNA, RNA, peptides, and lipids. This can lead to direct cytotoxicity and death to normal lung cells and tissue, especially high turnover cells such as surfactant-producing cells.
- Radiation energy, cell damage, and cell death lead to the activation of inflammatory pathways and the release of a large number of cytokines that can cause inflammatory reactions in lung tissue. Pro-inflammatory cytokines up-regulated after exposure to radiation include, transforming growth factor beta, tumor necrosis factor alpha, interleukin 1-alpha, interleukin-6, platelet-derived growth factor, and basic fibroblast growth factor.
- There are several factors that affect the incidence and risk of the development of radiation pneumonitis.
  - Genetics. In patients with small cell and non-small cell lung cancer, the presence of a mutation in the methylene tetrahydrofolate reductase gene has been shown to be associated with an increased risk for the development

of radiation pneumonitis. There are other, less well-defined, genetic associations in both breast and lung cancer.
- The risk of developing radiation pneumonitis is directly related to the volume of lung tissue exposed to radiation.
- Using the modality of radiation delivery that most limits the dose to the affected tissue helps to prevent the development of radiation-induced lung injury.
- The risk also increases directly with increasing doses of radiation.
- Some chemotherapeutic agents are known to increase tissue sensitivity to radiation. These include doxorubicin, gemcitabine, taxanes, dactinomycin, bleomycin, cyclophosphamide, vincristine, mitomicin, recombinant interferon-alpha, and bevacizumab.
- Concurrent chemotherapy and radiotherapy also appears to increase the risk of radiation pneumonitis, especially in the treatment of breast cancer.
- Current tobacco-smoking and chronic obstructive pulmonary disease have been associated with a lowered risk of developing radiation pneumonitis in some studies.

- The pathologic changes within the lung after exposure to radiation can be divided into five phases.
    - Immediate phase. These changes occur within hours to days after radiation exposure. It consists of mucosal inflammation, increased capillary permeability, mucous hypersecretion, with subsequent sloughing of alveolar epithelial cells. This is usually asymptomatic.
    - Latent phase. During this phase, goblet cells start to proliferate, leading to an increase in secretions. Radiation has also induced ciliary dysfunction, leading to an inability to clear these increased secretions, which then pool in alveoli.
    - Acute exudative phase. This phase occurs anywhere from 3 to 12 weeks after exposure to radiation. It is during this phase that the clinical syndrome of radiation pneumonitis usually occurs. It is characterized by increased sloughing of epithelial and endothelial cells, microvascular thrombosis, alveolar exudate, with subsequent hyaline membrane formation with narrowing of small airways and pulmonary capillaries.
    - Intermediate phase. During this phase, many patients will have resolution of all changes. Some patients, however, will continue to progress with increased collagen deposition by fibroblasts, resulting in thickening and distortion of the interstitial tissues.
    - Fibrosis. In some cases, fibroblasts can continue to migrate into lung tissue and continue to produce collagen, which leads to disruption of alveolar and vascular tissue. These changes can become clinically apparent in anywhere from 6 months to several years after radiation exposure.



Key cell types associated with fibrosis and the differentiation pathways and mediators that promote and inhibit these pathways. Fibrosis is characterized by excess extracellular matrix deposition from collagen-producing cells including fibroblasts and myofibroblasts. These cells are resident within tissues, generating matrix to support tissue function and homeostasis. However, during fibrosis, fibroblasts become activated, proliferate at greater rates than unactivated cells and are resistant to apoptosis. There is also an increased number of myofibroblasts, which are normally at low levels in non-fibrotic tissue. Monocytes activate fibroblasts through either differentiating to fibrocytes or alternatively activated M2 macrophages. Both of these monocyte-derived cells are found at elevated numbers in the circulation of patients with chronic lung fibrosis and at sites of tissue remodeling. Both epithelial cell and endothelial cell injury is observed at sites of fibrotic tissue remodeling. Moreover, the transition of epithelial cells to mesenchymal cells and endothelial cells to mesenchymal cells has been hypothesized as sources for increased mesenchymal cell numbers in fibrosis. Multiple mediators, especially radiation exposure, have been shown to promote fibrosis and to direct cells to a pro-fibrotic or anti-fibrotic phenotype, with the cellular environment also helping to direct cell phenotype. Many of the mediators shown to induce pro-fibrotic responses are pleiotropic, directing more than cellular response on multiple cell types [Murray LA, Sleeman MA. Fibrosis. In: Sonis ST, Keefe DM, editors. Pathobiology of Cancer Regimen-Related Toxicities [Internet]. New York, NY: Springer New York; 2013 [cited 2015 Dec 22]. p. 167–86. Available from: http://link.springer.com/10.1007/978-1-4614-5438-0_9] *Caption adapted from original*



Radiation pneumonitis. **a** Chest radiograph showed an area of consolidation in the right lung with an air bronchogram. There was also loss of volume of the right lung. **b** CT showed the therapy response of the tumor. There was patchy distribution of a

crazy-paving pattern with increased lung attenuation (ground-glass opacity) and thickening of the interlobular septa in the right lung (1). **c** Radiological-histopathological correlation. Histological examination after autopsy showed air-space filling with an exudate in combination with thickening of the interlobular septa (arrow), thickening of the interstitium surrounding the airspaces and also the presence of irregular fibrosis (dotted arrow). Alveolar spaces filled with an exudate of proteinaceous material were responsible for the ground-glass opacities on CT. The reticular pattern was due to congestion of capillaries and oedema of the interstitium [De Wever W, Meersschaert J, Coolen J, Verbeken E, Verschakelen JA. The crazy-paving pattern: a radiological-pathological correlation. Insights into Imaging. 2011 Apr;2(2):117–32.] *Caption from original*

Presentation

Typical/"Classic"

- There are two distinct clinical syndromes associated with radiation damage to the lungs: an acute clinical syndrome due to pneumonitis, and a later syndrome caused by fibrosis.
    - Acute radiation pneumonitis. This develops anywhere from 2 weeks to 3 months after exposure to radiation.
        - Most patients remain asymptomatic throughout this period.
        - Most patients will develop radiographic evidence of pneumonitis (patchy opacities within irradiated areas), but only about 50 % have symptoms.
        - As noted in the Pathophysiology section, the pathologic changes during this period include mucosal inflammation with increased and thickened secretions. These pathologic changes lead to the classic symptoms.
        - The classic symptoms include:
            - Dry cough
            - Shortness of breath
            - Fever
        - Physical examination may be normal, but crackles in the area of consolidation may be noted. Patients may also be tachypneic. In about 10 % of cases a small pleural effusion may be present and decreased breath sounds and dullness to percussion over the effusion may be noted. Pleural inflammation may be noted with a pleural rub.
        - The majority of patients who develop symptoms improve spontaneously over 2 – 4 weeks.

- Late radiation pneumonitis/radiation fibrosis. Although the pathologic process leading to fibrosis can start within 2 weeks of radiation exposure, symptoms (if present) don't usually start until 6 months to even years later.
  - Up to 50 % of patients with radiographic abnormalities will remain asymptomatic.
  - The most common symptoms are dry cough and shortness of breath. Fever can occur but is less common than in acute radiation pneumonitis.
  - In advanced cases of radiation fibrosis, patients may develop signs of pulmonary hypertension and cor pulmonale.

Atypical

- Atypically, patients may present with chest pain. The pain is often pleuritic, and often due to pleural inflammation.
- Chest pain may also occur secondary to esophageal irritation or inflammation. Chest pain in this setting in often worsened by swallowing.

Primary Differential Considerations

- Patients with radiation pneumonitis may present with symptoms that prompt consideration of:
  - Other causes of pulmonary fibrosis
  - Acute pneumonia
  - Pulmonary embolism

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination findings that can completely confirm the diagnosis.

Factors That Suggest Diagnosis

- The diagnosis is suggested when a patient presents with the typical symptoms or radiographic changes in the appropriate time frame after receiving radiation, especially when the radiographic changes are confined to the areas irradiated.

Factors That Exclude Diagnosis

- There are no historical or physical examination findings that can completely exclude the diagnosis, except for an absence of exposure to radiation.

Ancillary Studies

Laboratory

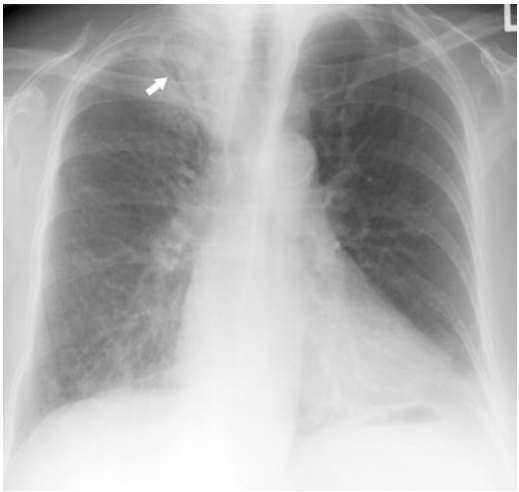
- There are no laboratory studies specific to the diagnosis of radiation pneumonitis.
- Routine laboratory studies are often performed in the evaluation to seek other possible causes of symptoms and radiographic changes.
  - For example, a complete blood count (CBC) showing a leukocytosis with a bandemia or leftward shift may help increase the suspicion for an infectious cause. Patients with radiation pneumonitis may have a slight leukocytosis, but without a bandemia or left shift.
  - An elevated brain natriuretic peptide (BNP) may suggest a diagnosis of congestive heart failure.

Imaging

- Chest x-ray. The classic CXR pattern is one of patchy alveolar densities in the areas treated with radiation. Patients who progress to radiation fibrosis may exhibit lung-volume loss with dense opacities. Again, these are within the areas that received radiation. Some patients may have small pleural effusions.
  - Historically, the CXR in radiation pneumonitis would often show a "straight-line" effect. This straight line of radiographic changes did not conform to anatomic boundaries but to the area that was irradiated. Modern methods of radiation administration allow mostly three-dimensional therapy that can closely conform to the tissue needing treatment, so the straight-line effect is no longer a common finding.

Features of alveolar pattern
Lesions in radiation field
Airspace 1–3 months
Fibrosis 6–12 months
Organizing pneumonia may appear

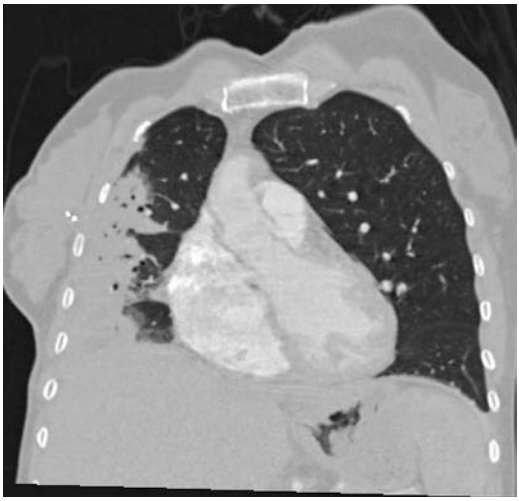
Imaging findings in radiation pneumonitis. The diagnosis of radiation pneumonitis should be made when focal pulmonary disease coincides with the areas of the radiation field [Vilar J, Andreu J. The Lung Parenchyma: Radiological Presentation of Alveolar Pattern. In: Coche EE, Ghaye B, de Mey J, Duyck P, editors. Comparative Interpretation of CT and Standard Radiography of the Chest [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2011 [cited 2015 Dec 21]. p. 221–45. Available from: http://link.springer.com/10.1007/978-3-540-79942-9_9] *Caption and text from original*



Radiation pneumonitis. PA radiograph shows consolidation (arrow) in the right upper lobe. [Kanne JP, Godwin JD. Imaging the Chest Following Radiation Therapy. In: Ravenel JG, editor. Lung Cancer Imaging [Internet]. New York, NY: Springer New York; 2013 [cited 2015 Dec 21]. p. 153–68. Available from: http://link.springer.com/10.1007/978-1-60761-620-7_13] *Caption from original*

- Computed tomography (CT) of the chest. A CT scan of the chest is frequently performed during the evaluation of these patients. CT is more sensitive than CXR for the diagnosis of radiation pneumonitis. However, a CT scan is more frequently performed to help exclude other causes of the patient's symptoms (as per the Differential Diagnosis section). As with the CXR, lung involvement should follow the irradiated areas.

Early radiation pneumonitis changes with ground-glass attenuation in the radiation field 6 weeks after radiotherapy for a localized right side breast cancer.[Murchison JT, van Beek EJR. Complications and Toxicity of Radiotherapy for the Breast, Lung and Heart. In: Kauczor H-U, Bäuerle T, editors. Imaging of Complications and Toxicity following Tumor Therapy [Internet]. Cham: Springer International Publishing; 2015 [cited 2015 Dec 21]. p. 115–28. Available from: http://link.springer.com/10.1007/174_2015_1083] *Caption from original*



Subacute radiation pneumonitis in a patient treated with radiotherapy for breast cancer 10 weeks earlier. There is consolidation with air bronchograms which is largely limited by the radiation field and is not bounded by fissures [Murchison JT, van Beek EJR. Complications and Toxicity of Radiotherapy for the Breast, Lung

and Heart. In: Kauczor H-U, Bäuerle T, editors. Imaging of Complications and Toxicity following Tumor Therapy [Internet]. Cham: Springer International Publishing; 2015 [cited 2015 Dec 21]. p. 115–28. Available from: http://link.springer.com/10.1007/174_2015_1083] *Caption from original*

Other

- Pulmonary Function Tests (PFTs). If performed, PFTs will often show diffusely reduced lung volumes, a decreased diffusing capacity for carbon monoxide (DLCO), and an increased alveolar-arterial oxygen gradient. In advanced fibrosis, patients may be hypoxic.
- Bronchoscopy. Bronchoscopy is useful to exclude other diagnoses (as per the differential diagnosis section).

Special Populations

Age

- Age is not a factor in developing radiation pneumonitis. It can occur in any patient who has received radiation to the chest.

Co-morbidities

- Patients with radiation pneumonitis often have multiple co-morbid conditions that can make the diagnosis and management of radiation pneumonitis challenging. Such conditions include chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), cardiomyopathies, and interstitial lung diseases (ILD).

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critical to carefully consider and evaluate for all diagnoses in the differential.

Mimics

- As the symptoms of radiation pneumonitis are non-specific and also occur with many other conditions, many diseases can present identically to radiation pneumonitis (as per the differential diagnosis section).

Time-Dependent Interventions

- Patients with a known cancer, and who present with shortness of breath, cough, and fever, need to be urgently evaluated for either an infectious or thrombotic (pulmonary embolism) etiology as cause of their symptoms. It may be necessary to treat for infection empirically until this can be adequately ruled out. A CT scan of the chest (or suitable alternative) may be necessary to exclude pulmonary embolism.
- Any patient with hypoxia should receive supplemental oxygen.

Overall Principles of Treatment

- Asymptomatic (or minimally symptomatic) patients who are found to have radiographic abnormalities consistent with radiation pneumonitis can be followed without treatment, as many (up to 50 %) will have a spontaneous recovery.
- All symptomatic patients should be offered supportive, symptomatic treatments such as oxygen for hypoxia, anti-tussives for cough, and anti-pyretics for fever.
- Patients who are symptomatic and have had or are in the process of having alternative diagnoses evaluated can be started on glucocorticoids, specifically prednisone starting at 0.5–1 mg/kg/day in divided doses. This treatment recommendation is based upon consensus, expert opinion, as there are no randomized, controlled trials of glucocorticoids in the treatment or radiation pneumonitis.
- When initiated, steroids should be tapered gradually (over 1–3 months) to prevent a recurrence of symptoms.
- Patients who fail to respond to steroids often have rapid disease progression.
- There is no indication for the treatment of radiation fibrosis with steroids.
- Prophylactic administration of glucocorticoids has not been shown to prevent the development of radiation pneumonitis.

Disease Course

- Many patients with radiation pneumonitis (especially if asymptomatic or minimally symptomatic) will improve spontaneously.
- Patients who progress to fibrosis have less likelihood of spontaneous improvement.
- Fibrosis can continue to progress, but many patients will have both clinical and pathologic stabilization after about 18 months.

Chapter 65
Retropharyngeal Abscess

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Retropharyngeal Abscess; Retropharyngeal Cellulitis

Incidence/Epidemiology

- The incidence of retropharyngeal abscess has decreased as the use of antibiotics for pharyngeal and dental infections has increased.
- In children, it is most prevalent between the ages of 2 and 4 years.
- Retropharyngeal abscesses are among the most serious of the cervical deep space infections, as they may spread directly into the mediastinum.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_65

Differential Diagnosis

- The differential diagnosis of retropharyngeal abscess includes all the other deep neck space infections, pharyngitis, epiglottitis, cervical osteomyelitis, meningitis, angioedema, tumors, and other space-occupying lesions.

Pathophysiology and Etiology

- About half of pediatric cases are preceded by an upper respiratory tract infection. Another quarter are the result of penetrating trauma (e.g., from swallowing chicken bones, iatrogenic trauma after procedures); the remainder are secondary to pharyngitis, dental infections, and, rarely, vertebral osteomyelitis.
- In adults, it now is seen most commonly as an iatrogenic complication of oropharyngeal procedures, a direct extension from other contiguous infectious foci, or a result of penetrating trauma (swallowing of chicken bones, stab wounds, gunshot wounds).
- The retropharyngeal space is a potential space between the posterior prevertebral fascia and the alar fascia. It extends from the base of the skull to the posterior mediastinum at the tracheal bifurcation. It is fused in the midline (so infections usually stay localized to one side) and contains two chains of lymph nodes that drain the nasopharynx, adenoids, and posterior nasal sinuses.
- Children usually have an antecedent infection that is drained by one of the lymph node chains in the retropharyngeal space. The lymph nodes become infected, suppurate, and develop into an abscess. Adults tend to develop infection in the space by direct contamination from penetrating trauma or by contiguous spread from other infections.
- The retropharyngeal space communicates directly with the mediastinum and the lateral pharyngeal space, both of which communicate with the carotid sheath. Infection may spread within all these spaces.
- The infections typically are polymicrobial and include normal flora of the oropharynx.
- The infection often includes oral anaerobes.
- The most commonly found organisms include *Streptococcus viridans*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Enterobacter*, *Peptostreptococcus*, and *Fusobacterium*.

Presentation

Typical/"Classic"

- Children more commonly present classically than do adults.
- Commonly presents with fever (65 %), sore throat (76 %), pain or difficulty with swallowing (35 %), and neck spasms with the patient's unwillingness or inability to move (especially extend) the neck (37 %)
- Neck swelling or a discreet neck mass may be present.
- Cervical lymphadenopathy often is present.
- Children often drool and cannot handle oral secretions appropriately.
- Vocal quality may change, with hoarseness or a muted quality to the voice.
- The patient may have respiratory distress and stridor.
- Trismus (difficulty or inability to open the jaw) is present in 20 %.
- Affected patients usually appear ill and toxic, and the onset generally is acute.
- The nonconstitutional symptoms manifested by the patient usually are related to whatever structures are being obstructed or compressed by the abscess cavity.

Atypical

- Onset may be more insidious and less dramatic, especially if the patient has been on antibiotics.
- Early in the course of illness, the symptoms may be identical to those of pharyngitis.

Primary Differential Considerations

- When evaluating a patient in whom retropharyngeal abscess is suspected, early consideration also should be given to the following differential diagnoses:
  - Angioedema
  - Epiglottitis
  - Meningitis
  - Pharyngitis
  - Peritonsillar abscess
  - Caustic ingestion

History and Physical Exam

Findings That Confirm Diagnosis

- There are no confirmatory findings on history and physical examination. The other diagnoses in the differential may present with remarkable similarity.

Factors That Suggest Diagnosis

- The index of suspicion should be high for any child who presents febrile with any combination of the symptoms reviewed in the classic presentation.
- Adults may give a history of a recent procedure or trauma, leading to consideration of the diagnosis.

Factors That Exclude Diagnosis

- There are no historical or physical findings that exclude the diagnosis.
- The diagnosis is excluded only by the absence of an abscess on advanced imaging.

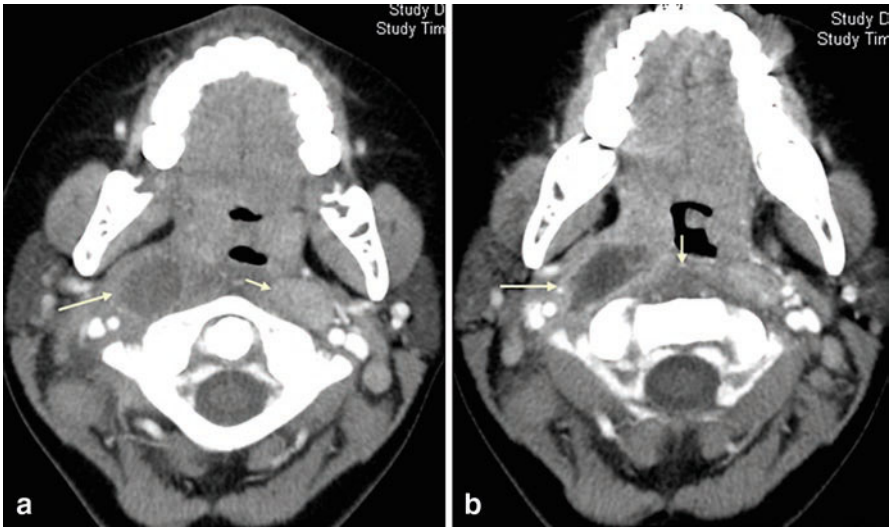
Ancillary Studies

Laboratory

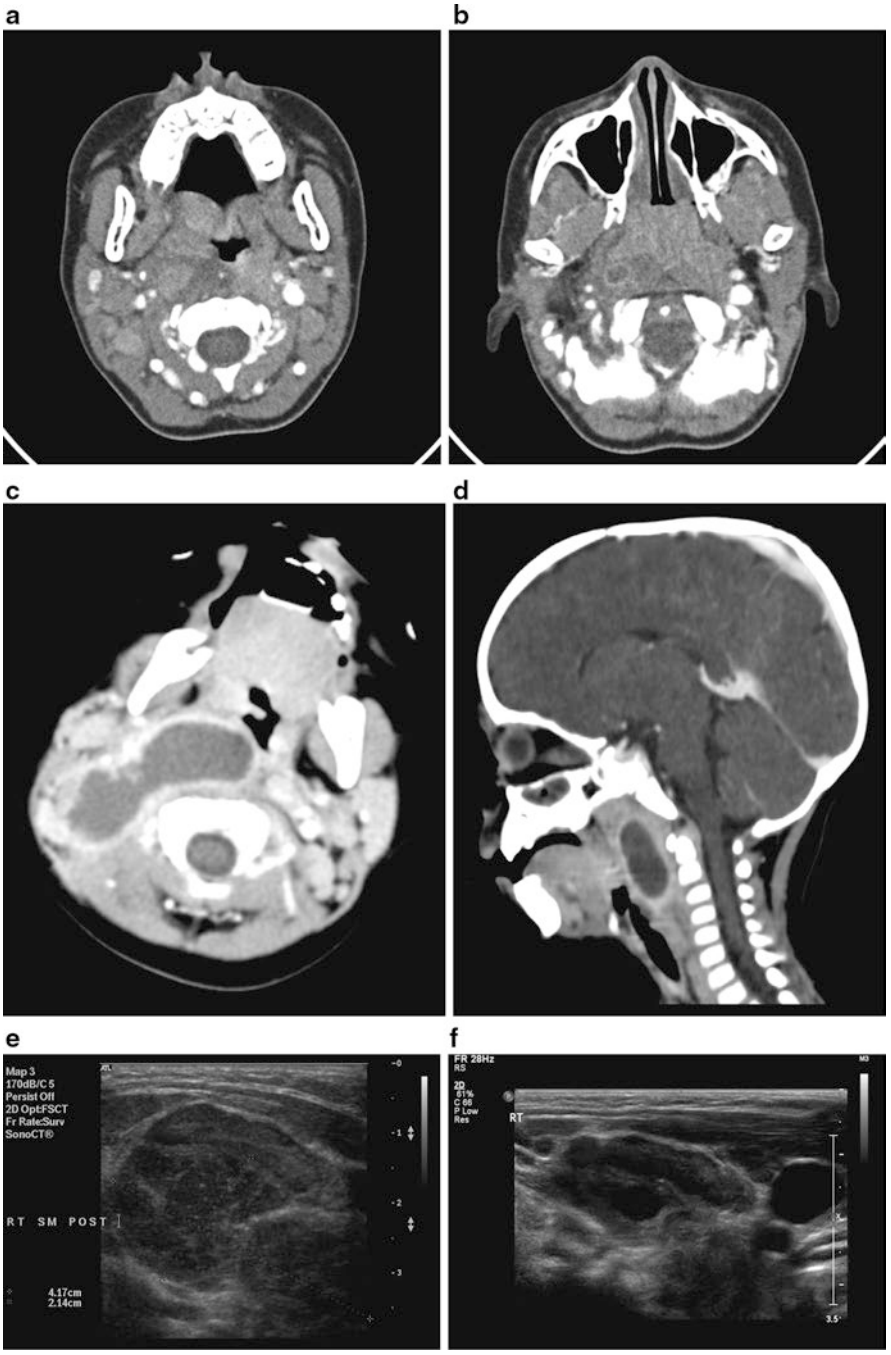
- Lab studies should include the typical tests for any patient who presents febrile with an acute illness. These include (but are not limited to) a complete blood count with differential, electrolyte and renal function tests, serum lactate measurement, blood cultures, and pharynx culture if possible.

Imaging

- Contrast-enhanced CT of the neck is the diagnostic test of choice. A CT scan can differentiate among the different cervical deep space infections, epiglottitis, and other diseases in the differential. CT also may help the otolaryngologist plan appropriate operative intervention.
- Contrast-enhanced MRI also may be performed, but it takes longer and is more difficult for children.



Retropharyngeal abscess. CT scans of the neck of a child at early and later stages of suppurative adenitis evolving into a retropharyngeal abscess. a At an earlier stage, CT image shows right parapharyngeal adenopathy with central necrosis (long arrow). Note the prominent hyperdense adenopathy on the contralateral side (short arrow). b There was no clinical improvement after antibiotic administration. A repeat examination at the same level shows abscess formation on the right (long arrow) causing a mass effect upon the airway and improvement of the adenopathy on the left. The hypodense area in the prevertebral space indicates edema/exudate (short arrow). [Restrepo R, Oneto J, Lopez K, Kukreja K. Head and neck lymph nodes in children: the spectrum from normal to abnormal. Pediatr Radiol. 2009 Aug;39(8):836–46.] *Caption from original*



Retropharyngeal infection in two different patients. First patient is an infant with acute pharyngitis and tonsillitis. Axial image of contrast-enhanced CT at the level of the tonsils (a) demonstrates enlarged enhancing retropharyngeal lymph nodes with

associated inflammatory phlegmon displacing the right tonsil anteriorly; in the same patient, an axial image at the level of the nasopharynx demonstrates a right-sided suppurated retropharyngeal lymph node (b). Second patient is a 1-year-old girl with complicated ear infection, and axial (c) and sagittal reformat (d) images from contrast-enhanced neck CT demonstrate a large retropharyngeal fluid density rim-enhancing collection consistent with an abscess, which involves the posterior triangle of the neck. An US study before (e) and after (f) surgical drainage of the abscess demonstrated a more complex appearance of the abscess content with thick pus as opposed to the relative simple fluid-like appearance on the CT; the US allows follow-up after drainage and demonstrates collapse of the abscess cavity. [Shiran SI. Imaging of pediatric neck and airway. In: Kountakis SE, editor. Encyclopedia of otolaryngology, head and neck surgery [Internet]. Berlin, Heidelberg: Springer; 2013 [cited 2015 Aug 24]. p. 1277–307. Available from: http://link.springer.com/10.1007/978-3-642-23499-6_414] *Caption from original*

Special Populations

Age

- Retropharyngeal abscess is more common in children, especially those between the ages of 2 and 4 years.
- The child appears ill, sometimes toxic, and febrile.
- Associated signs and symptoms include dysphagia, drooling, neck stiffness, torticollis, change in vocal tone, and trismus.
- In the young child or infant, CT scanning may be necessary to define the extent of the problem.

Co-morbidities

- There are no specific co-morbidities associated with retropharyngeal abscess.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step.
- Ensuring that the patient has a secure airway, especially if undergoing diagnostic testing, is critically important.

Mimics

- Retropharyngeal abscess can mimic and be mimicked by all the other cervical deep space infections, pharyngitis and pharyngeal cellulitis, epiglottitis, and the other diagnoses in the differential.

Time-Dependent Interventions

- Retropharyngeal abscesses may progress rapidly. Appropriate resuscitation, cultures, antibiotic treatment, and confirmatory imaging should proceed as quickly as possibly once the diagnosis is considered.

Overall Principles of Treatment

- When the diagnosis of retropharyngeal abscess is seriously considered, patients should undergo rapid resuscitation and receive antibiotic therapy even before confirmatory imaging.
- It is critical to ensure that the patient has a secure airway, especially when going "off unit" for any diagnostic testing.
- Broad-spectrum antibiotic coverage should be initiated to cover the usual oropharyngeal pathogens, including anaerobes.
- Urgent otolaryngologic consultation should be obtained.
- Definitive care often is guided by imaging. If the patient presents early in the course and there is no discrete collection, antibiotic therapy without surgery may arrest further abscess development and be curative. If collection is present, definitive treatment is operative drainage along with continued antibiotic therapy.

Disease Course

- With early and appropriate treatment, most patients will recover fully with few sequela.
- Delays in presentation and treatment may lead to serious complications, including death. Airway compromise may occur; the abscess may rupture spontaneously, with direct spread to contiguous structures, most ominously the mediastinum and carotid sheath.

Chapter 66
Sarcoidosis

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Sarcoidosis; Sarcoid

Incidence/Epidemiology

- Sarcoidosis occurs throughout the world, but its prevalence and racial mix varies from country to country. For example, in the United States sarcoidosis is 3–4 times more common in blacks than whites, but in Ireland and Northern Europe (especially the Nordic countries), it is more prevalent among whites.
- The estimated worldwide prevalence of sarcoidosis is 20–60 cases per 100,000 people per year.
- The disease is usually diagnosed in young, otherwise healthy adults between the ages of 20 and 40, but there is also a second peak at about age 60. There is a slight female predominance. It is rare in children.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_66

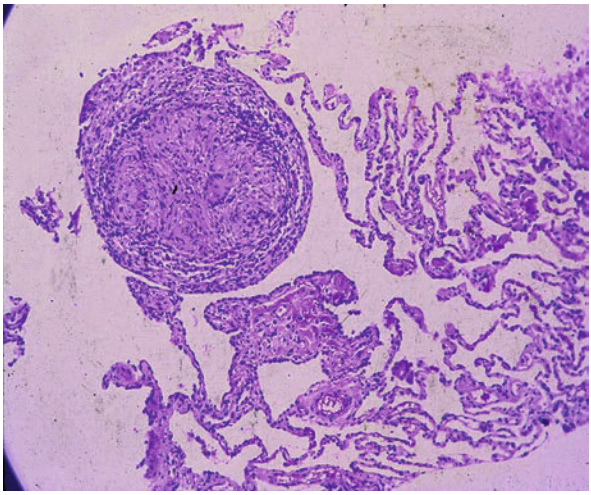
- In the United Stavtes, the lifetime risk among the black population is about 2.5 %. The lifetime risk in the white population is only about 0.85 %.
- Blacks are more likely to present younger and with more acute and severe disease.
- In Ireland, and among African Americans in the United States, there can be a familial predisposition to the disease. This is thought to be due to linkage to the major histocompability complex (MHC). Increased susceptibility to the disease is noted in the presence of certain human leukocyte antigen (HLA) alleles (DRB1, 11, 12, 14, 15, and 17).

Differential Diagnosis

- The differential diagnosis of sarcoidosis is broad, and includes all the diseases that can cause shortness of breath and cough, such as asthma, COPD, interstitial lung disease, pneumonia, and congestive heart failure.
- Sarcoidosis can also present with hilar adenopathy on chest x-ray, so the differential must also include all the diseases associated with mediastinal and hilar adenopathy. This includes tuberculosis (both tuberculosis and atypical mycobacterial infections), fungal infections (such as histoplasmosis, blastomycosis, and Pneumocystis), and cancer (especially lymphoma).
- Other granulomatous diseases of the lungs that need to be considered include: hypersensitivitiy pneumonitis, pneumoconioses (beryllium), drug-induced hypersensitivity (causative agents include methotrexate, etanercept, infliximab, adalimumab, amoxicillin, sirolimus, and fluoxetine, among others), Pulmonary Langerhans cell histiocytosis, foreign body granulomatosis, vasculitides (Wegener's, Churg-Strauss, primary lymphomatoid granulomatosis), and primary immunodeficiencies.
- It is important in the evaluation of someone for presumed sarcoidosis that all these diseases be considered.

Pathophysiology and Etiology

- Sarcoidosis is a multi-system, inflammatory, granulomatous disease of unknown cause.
- The characteristic pathologic finding of sarcoidosis is the presence of noncaseating granulomas in affected tissues. The granulomas contain a mixture of multiple different inflammatory cells, epithelial cells, multi-nucleated giant cells, and fibroblasts. The majority of these granulomas gradually resolve without scarring or fibrosis. Large amounts of scarring, fibrosis, or necrosis should make one consider an alternative diagnosis.



Sarcoidosis: a non-caseating granuloma. [Mahmoudi M, Sharma OP. Sarcoidosis. In: Mahmoudi M, editor. Challenging Cases in Pulmonology [Internet]. New York, NY: Springer New York; 2012 [cited 2015 Jun 9]. p. 253–74. Available from: http://link.springer.com/10.1007/978-1-4419-7098-5_15] *Caption from original*

- Sarcoidosis is thought to result from an exaggerated cell-mediated immune response to an as yet unidentified antigen.
- The etiology remains unknown, despite extensive investigations. An NIH-funded case-control study, Access, that included 700 patients with known sarcoidosis, and nearly 30,000 relatives, could not identify a single etiologic agent.
- Population studies have identified two possible associations: exposure to beryllium and beryllium salts, which can produce granulomas very similar to sarcoidosis. There has also been an increased incidence of sarcoid-like granulomatous disease in people exposed to the dust from the collapse of the World Trade Centers.

Presentation

Typical/"Classic"

- The most common presenting symptoms of sarcoidosis are cough, dyspnea, and chest pain. They are often associated with more constitutional symptoms such as fatigue, fever, and weight loss.
- Nearly one-third of patients are asymptomatic on presentation, and only present with an abnormal CXR.
- Sarcoidosis can affect virtually all organs of the body, but the lung, impacted in over 95 % of cases, is the most frequently affected. The next most fre-

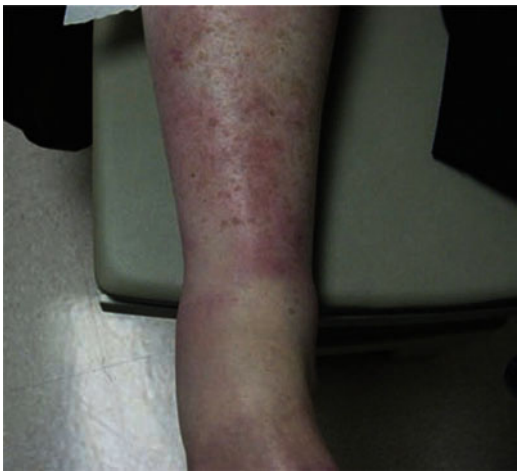
quently involved organ is the skin, which is affected in about 25 % of cases at presentation, but will be involved in nearly one-third of all cases throughout the course of the disease.
- Ninety-five percent of patients eventually diagnosed with sarcoidosis will have pulmonary involvement at presentation. This may manifest as pulmonary symptoms or chest x-ray findings.
- The classic CXR findings of sarcoidosis are hilar adenopathy with associated reticular opacities.
- Patient will often also note eye problems (uveitis) and skin and/or joint lesions on presentation.

Atypical

- Thirty percent of patients will present with predominantly extra-thoracic manifestations of sarcoidosis.
- Löfgren Syndrome is an uncommon, acute, systemic presentation of sarcoidosis. Patients will have fever, erythema nodosum, polyarthralgia, uveitis, and bilateral hilar adenopathy on the CXR.
- Sarcoidosis can affect virtually any organ system in the body. Most of the pathologic and clinical manifestations are due to granulomatous infiltration of the relevant tissues. Some of the more common extra-pulmonary manifestations of sarcoidosis are reviewed below.
    - Skin. Overall, about one-third of patients will develop skin involvement. There are many different skin lesions associated with sarcoidosis, including:
        - Erythema nodosum

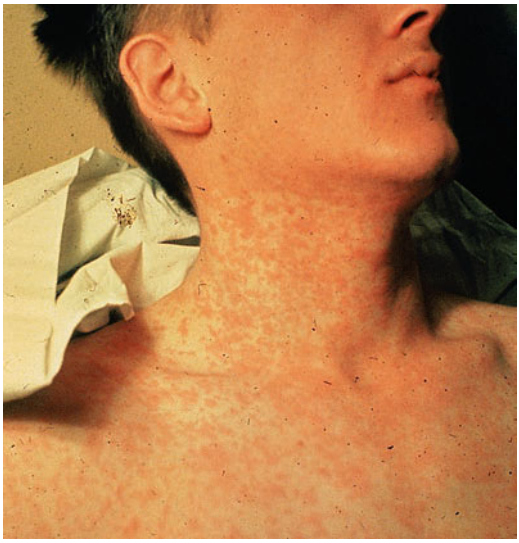
Erythema nodosum. Red nodules of erythema nodosum in the pretibial area. Lesions are usually tender, poorly circumscribed, and located deep within the subcutaneous

fat. Their appearance is usually accompanied by an exacerbation in the underlying inflammatory bowel disease. Erythema nodosum occurs in about 4% of patients with ulcerative colitis and in 2% of patients with Crohn's disease. Treatment includes bed rest, systemic or intralesional steroids, nonsteroidal anti-inflammatory agents, potassium iodide, colchicine, and dapsone. [Pandya A. Chapter 12. In Feldman, M, editor. Gastroenterology and Hepatology, Volume 03. Philadelphia: Current Medicine; 1996. ISBN: 0-443-07843-2] *Caption from original*



Erythema nodosum on the leg of a sarcoidosis patient [Baughman RP, Lower EE. Sarcoidosis. In: Stone JH, editor. A Clinician's Pearls and Myths in Rheumatology [Internet]. London: Springer London; 2009 [cited 2015 Jun 17]. p. 409–20. Available from: http://link.springer.com/10.1007/978-1-84800-934-9_42] *Caption from original*

- Maculopapular lesions. These are the most common form of skin involvement, and the most common form of chronic disease. They are often asymptomatic and overlooked by patients.



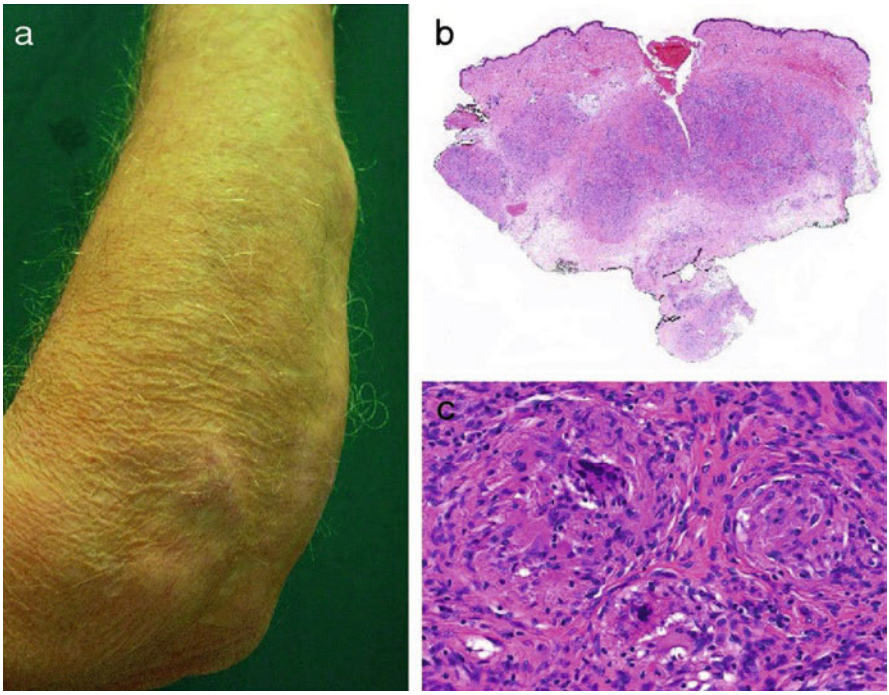
Rash of acquired rubella. The rash of acquired rubella is usually maculopapular, which may eventually coalesce. The rash is usually mild. [Maldonado Y. Chapter 01. In: Wilfert CM, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1999. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8] *Caption from original*

- Hyper and hypo-pigmentation.

Sarcoidosis on the arm of an African American female demonstrating hypopigmentation. [Goldman S, Pandya AG. Post-inflammatory Hypopigmentation. In: Jackson-Richards D, Pandya AG, editors. Dermatology Atlas for Skin of Color [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 Jun 17]. p. 9–12.

Available from: http://link.springer.com/10.1007/978-3-642-54446-0_2] *Caption adapted from original*

- Keloid formation.
- Subcutaneous nodules (these are actual granulomas).



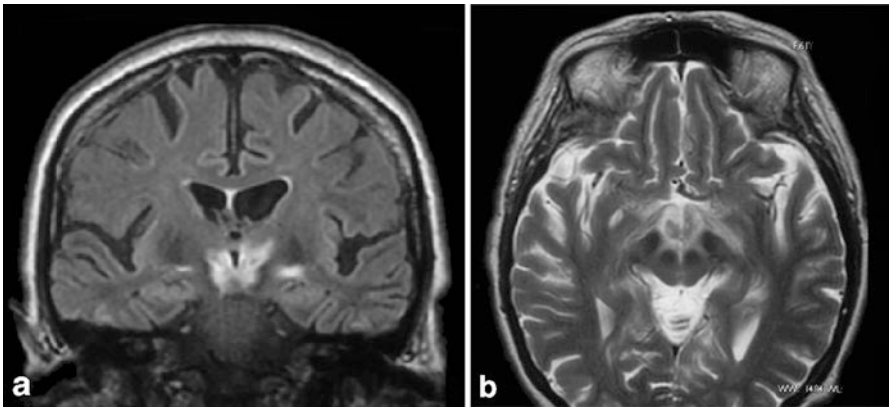
Subcutaneous nodules covered by normal-looking skin on the right forearm (a). Histology confirmed the presence of subcutaneous nodular infiltrates (×4, haematoxylin and eosin) (b), showing the typical features of sarcoid granuloma (×200, haematoxylin and eosin) (c). [Dalle Vedove C, Colato C, Girolomoni G. Subcutaneous sarcoidosis: report of two cases and review of the literature. Clinical Rheumatology. 2011 Aug;30(8):1123–8.] *Caption adapted from original*

- Lupus pernio is a specific complex of skin findings that involves the bridge of the nose, the area beneath the eyes, and the cheeks. This is more common in African Americans and it predicts a progression to chronic disease.

Lupus pernio in an African American female, left face [Jackson-Richards D. Sarcoidosis. In: Jackson-Richards D, Pandya AG, editors. Dermatology Atlas for Skin of Color [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2016 Mar 24]. p. 141–5. Available from: http://link.springer.com/10.1007/978-3-642-54446-0_26] *Caption from original*

- Eyes. Anterior uveitis is the most common ophthalmologic manifestation of sarcoidosis. Patients can note tearing, pain, and sometimes changes in visual acuity. In the U.S., only about 10–20 % of sarcoid patients will have eye involvement, but it is more common in African Americans. In Japan, greater than 70% may have eye involvement.

- Liver. Liver involvement can be found in about 50% of patients, but only 10–15 % have elevated liver function tests and clinically significant liver disease.
- Bone Marrow. Bone marrow involvement is often noted by the presence of lymphopenia and anemia. There is infiltration of the bone marrow with granulomas and also sequestration of blood cells in lymphoid tissue (splenomegaly).
- Renal. Seen in less than 5 % of patients. Direct granulomatous infiltration may cause nephritis. Most of the renal complications are secondary to hypercalcemia and hypercalciuria.
- Neurologic. Seen in about 5–10 % of patients. Sarcoidosis can affect any part of the central or peripheral nervous system. Neurosarcoid can cause cranial nerve abnormalities, seizures, and cognitive changes. Involvement of the optic nerve can cause an optic neuritis that is difficult to distinguish from multiple sclerosis.



Presumed intracranial sarcoidosis. a The coronal FLAIR and b axial T2-weighted MRI scan show a hyperintense lesion involving the optic chiasm and hypothalamus with posterior extension along both optic tracts which appear hyperintense. [Jäger HR. Loss of vision: imaging the visual pathways. European Radiology. 2005 Mar;15(3):501–10.] *Caption from original*

- Cardiac. Cardiac manifestations are seen in about 2–5 % of patients in the U.S. and Europe, but in up to 25 % of patients in Japan. The most common cardiac manifestations are cardiomyopathy and CHF from diffuse myocardial infiltration, and conduction system abnormalities due to granulomatous infiltration of conduction tissue.
- Bone/joint/muscle. The patient can present with bone cysts that cause myalgias and arthralgias.

Primary Differential Considerations

- When patients present with signs and symptoms such as those that suggest pulmonary sarcoidosis, other diagnoses warranting early consideration include:
  - infection, especially with fungi and tuberculosis.
  - reactions to minerals and metals such as beryllium and aluminum.
  - Wegener granulomatosis.

History and Physical Exam

Findings That Confirm Diagnosis

- There are no pathognomonic historical or physical findings of sarcoidosis.
- Lung exam is often normal. Wheezing is present only when there is endobronchial involvement that causes airway obstruction.
- The diagnosis is confirmed only when typical noncaseating granulomas are found on biopsy of an involved organ in the presence of the usual clinical and radiographic findings and the exclusion of other causes. It is important to remember that there are causes of noncaseating granulomas other than sarcoidosis.
- The identification of classic Löfgren's Syndrome can usually confirm the diagnosis without a need for biopsy.

Factors That Suggest Diagnosis

- The diagnosis can be suggested by the presence of typical symptoms and bilateral hilar adenopathy on the CXR.
- Typical CXR findings can be found in asymptomatic patients who are having a CXR for other reasons.

Factors That Exclude Diagnosis

- The confirmation of an alternative diagnosis that can explain the patient's symptoms and findings can essentially exclude the diagnosis.

Ancillary Studies

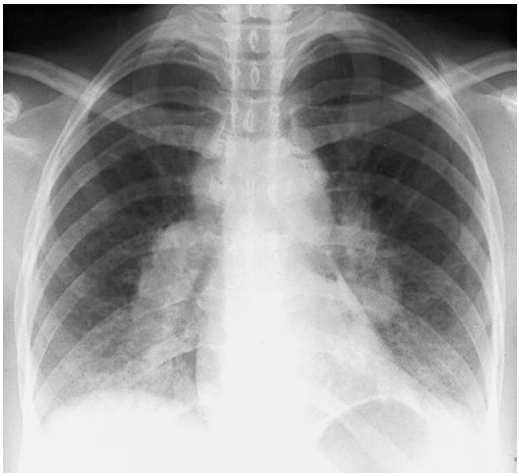
Laboratory

- All patients being evaluated for sarcoidosis should have a complete laboratory evaluation that includes a CBC with differential, complete metabolic panel, liver function tests, and a urinalysis. These may not be helpful in diagnosing sarcoidosis, but may lead to a consideration of an alternative diagnosis.
- Testing for HIV should be considered.
- Patients should also have testing for tuberculosis with either a TB skin test, or an interferon gamma release assay.
- Angiotensin converting enzyme (ACE) levels are elevated in about three-quarters of patients with acute, untreated sarcoidosis, but this test is neither sensitive nor specific for the diagnosis of sarcoidosis, with about a 10 % false positive rate. Many diseases can cause a small elevation (about 10% above upper limit of normal) in the ACE level (such as diabetes), while fewer disease are associated with an ACE level that is greater than 1.5 times the upper limit of normal. These include: sarcoidosis, leprosy, Gaucher's disease, hyperthyroidism, miliary tuberculosis.
- Common laboratory abnormalities found in patients with sarcoidosis include:
  - Anemia, usually secondary to anemia of chronic disease (AOCD).
  - Leukopenia, seen in 5–10 % of patients.
  - Hypercalcemia/hypercalciuria are seen in about 10% of patients, and are more common in Caucasians. Sarcoid granulomas can produce 1,25-dihydroxyvitamin D, which leads to increased intestinal absorption of calcium with resultant hypercalcemia and hypercalciuria.
  - While sarcoid granulomas can produce 1,25-dihydroxyvitamin D, nearly all patients with sarcoidosis will have a deficiency of 25-hydroxyvitamin D. The pathologic basis of this has not been elucidated.
  - Elevated alkaline phosphatase (suggests liver involvement).

Imaging

- Imaging is necessary in the evaluation and diagnosis of sarcoidosis.
- The classic finding on plain chest x-ray is bilateral hilar adenopathy. The lung parenchyma may be normal (especially in early disease), or may show diffuse reticular or ground glass opacities.
- The chest x-ray findings have been classified into stages. These stages are only a reflection of the anatomic extent of pulmonary disease, and may not correspond to symptoms and disease activity. They may, however, offer some prognostic information.

- Stage I. Bilateral hilar adenopathy (with or without right paratracheal lymph node enlargement) with no parenchymal changes in the lung. Up to half of all patients will have this as their initial finding of sarcoidosis. Up to 75 % of patients with Stage 1 disease on presentation will have spontaneous regression of adenopathy within 1–3 years. Fewer than 10% will develop chronic enlargement.



Chest radiograph of a patient with stage I sarcoidosis. [Tanoue L, Elias J. Sarcoidosis. In: Crapo J, editor. Bone's atlas of pulmonary medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7; 2005-01-14] *Caption adapted from original*

- Stage II. Bilateral hilar adenopathy with associated parenchymal changes, usually reticular opacities (upper lobes predominantly). These changes are found in about 25 % of patients at diagnosis. About two-thirds of patients with stage II findings on CXR at diagnosis will have spontaneous regression, and one-third will go on to have chronic changes. Patients with stage II disease at diagnosis are generally symptomatic.

Stage II sarcoidosis. [Tanoue L, Elias J. Sarcoidosis. In: Crapo J, editor. Bone's atlas of pulmonary medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7; 2005-01-14] *Caption adapted from original*

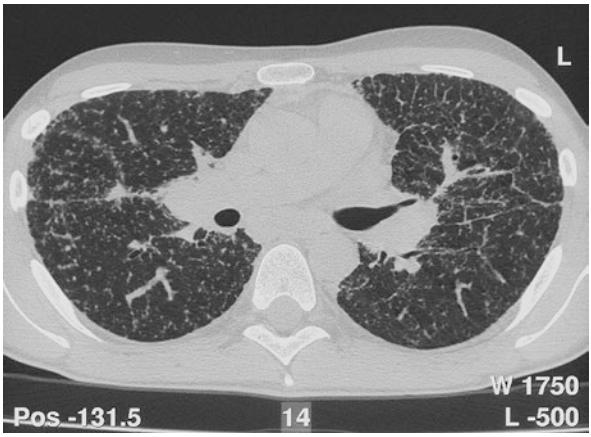
- Stage III. Marked reticular opacities (again upper lungs >> lower lungs) with regression of hilar nodes.

Stage III sarcoidosis. [Tanoue L, Elias J. Sarcoidosis. In: Crapo J, editor. Bone's atlas of pulmonary medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7; 2005-01-4] *Caption adapted from original*

- Stage IV. Reticular opacities with evidence of volume loss (upper lungs). Consolidated masses of granulomas causing traction bronchiectasis may be seen. Lung tissue calcification, cavitation, and cyst formation may be seen.

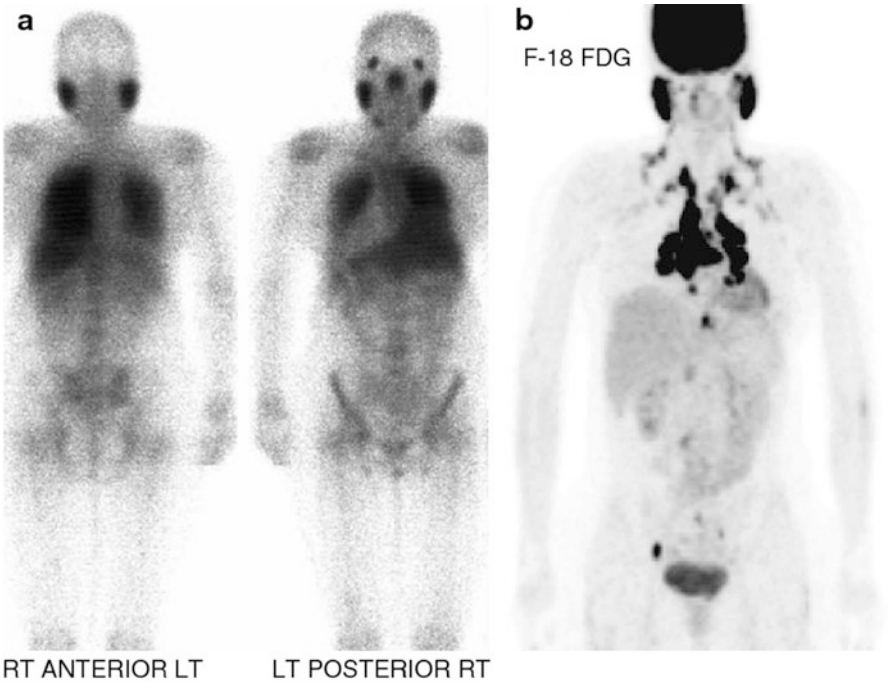
Stage IV sarcoidosis. With extensive fibrosis. [Tanoue L, Elias J. Sarcoidosis. In: Crapo J, editor. Bone's atlas of pulmonary medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7; 2005-01-4] *Caption adapted from original*

- Other radiologic studies (such as high resolution CT scan [HRCT], PET scanning, gallium scanning), are not necessary in the evaluation of suspected sarcoidosis, but may be obtained for other reasons. They may be helpful in evaluating for alternative diagnoses, and for further supporting the diagnosis of sarcoidosis.
  - HRCT may be performed for the evaluation of dyspnea and cough in a patient with an unremarkable CXR. Many patients will have a HRCT, as it is standard of care in the evaluation of suspected interstitial lung disease. Findings on HRCT in that situation may lead to earlier consideration of the diagnosis. Findings on HRCT that are highly suggestive of sarcoidosis include:
    - Hilar and mediastinal adenopathy
    - Beading or intermittent thickening of the bronchovascular bundles



HRCT with the classical perilymphatic distribution of nodules in a patient with sarcoidosis. Note the occurrence of small nodules along subpleural surface and fissures, along interlobular septa and the peribronchovascular bundles giving these structures a "beaded" appearance. This is thought to be pathognomic for sarcoidosis. [Veltkamp M, Grutters JC. The Pulmonary Manifestations of Sarcoidosis. In: Judson MA, editor. Pulmonary Sarcoidosis [Internet]. New York, NY: Springer New York; 2014 [cited 2015 Jun 17]. p. 19–39. Available from: http://link.springer.com/10.1007/978-1-4614-8927-6_2] *Caption from original*

- The use of gallium scanning for the diagnosis of sarcoidosis is currently of only historic interest, as the sensitivity and specificity are low. Gallium scanning may be useful in the unlikely event that there are no easily amenable areas for biopsy. The presence of a panda sign (increased uptake in the parotid and lacrimal glands), and/or a lambda sign (increased activity in the right paratracheal and left hilar lymph nodes), is considered very suggestive of sarcoidosis.



(a) Gallium-67 images for a patient with sarcoidosis illustrating diffuse lung uptake in addition to uptake in salivary glands, lacrimal glands, and inguinal lymph nodes. (b) 18 F-FDG image of a 35-year-old female with proven sarcoidosis. The study shows uptake in the areas of active inflammation in mediastinum, pulmonary hilus, salivary glands, cervical, supraclavicular, axillary, para-aortic, iliac, and inguinal lymph nodes. [Elgazzar AH. Respiratory System. Synopsis of Pathophysiology in Nuclear Medicine [Internet]. Cham: Springer International Publishing; 2014 [cited 2015 Aug 26]. p. 253–72. Available from: http://link.springer.com/10.1007/978-3-319-03458-4_11] *Caption from original*

- Cardiac MRI may be useful in the diagnosis of cardiac sarcoid.

Other

- All patients should have an ECG to screen for conduction abnormalities
- Pulmonary Function Testing. PFT's are not helpful in the diagnosis of sarcoidosis, but they are used to assess the severity of respiratory disease and to monitor the course of the disease. Most patients with early (stage I or II) disease will have normal PFT's. As symptoms worsen patients will usually demonstrate a restrictive pattern on PFT's with a reduced diffusing capacity for

carbon monoxide. If the patient has significant and lumen-narrowing endobronchial lesions, an obstructive pattern may be present on PFT's.

- Biopsies. The majority of patients with suspected sarcoidosis will need to have a biopsy to confirm the diagnosis. In general, biopsies should be obtained from the most accessible of the sites that are affected. This can include skin lesions (except for erythema nodosum), conjunctival lesions, and palpable lymph nodes, among others.
  - Patients who may not need a biopsy include asymptomatic patients with stage I disease on CXR, as the majority of these patients will have spontaneous resolution without progression, and those with classic Löfgren's syndrome.
- Fiber optic bronchoscopy (FOB). Flexible, fiber optic bronchoscopy can be a useful, minimally invasive procedure for the diagnosis of sarcoidosis. During FOB, Bronchoalveolar lavage (BAL), endobronchial biopsy, or transbronchial biopsy can be performed.
  - BAL via flexible bronchoscopy can be a useful and minimally invasive method to help diagnose sarcoidosis. BAL fluid can be evaluated for numbers of CD 4 and 8 cells. Sarcoid is usually associated with a reduced number of CD8 cells, with a ratio of CD4 to CD8 cells greater than 3.5–4:1. BAL is also useful to help exclude malignancy or infections as alternative diagnoses.
  - Endobronchial and transbronchial biopsies have a high yield for the diagnosis of sarcoidosis.

Special Populations

Age

- Sarcoidosis is unusual in children.
- It is, however, well described in patients less than 4 years of age, who most often present with skin, joint, and eye involvement without "typical" pulmonary disease.
- U.S. demographics indicate that southeastern and south central states contain more than 65% of reported cases (Virginia, North and South Carolina, and Arkansas)
- Sarcoidosis is most commonly diagnosed in young to middle-aged adults.

Co-morbidities

- The presence of HIV can make the diagnosis more challenging, as these patients may present atypically, and they are at risk for atypical presentations of many of the alternative diagnoses that need to be considered.
- All the diseases that can present with dyspnea and cough (such as asthma, COPD, CHF, other interstitial lung diseases) can make the diagnosis and management of sarcoidosis more challenging if they exist concurrently.
- However, many of the patients diagnosed with sarcoidosis are young adults and have few if any co-morbid conditions.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step.
- Consideration of all alternative diagnoses.
- Recognizing that a gold-standard diagnostic test does not exist, and that the diagnosis generally requires three elements: 1) consistent clinical and radiographic abnormalities; 2) detection of noncaseating granulomas on biopsy; and 3) the exclusion of alternative diagnoses.

Mimics

- As per the differential diagnosis section, many diseases can present with either symptoms consistent with sarcoid (dyspnea, cough, fever, fatigue), granulomas, or hilar adenopathy.

Time-Dependent Interventions

- Sarcoidosis is generally not an acute disease. Löfgren's syndrome (fever, erythema nodosum, arthralgias, and bilateral hilar adenopathy) may present acutely, but often will resolve spontaneously with no specific treatment.
- Symptoms that may indicate involvement of some extra-pulmonary organ systems, especially cardiac, central nervous system, or renal involvement, may require urgent diagnosis and treatment.

Overall Principles of Treatment

- When the diagnosis of sarcoidosis is considered likely, a thorough search should be undertaken to find the presence and extent of involvement of other organ systems.
- All patients should have a complete history that includes an occupational and hobby history.
- All patients should have a thorough skin examination.
- All patients should have an ophthalmologic examination to assess for ocular involvement.
- All patients should have an ECG to screen for conduction abnormalities.
- Laboratory testing as detailed above should be performed.
- Treatment is based upon symptoms. If the patient is asymptomatic and only has CXR findings, it is appropriate to just monitor for the development of symptoms.
- It also is appropriate to monitor patients with only mild symptoms, as about 50 % of cases will resolve spontaneously within 2–5 years.
- If there is mild-to-moderate skin or ocular involvement, it is reasonable to attempt a trial of topical treatment with topical steroids. This treatment should be guided and monitored by an experienced dermatologist/ophthalmologist.
- Systemic glucocorticoids (prednisone, methylprednisolone) are the treatment of choice if systemic treatment is warranted.
- Patients on long-term glucocorticoids, or with intolerable side effects from glucocorticoids, may be candidates for steroid-sparing therapy.
    - Hydroxychloroquine and minocycline may be useful for patients with predominant skin involvement.
    - Cytotoxic therapy may be necessary for patients with significant extrapulmonary sarcoidosis. Methotrexate is the cytotoxic agent with the most clinical experience. It is effective in managing symptoms in up to 65–70 % of those with extrapulmonary sarcoidosis. Other agents include, azathioprine, chlorambucil, and cyclophosphamide.
    - Infliximab, a monoclonal antibody against tumor necrosis factor, has recently been shown to improve lung function in those with chronic sarcoidosis already on glucocorticoids and cytotoxic agents. This agent is a potent immune suppressor, and has been associated with an increased risk for infections, especially reactivation tuberculosis.

Disease Course

- Fifty percent of cases will resolve within 2–5 years.
- About 20 % will go on to develop chronic sarcoidosis.

- The disease is generally non-life-threatening, but organ-threatening disease can occur, especially when there is ocular, cardiac, neurologic, and renal disease.
- Death due to sarcoidosis occurs in less than 5 % of cases, and mostly occurs due to progressive lung, cardiac, neurologic, or renal disease.
- The following factors have been found to be markers for progressive disease:
    - Fibrosis on CXR
    - Lupus pernio
    - Bone cysts
    - Cardiac or neurologic disease
    - Renal calculi due to hypercalciuria
    - Disease requiring systemic glucocorticoid treatment within the first six months of diagnosis

Chapter 67
Sepsis

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Jaime Friel Blanck

Name and Synonyms

Sepsis; Severe Sepsis; Septic Shock; Systemic Inflammatory Response Syndrome (SIRS)

Incidence/Epidemiology

- Tenth leading cause of death in the United States.
- 750,000 patients will be hospitalized annually for sepsis in the United States.
  - Males have a higher incidence of sepsis than females.
- Two percent of all hospitalized patients in developed countries suffer from sepsis.
- More than 50 % of severe sepsis patients will require intensive care.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_67

- Mortality rate of septic shock is nearly 50 %.
- In developing countries sepsis is more common in younger people.
  - Gram negative and atypical pathogens are usually the cause (e.g., malaria)
- Improvement in treatments has decreased the fatality rate, but due to the increase of incidence the number of deaths has increased.
- Most cases of septic shock are hospital-acquired Gram-negative bacilli or Gram-positive cocci.
  - Immunocompromised and chronic illness are risk factors for sepsis.
- Candida or other fungi are rare causes of sepsis.

Differential Diagnosis

- Trauma
- Pancreatitis
- Adrenal insufficiency
- Toxic Shock Syndrome
- Cardiogenic shock
- Hemorrhage
- DIC-Disseminated Intravascular Coagulation
- Heatstroke
- MI
- Myocardial rupture
- Shock

Pathophysiology and Etiology

- Sepsis is a complex, multimediated state that is generally considered to be inflammatory in response to infection. Mediators of inflammation generally cause peripheral vasodilation which, if not reversed, causes blood pressure to drop (“septic shock”) and tissues to be hypoperfused.
  - This can be identified by an increase in serum lactate.
  - If severe, this can result in multi-organ system failure.

Mediator	Potential role in intra-abdominal sepsis or injury	Reference(s)
CRP	A serum marker of sepsis that increases in concentration in plasma following abdominal surgery	[20-22]
Haptoglobulin	Elevated expression in blood leukocytes following severe blunt trauma	[23]
IL-1ra	Elevated in plasma following trauma; elevated expression in blood leukocytes following severe blunt trauma	[23,24]
IL-6	Potent inflammatory mediator and marker of sepsis; elevated levels correlate with length of hospital stay, complications, and mortality among patients with intra-abdominal sepsis; elevated levels in peritoneal fluid in a porcine model of intra-abdominal sepsis; elevated plasma/serum levels following abdominal surgery; elevated plasma levels following severe trauma associate with injury severity, development of organ dysfunction, and poor outcomes, including mortality	[21-23,25-28,44-50]
IL-8	Potent neutrophil chemoattractant; elevated expression in blood leukocytes following severe blunt trauma	[23,29]
IL-10	Elevated serum levels during intra-abdominal sepsis; blocks pro-inflammatory cytokine release; elevated after abdominal surgery	[30-32]
IL-15	Elevated levels in serum correlate with organ dysfunction and poor patient prognosis	[33]
IL-17	Potent pro-inflammatory mediator; promotes neutrophil recruitment to the peritoneal cavity and enhanced bacterial clearance in a mouse model of intra-abdominal sepsis; elevated plasma levels in select patients following severe trauma	[28,34,35]
IL-22	Elevated serum levels during intra-abdominal sepsis	[30]
IL-33	Mediates neutrophil recruitment to peritoneum; promotes bacterial clearance and reduces mortality in a mouse model of intra-abdominal sepsis	[36]
MCP-1 (CCL2)	Potent monocyte chemoattractant; serum levels elevated in a rat model of intra-abdominal sepsis; elevated expression in blood leukocytes following severe blunt trauma	[23,37]
M-CSF	Elevated in plasma following trauma	[24]
MIF	Present early in sepsis and remains elevated for a prolonged time period; significantly higher levels in non-survivors of sepsis compared to survivors; MIF neutralization reduces mortality in a mouse model of intra-abdominal sepsis	[38,39]
PDGF	Elevated in plasma following trauma	[24]
Procalcitonin	Marker of infectious complications following abdominal surgery and negatively associated with survival; elevated after abdominal surgery	[32,40]
TNF-α	Serum levels elevated in a rat model of intra-abdominal sepsis	[37]
tPA	Enhances bacterial clearance, reduces cellular influx, increases plasma and peritoneal IL-12 and IL-10 levels, and reduces lung and liver damage in a mouse model of intra-abdominal sepsis	[16]
TRAIL	Promotes inflammatory cell recruitment to the peritoneum, enhances bacterial clearance, and reduces mortality in a mouse model of intra-abdominal sepsis; modulates apoptosis	[41,42]

CCL2, Chemokine (C-C motif) ligand 2; CRP, C-reactive protein; IL-1ra, Interleukin-1 receptor antagonist; IL-6, Interleukin-6; IL-8, Interleukin-8; IL-10, Interleukin-10; IL-15, Interleukin-15; IL-17, Interleukin-17; IL-22, Interleukin-22; IL-33, Interleukin-33; MCP-1, Monocyte chemoattractant protein-1; M-CSF, Macrophage colony-stimulating factor; MIF, Macrophage migration inhibitory factor; PDGF, Platelet-derived growth factor; TNF-α, Tumor necrosis factor-alpha; tPA, Tissue plasminogen activator; TRAIL, Tumor necrosis factor-related apoptosis-inducing ligand.

Inflammatory mediators associated with intra-abdominal sepsis or injury, including abdominal surgery, among studies of animals or humans [From article: Efficacy and safety of active negative pressure peritoneal therapy for reducing the systemic inflammatory response after damage control laparotomy (the Intra-peritoneal Vacuum Trial): study protocol for a randomized controlled trial. Trials. 2013;14(1):141. https://doi.org/10.1186/1745-6215-14-141, at http://link.springer.com/article/10.1186%2F1745-6215-14-141; by Derek J Roberts, Craig N Jenne, Chad G Ball, Corina Tiruta, Caroline Léger, Zhengwen Xiao, Peter D Faris, Paul B McBeth, Christopher J Doig, Christine R Skinner, Stacy G Ruddell, Paul Kubes, Andrew W Kirkpatrick, © Roberts et al.; licensee BioMed Central Ltd. 2013; licensed under Creative Commons Attribution License BY 2.0 http://www.creativecommons.org/licenses/by/2.0] *Caption from original; See http://link.springer.com/10.1186/1745-6215-14-141 for references*

- Sepsis can result from any infectious etiology, bacterial, viral, or fungal. Nonbacterial causes are more common in immunocompromised patients.

Presentation

Typical/"Classic"

- Fever, dyspnea, altered mental status, nausea and vomiting, cough, SOA, abdominal pain, diarrhea and dysuria.
  - **SIRS**-4 criteria, **Sepsis = infection with ≥ 2 SIRS criteria**
    - Temperature > 38°C or < 36°C
    - HR > 90 bpm
    - RR > 20/min or $PaCO_2$ < 32 mm Hg
    - WBC > 12,000/mm^3, or > 10 % band forms

Stage	Clinical symptoms	Value
SIRS (≥2 symptoms)	Temperature	<36 °C or >38 °C
	Heart rate	>90 beats/minute
	Respiratory rate	>20 breaths/minute or $PaCO_2$<32 mmHg
	White blood cell count	>12,000 cells/mm^3 or < than 4,000 cells/mm^3
Sepsis	SIRS with proven infection	
Severe sepsis	Sepsis with organ dysfunction hypoperfusion and/or hypotension	
Septic shock	Severe sepsis, hypoperfusion and/or hypotension despite adequate fluid resuscitation	

Systemic Inflammatory Response Syndrome (SIRS) and sepsis stages [Loonen AJM, Wolffs PFG, Bruggeman CA, van den Brule AJC. Developments for improved diagnosis of bacterial bloodstream infections. European Journal of Clinical Microbiology & Infectious Diseases. 2014 Oct;33(10):1687–702.] *Caption from original*

- **Severe Sepsis** is indicated if the patient presents with an additional sign or symptom, such as those in the following list, that indicates an organ may be failing:
  - Decrease urine output
  - Confusion
  - Difficulty breathing
  - Decreased platelet count
- **Septic Shock:** The patient must present signs and symptoms of severe shock and decreased blood pressure that is not responding to fluid replacement treatments.

Atypical

- Older patients, immunocompromised patients, and patients on beta blockers may present without overt signs of shock. Younger patients with normal physiologic reserve may maintain normal vital signs and mentation for a relatively long period of time before suddenly manifesting shock.

Primary Differential Considerations

- Consider the following alternative diagnoses:
  - ARDS
  - Cardiogenic shock
  - DKA
  - Myocardial rupture
  - Toxic shock syndrome

History and Physical Exam

- **History and risk factors:**
  - Immunosuppressive states
  - Underlying terminal illnesses
  - Recent chemotherapy
  - Malignancy
  - Splenectomy
  - HIV
  - Diabetes
  - Nursing home
  - Source of infections: abdominal exam, rectal exam, chest exam, any rashes, decubitus ulcers, indwelling catheters, CNS infections.

Findings That Confirm Diagnosis

- Dyspnea
- Fever
- Nausea/vomiting
- Blood Pressure <90 mmHg, mean arterial pressure <70 mmHg, decrease in SBP>40 mmHg.
- Poor organ perfusion with early sign of flushed skin or later signs with cool skin due to redirection of blood flow to organs.
- Tachycardia >90 bpm
- Confusion/depressed consciousness-may be caused by encephalopathy
- Components of the "SIRS" (Systemic Inflammatory Response Syndrome) score are helpful in establishing the diagnosis of sepsis. A calculator and guidance for interpreting a SIRS score can be found at http://www.mdcalc.com/sirs-sepsis-and-septic-shock-criteria/.

Factors That Suggest Diagnosis

- Hyperthermia/hypothermia
- Tachypnea
- Tachycardia
- Prolonged capillary refill time

Factors That Exclude Diagnosis

- Negative blood cultures

Ancillary Studies

Laboratory

- CBC
- Lactate: Elevated lactate can be a manifestation of organ hypoperfusion.
- Blood cultures prior to antibiotics
- Platelet count
- Hematocrit
- Electrolytes
- BUN
- Creatinine
- Bilirubin
- Ca, Mg, pH
- C-reactive protein
- Cortisol level
- INR/prothrombin time/partial thromboplastin time
- LFT's
- Urine analysis and culture
- Pro calcitonin

Screening tests	Prothrombin time
	APTT
	Platelets
	Fibrinogen INR
Confirmatory tests	Soluble fibrin monomer complex
	Fibrinogen degradation products
	D-dimer
	Prothrombin fragments 1 and 2
	Antithrombin III

Screening and coagulopathy tests in the diagnosis of consumption coagulopathy (DIC) [Gullo A, Celestre CM, Paratore AL, Silvestri L, van Saene HK. Sepsis and Organ(s) Dysfunction. In: Gullo A, editor. Anaesthesia, Pharmacology, Intensive Care and Emergency APICE [Internet]. Milano: Springer Milan; 2014 [cited 2015 Aug 31]. p. 157–91. Available from: http://link.springer.com/10.1007/978-88-470-5516-2_14] *Caption from original*

Imaging

- Chest X-ray
- Soft tissue plain films
- Imaging to locate source of infections
  - CT of abdomen and pelvis
  - Ultrasound for gallbladder, etc.

Other

- Lumbar puncture
- Central Venous pressure measurement
- $Sv0_2$ measurement

Special Populations

Age

Pediatric

- Reports of pediatric sepsis are increasing nationwide, accounting for nearly 8 percent of patients treated in Pediatric ICUs.
- Primary sources of sepsis are primary bacteremia and respiratory infection.
- Organisms to consider are:
  - Staphylococcus aureus, including MRSA
  - S pneumonia
  - S pyogenes
  - Group B streptococcus in neonates
  - Coagulase negative Staphylococcus in children with indwelling catheters
- Viral infections may mimic bacterial sepsis, particularly respiratory pathogens.
- It is not unusual to have co-infections with viral etiologies and bacterial superinfection.
- Hallmarks of treatment remain early recognition, culture acquisition, volume replacement, and the administration of broad spectrum antibiotics.
- When treating children for sepsis, check labs frequently, as it is important to avoid hyponatremia and hypoglycemia.
- Dexamethasone should be given early for streptococcal bacterial meningitis.

Neonate

- Septic shock often manifests with:
  - Hypoglycemia
  - Seizures
  - Disseminated intravascular coagulation (DIC)
  - Cardiovascular collapse and death if untreated

Antibiotic class	Oral bioavailability	Protein binding	CNS penetration	Metabolism	Excretion	$t_{½}$
Aminoglycosides						
Gentamicin	Poorly absorbed	<25 %	Extracellular fluids and vascularized tissues; poor CSF penetration	None	Renal	<1 week PGA: 5–14 h; ≥1 week PGA: 3–5 h[a]
Aminopenicillins						
Ampicillin	50 %	10 %	Penetrates most tissues; poor CSF penetration	Hepatic (10 %)	Renal (25–40 %)	2–7 days PNA: 4 h; 8–14 days PNA: 2.8 h; 15–30 days PNA: 1–1.8 h
Cephalosporins						
Cefotaxime	Not administered orally	30–50 %	Penetrates most tissues; adequate CSF penetration when meninges are inflamed	Hepatic	Renal (60 %)	BW ≤1.5 kg: 4.6 h BW >1.5 kg: 3.4 h
Glycopeptides						
Vancomycin	Poorly absorbed	30 %	Penetrates most tissues; erratic CSF penetration	None	Renal; minimal biliary	4–11 h (dependent upon renal maturation)

Comparative pharmacokinetic data are derived from DiCenzo et al., Yoshioka et al., Rodvold et al. [132–134]

[a] For neonates <1 week PGA, the $t_{½}$ of aminoglycoside agents is inversely associated with BW

BW birthweight, *CNS* central nervous system, *CSF* cerebrospinal fluid, *PGA* post-gestational age, *PNA* postnatal age, $t_{½}$ elimination half-life

Comparative pharmacokinetics, bioavailability, protein binding, central nervous system penetration, metabolism, and excretion of antibiotics used in the empiric treatment of neonatal sepsis [Stockmann C, Spigarelli MG, Campbell SC, Constance JE, Courter JD, Thorell EA, Olson J, Sherwin CMT. Considerations in the Pharmacologic Treatment and Prevention of Neonatal Sepsis. Pediatric Drugs. 2014 Feb;16(1):67–81.] *Caption from original*; *See http://link.springer.com/10.1007/s40272-013-0057-x for references*

Antifungal class	Oral bioavailability	Protein binding	CNS penetration	Metabolism	Excretion	$t_{½}$
Polyenes						
Amphotericin B	Poorly absorbed[a]	90 %[a]	Poor CSF penetration (<5 % of plasma concentration)[a]	Minimal hepatic[a]	Renal[a]	50 h
Liposomal amphotericin B	Poorly absorbed[a]	Unknown	Poor CSF penetration (<1 % of plasma concentration)[a]	Unknown	Unknown	100–153 h[a]
Cytosine analogs						
5-Fluorocytosine	80 %[a]	3–4 %[a]	Good CSF penetration (74 % of plasma concentration)[a]	Minimal hepatic[a]	Renal (90 %); feces (10 %)	3–6 h
Azoles						
Fluconazole	>90 %[a]	11–12 %[a]	Good CSF penetration (75 % of plasma concentration)[a]	Minimal[a]	Renal[a]	Pre-term: 74 h; 1 week PNA: 53 h; 2 weeks PNA: 47 h
Echinocandins						
Caspofungin	Poorly absorbed	97 %[a]	Poor CSF penetration (0 % of plasma concentration)[a]	Hepatic[a]	Renal (42 %); feces (35 %)	40 h
Micafungin	Poorly absorbed	>99 %	Poor CSF penetration (0 % of plasma concentration)[a]	Hepatic	Feces (71 %)	7 h

Comparative pharmacokinetic data are derived from Baley et al., Walsh et al., Smith et al., Wurthwein et al., Piper et al., Wade et al., and Doby et al. [69, 72, 74, 135–138]

[a] Data obtained from adults (applicability to neonates is unclear)

Comparative pharmacokinetics, bioavailability, protein binding, central nervous system penetration, metabolism, and excretion of antifungals used in the empiric treatment of neonatal sepsis [Stockmann C, Spigarelli MG, Campbell SC, Constance JE, Courter JD, Thorell EA, Olson J, Sherwin CMT. Considerations in the Pharmacologic Treatment and Prevention of Neonatal Sepsis. Pediatric Drugs. 2014 Feb;16(1):67–81.] *Caption from original; See http://link.springer.com/10.1007/s40272-013-0057-x for references*

Co-morbidities

- Cancer
- Chronic-obstructive pulmonary Disease
- Immunosuppressed
- Congestive Heart Failure (CHF)
- Diabetes
- HIV/AIDS
- Renal Disease

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Misdiagnosing septic arthritis
- In elderly and nursing home patients, watch for bedsores, UTI's, etc.
- Always consider the risk of sepsis in immunocompromised patients (diabetes, HIV, cancer on chemotherapy, etc.)
- Serum lactate should be done early and blood cultures prior to antibiotics. Placement of central line and broad spectrum of tests to identify source or infection.

Mimics

- Inflammatory colitis
- Hypovolemia
- Medication effects
- Adrenal insufficiency
- Acute myocardial infarction
- Acute pulmonary embolus

Time-Dependent Interventions

- Airway and breathing stabilization are a priority. Utilize supplemental oxygen with pulse oximetry. Intubation may be required.
- Assess perfusion. Utilize aggressive fluid resuscitation for hypotension (excluding patients with heart failure).
- Central line.
- Saline boluses until CVP > 8 cm H_2O
- Initiate pressors—Norepinephrine or dopamine.
- Administer antibiotics early, based on most likely organism.
- Additional therapies (conflicting evidence) include inotropic therapy or red blood cell transfusions

Sepsis resuscitation bundle—(to be started immediately and completed within 6 h)
• Serum lactate measured
• Blood cultures obtained prior to antibiotic administration
• Broad-spectrum antibiotics administered within 3 h for ED admissions and 1 h for non-ED ICU admissions
• In the event of hypotension and/or lactate >4 mmol/L:
– Deliver a minimum of 20 ml/kg of crystalloid (or colloid equivalent)
– Apply vasopressors for hypotension not responding to initial fluid resuscitation to maintain mean arterial pressure (MAP) ≥65 mmHg
• In the event of persistent arterial hypotension despite volume resuscitation (septic shock) and/or initial lactate >4 mmol/L (36 mg/dl):
– Achieve central venous pressure (CVP) of ≥8 mmHg
– Achieve central venous oxygen saturation ($ScvO_2$) of ≥70%[a]
Sepsis management bundle—(to be started immediately and completed within 24 h)
• Low-dose steroids administered for septic shock in accordance with a standardized ICU policy
• Glucose control maintained ≥lower limit of normal, but <150 mg/dl (8.3 mmol/L)
• For mechanically ventilated patients inspiratory plateau pressures maintained <30 cmH_2O

[a]Achieving a mixed venous oxygen saturation of 65% is an acceptable alternative

Sepsis Bundles: The goal is to perform all indicated tasks 100% of the time within the first 6 h (Sepsis Resuscitation Bundle) or first 24 h (Sepsis Management Bundle) of the diagnosis of severe sepsis [Kreiner LA, Moore LJ. Early Management of Sepsis, Severe Sepsis, and Septic Shock in the Surgical Patient. In: Moore LJ, Turner KL, Todd SR, editors. Common Problems in Acute Care Surgery [Internet].

New York, NY: Springer New York; 2013 [cited 2015 Aug 31]. p. 73–91. Available from: http://link.springer.com/10.1007/978-1-4614-6123-4_6] *Caption from original*

Overall Principles of Treatment

- The primary goal of managing sepsis is to address inflammation by restoring perfusion and treating the infection.
- Early goal-directed therapy (EGDT) targets to be measured:
  - Mean arterial pressure (MAP) ≥65 mmHg
  - Urine output ≥0.5 mL/kg/hr
  - Predictors of fluid responsiveness
  - Central venous oxyhemoglobin saturation ($Scv0_2$) ≥65 percent
  - Lactate clearance should be followed
- Protocol-directed therapies assist in management of septic patients.
- Early antimicrobial therapy is important and should be targeted at the likely primary site. Broad-spectrum coverage with at least two agents is usually indicated.
- Additional therapies:
  - Glucocorticoids: pathogenesis of sepsis involves host inflammatory response.
  - Nutrition: nutritional support improves nutritional outcomes.
  - Intensive insulin therapy: hyperglycemia and insulin resistance.
  - External cooling: controlling fever.
  - Investigational therapies: cytokine and toxin inactivation.

Prevention and Treatment Summary

Author (year)	Subject #	Method	Outcome
Primary Prevention			
Murugan (2012)	1,836	Prospective cohort	Statin use in patients with pneumonia not associated with reduction in acute kidney injury
Rothberg (2012)	121,254	Retrospective review	Modest reduction in non-ICU pneumonia mortality
Novack (2012)	17,802	Placebo controlled	No reduction in sepsis incidence. Modest reduction in pneumonia incidence
Nseir (2012)	342	Retrospective review	Mortality reduction in patients with bacteremia Statin use more than 12 weeks prior to bacteremia increased benefit
Leung (2012)	2,139	Retrospective cohort	Statin use not associated with improved survival in patients with bloodstream infection
Yende (2011)	1,895	Multicenter inception	No reduction in severe sepsis or 90-cohort day mortality
O'Neal (2011)	575	Prospective cohort	Reduction in risk of developing severe sepsis and acute lung injury
Al Harbi (2011)	763	Nested cohort	Reduction in severe sepsis related hospital mortality
Williams (2011)	2,642	Prospective cohort	No reduction in infection related 30-day mortality
Goodin (2011)	568	Retrospective cohort	No reduction of vasopressor duration, ICU length or stay, or hospital mortality
Secondary Prevention			
Kruger (2011)	150	Placebo-controlled	Continuation of statin in patients with infection did not reduce risk of developing sepsis
Novack (2009)	83	Placebo-controlled	Patients with infection randomized to statin therapy had reduced TNF-α and IL-6 levels
Treatment			
Patel (2011)	100	Placebo controlled	Atorvastatin reduced risk of sepsis progression
Dessap (2011)	76	Retrospective cohort	Continuation of statin in patients with severe sepsis and septic shock was not associated with reduction in severity of organ failure or mortality

Disease Course

- Sepsis is a high-risk syndrome that is sometimes fatal even with aggressive treatment. Current literature suggests that early recognition and early, aggressive, goal-directed treatment are associated with better outcomes.

Chapter 68
Tachyarrhythmias

Charles V. Pollack, Jr., Richard M. Cantor, and Jaime Friel Blanck

Name and Synonyms

Tachyarrhythmias

Incidence/Epidemiology

- "Tachyarrhythmias" include several distinct syndromes of varying incidence and epidemiology.
- A tachycardia (fast heart rate) is defined as a ventricular rate of 100 beats per minute or more, and may be regular or irregular in rhythm.
- The diagnoses addressed in this discussion include:
  - Sinus tachycardia, which is not a primary tachycardia (i.e., it is not caused by an abnormality of the cardiac conducting system).
  - Multifocal atrial tachycardia (MAT), which is most often seen in patients with lung disease such as COPD.
  - Atrial fibrillation (AFib), the most common arrhythmia, in which the atria do not beat in a coordinated fashion, and which may present with a "controlled" (less than 100 bpm) or "rapid" (greater than 100) ventricular rate.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_68

An American who lives until age 75 without atrial fibrillation has a one-in-four chance of developing AFib during the rest of his or her life.
  - Atrial flutter (AFlutt), a less stable rhythm than AFib, where the atria beat regularly, but not every beat is transmitted to the ventricles.
  - Paroxy mal supraventricular tachycardia (PSVT), which may be seen more often in younger patients than AFib or AFlutt.
  - Wolff-Parkinson-White syndrome, in which an alternate transmission route for the electrical impulses through the heart is present.
  - Ventricular tachycardia (VT), the most lethal of the tachyarrhythmias, is usually the result of myocardial ischemia.
- There are much rarer types of tachyarrhythmias that are beyond the scope of this review.

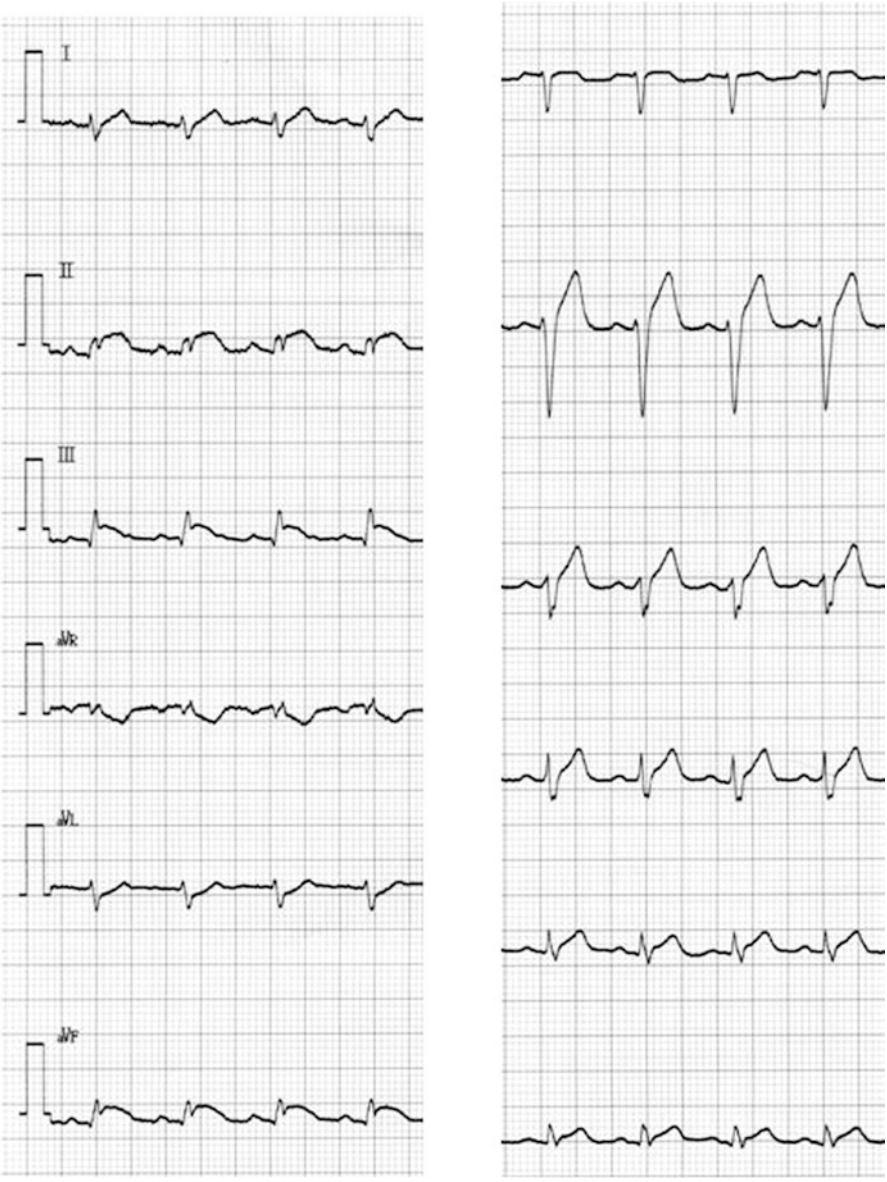
Differential Diagnosis

- Tachycardia is a straightforward diagnosis, confirmed with an ECG or even a manual pulse check. The important diagnostic inquiries related to tachycardia are centered on the actual rhythm (e.g., supraventricular vs ventricular) and underlying etiology of the rapid heart rate. Diagnostic considerations include but are not limited to:
  - Acute myocardial infarction
  - Acute heart failure
  - Pulmonary embolism
  - Sepsis
  - Myocarditis
  - Hypoxemia
  - Hypovolemia
  - Anemia
  - Hyperthyroidism
  - Poisoning or withdrawal syndrome

Pathophysiology and Etiology

- Tachyarrhythmias may be primary (i.e., the result of a defective cardiac electrical conduction system or cardiac injury) or secondary (e.g., tachycardia as a result of withdrawal syndromes, thyroid storm, or sepsis).
- Tachyarrhythmias may be associated with chest pain and dyspnea because they derive from a primary ischemic etiology such as acute myocardial ischemia, or they may cause ischemic pain because the rate does not allow sufficient time for perfusion of stressed myocardium.

- Sinus tachycardia is a normal physiologic response to stress, such as fever, anemia, exercise, anxiety, or hypotension. The patient's normal QRS morphology is present.

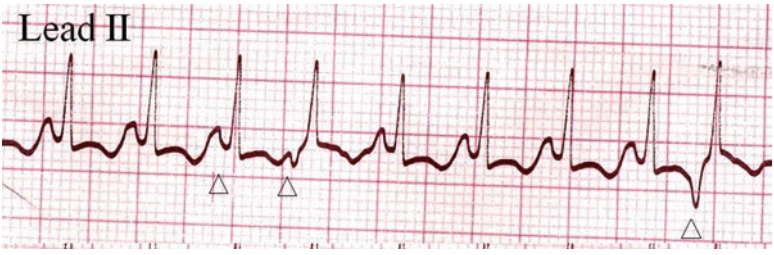


Electrocardiogram on admission showing sinus tachycardia with significant ST elevation in leads II, III, aVF, and V2–V4 [Okai I, Inoue K, Maruyama M, Maruyama S, Komatsu K, Nishizawa H, Okazaki S, Fujiwara Y, Sumiyoshi M, Daida H. Transbrachial intra-aortic balloon pumping for a patient with fulminant myocarditis. Heart Vessels. 2012 Nov 1;27(6):639–42.] *Caption from original*

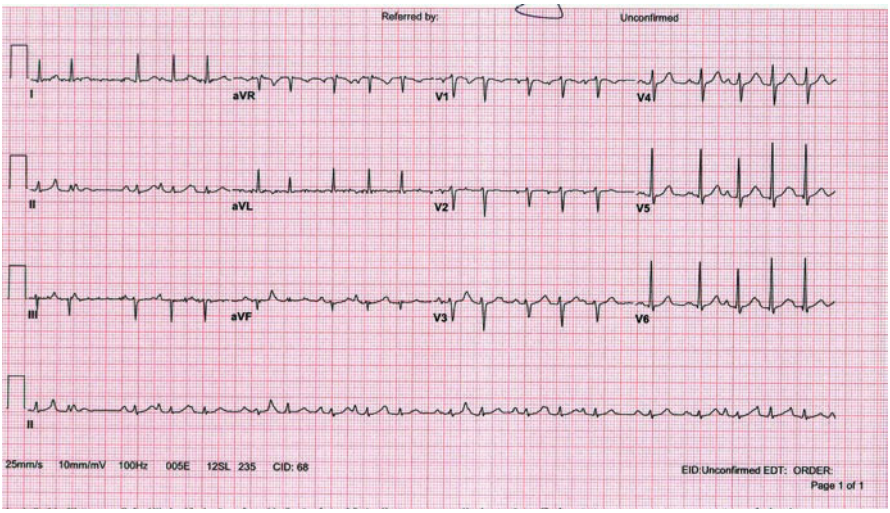
Medical conditions	Physiological	Drugs, substances
Hyperthyroidism	Exercise	Caffeine
Cushing's disease	Emotion	Alcohol
Pheochromocytoma	Pain	Tobacco
Anemia	Fever	Catecholamines
Infection	Pregnancy	Vasodilators
Dehydration	Volume depletion	Atropinic substances
Cardiomyopathy		Theophylline
Panic attack		Illicit drugs: cocaine
Pericarditis		Decongestants
Aortic or mitral regurgitation		Sympathomimetics
Myocardial infarction		Thyroid hormones
Postural hypotension		

Explainable causes of sinus tachycardia that should be ruled out before making the diagnosis of inappropriate sinus tachycardia. [Peyrol M, Lévy S. Clinical presentation of inappropriate sinus tachycardia and differential diagnosis. J Interv Card Electrophysiol. 2016 Jun 1;46(1):33–41.] *Caption from original*

- Multifocal atrial tachycardia is caused by multiple sites of competing atrial electrical activity. The atrial rate by definition exceeds 100 bpm, and there are multiple morphologically identifiable p-waves. Conduction to the ventricles is 1:1, but the P-P intervals are variable. It is characterized by an irregular atrial rate greater than 100 beats per minute (bpm).

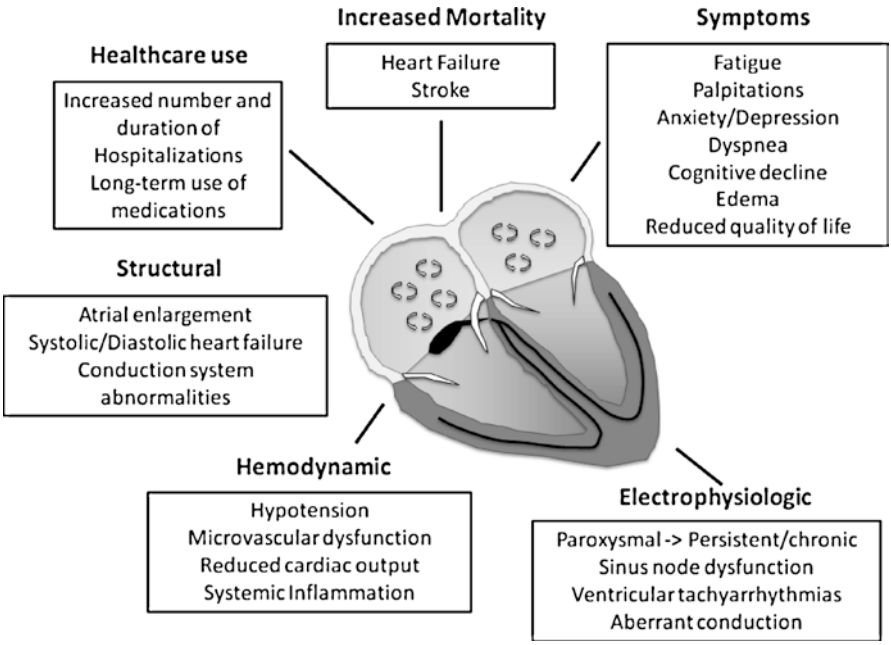


Three different morphologies of P-wave complexes (arrowheads) suggesting multifocal atrial tachycardia [Shabanian R, Kiani A, Rad EM, Eslamiyeh H. Lown-Ganong-Levine Syndrome in a 3-Month-Old Infant with Isolated Left Ventricular Noncompaction. Pediatr Cardiol. 2010 Feb 1;31(2):274–6.] *Caption from original*

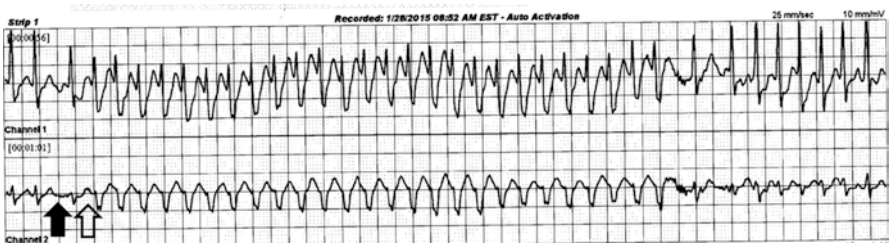


Multifocal atrial tachycardia (MAT). The diagnosis is made by three or more ectopic (i.e., not all sinus) P-waves. The heart rate (approximately 100–140 bpm) may be variable due to the site of ectopy or non-conduction of certain P-waves. MAT is commonly observed in patients with chronic obstructive pulmonary disease. [Chung EH, Martin DT. Management of Postoperative Arrhythmias. In: O'Donnell JM, Nácul FE, editors. Surgical Intensive Care Medicine [Internet]. Springer US; 2010 [cited 2017 May 24]. p. 209–27. Available from: http://link.springer.com/chapter/10.1007/978-0-387-77893-8_21] *Caption from original*

- Atrial fibrillation may be isolated, paroxysmal, or persistent. The first two are often prompted by an episode of emotional stress, hormonal stress, trauma, surgery, or intoxication. Persistent AFib usually is a manifestation of structural heart disease or chronic lung disease. It is manifest on the ECG and by manual pulse check as an "irregularly irregular" rhythm, reflecting uncoordinated, chaotic atrial activity that does not send the ventricles a clear and regular signal to contract. The ECG typically shows an erratic electrical baseline between QRS complexes.



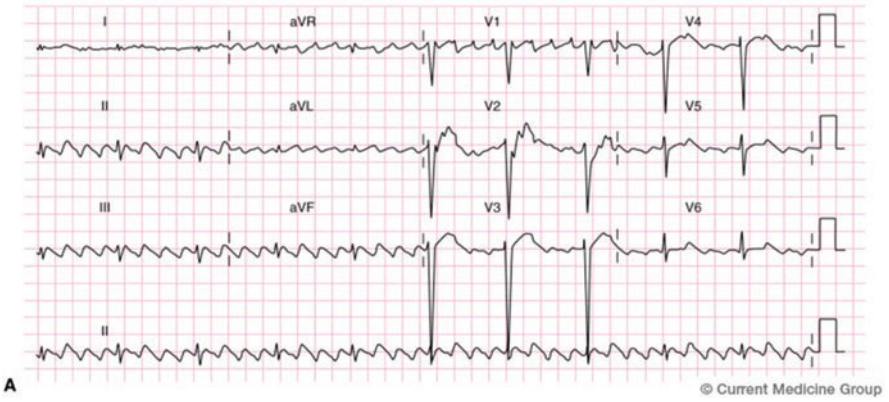
Broad consequences of atrial fibrillation. [Bunch TJ, Gersh BJ. Rhythm Control Strategies and the Role of Antiarrhythmic Drugs in the Management of Atrial Fibrillation: Focus on Clinical Outcomes. J GEN INTERN MED. 2011 May 1;26(5):531–7.] *Caption from original*



Ambulatory event monitor tracing showing long-short initiation of aberrant ventricular conduction during atrial fibrillation. The preceding long R-to-R interval is indicated by the *black-filled arrow* and the short R-to-R interval is indicated by the *unfilled arrow* [Winchester DE, Kaufmann MR, McKillop MS, Miles WM. Pitfalls in the Acute Management of Atrial Fibrillation. In: Peacock WF, Clark CL, editors. Short Stay Management of Atrial Fibrillation [Internet]. Springer International Publishing; 2016 [cited 2017 Jun 2]. p. 145–73. (Contemporary Cardiology). Available from: http://link.springer.com/chapter/10.1007/978-3-319-31386-3_14] *Caption from original*

- Atrial flutter is usually transient and is characterized by a regular atrial rate between 250 and 350 bpm, with a regular ventricular response to every third (3:1 conduction) or fourth (4:1 conduction) atrial beat. The ECG will typically show "sawtooth" p-waves in the inferior leads.

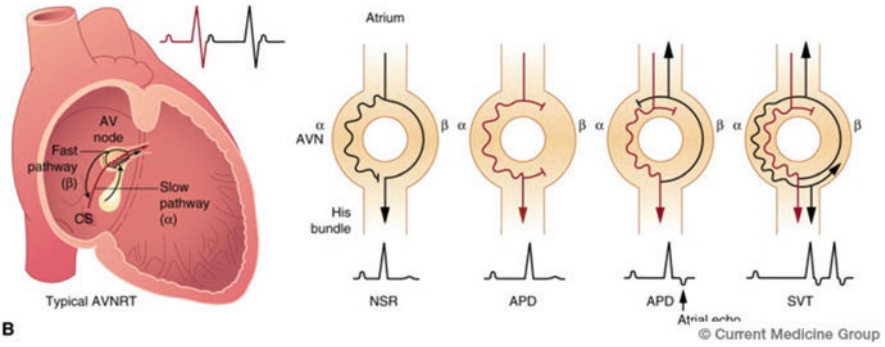
Six-lead ECG immediately after admission revealing the typical signs of atrial flutter [Haas NA, Wegendt C, Schäffler R, Kirchner G, Welisch E, Kind K, Blanz U, Kececioglu D. ECMO for cardiac rescue in a neonate with accidental amiodarone overdose. Clin Res Cardiol. 2008 Dec 1;97(12):878–81.] *Caption from original*



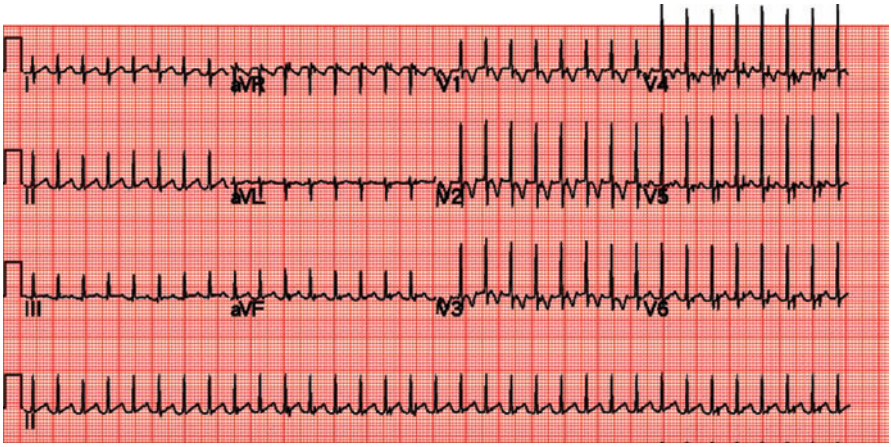
Macroreentrant atrial tachycardias. A, 12-Lead electrocardiogram (ECG) of common counterclockwise atrial flutter. Note the typical sawtooth P-waves in leads II, III, and aVF. [Epstein L, Stevenson W, Steven D, Seiler J, Roberts-Thomson K, See

V. Chapter 7 Arrhythmias. In: Libby P, editor. Essential atlas of cardiovascular disease. 4th ed. Philadelphia: Current Medicine Group; 2009.] *Caption adapted from original*

- PSVT is caused by functional differences in conduction and refractoriness in the AV node, or by the existence of an "accessory" or "bypass" tract involving the SA and AV nodes. The atrial rate is typically 120–180 bpm and conduction to the ventricles is usually 1:1 with a normal QRS morphology.

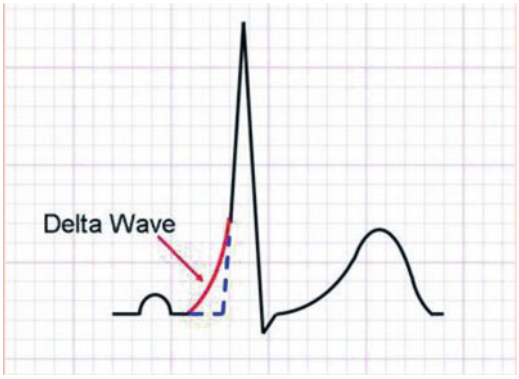


The mechanism of the common form of AVNRT. A lobe of the AV node extends inferiorly along the tricuspid annulus, anterior to the coronary sinus os, which functions as a slowly conducting pathway. During AVNRT-conduction occurs from inferior to superior through the slow pathway, then through the compact portion of the AV node to the His bundle and retrograde through this superior portion of the AV node to the atrium. The path from the compact AV node back down to the slow pathway may involve musculature around the coronary sinus, within the atrium, or may be largely confined to the AV node. Initiation of AV nodal reentry is shown in schematics on the right in which α is the slow AV nodal pathway and β is the fast pathway. During normal sinus rhythm (NSR), an impulse from the atrium enters the AV node and travels down both the slow and fast pathways with the impulse from the fast pathway reaching the His bundle first and activating the ventricles with a short PR interval. Collision of fast pathway and slow pathway impulses in the distal portion of the AV node prevents reentry. An atrial premature depolarization (APD) that blocks in the fast pathway (β) allows conduction of the impulse down the slow pathway to the ventricles, thus a longer PR interval. If this impulse blocks in the distal fast pathway, no reentry occurs. However, an APD can produce an atrial echo beat if the fast pathway has recovered allowing the impulse to continue retrogradely in the fast pathway back to the atrium. If the slow pathway has recovered to allow conduction, the impulse may continue circulating as supraventricular tachycardia (SVT). [Epstein L, Stevenson W, Steven D, Seiler J, Roberts-Thomson K, See V. Chapter 7 Arrhythmias. In: Libby P, editor. Essential atlas of cardiovascular disease. 4th ed. Philadelphia: Current Medicine Group; 2009.] *Caption adapted from original*



Electrocardiogram. Initial ECG with paroxysmal supraventricular tachycardia [From article: A male infant had subdural effusion and paroxysmal supraventricular tachycardia during the febrile episode of Kawasaki disease: a case report and literature review. BMC Pediatr. 2016 Dec 1;16(1):71. https://doi.org/10.1186/s12887-016-0606-x at https://link.springer.com/article/10.1186/s12887-016-0606-x by Chia-Pei Chou, I-Chun Lin, Kuang-Che Kuo, © Chou et al. 2016; licensee BioMed Central Ltd.; licensed under Creative Commons Attribution 4.0 International License http://creativecommons.org/licenses/by/4.0/] *Caption from original*

- WPW is a specific type of tachycardia that results from firing along an accessory electrical conduction tract. It is also called "pre-excitation syndrome" and often shows a particular upsloping of the QRS complex ("delta wave"). It can be associated with congenital cardiac anomalies such as Ebstein's anomaly. The QRS complex in WPW is often wide and the p-wave appears normal.



Delta wave, seen in WPW syndrome [Gnanaprakasam R, David S. Acute Cardiac Arrhythmias. In: David SS, editor. Clinical Pathways in Emergency Medicine

[Internet]. Springer India; 2016 [cited 2017 May 24]. p. 101–15. Available from: http://link.springer.com/chapter/10.1007/978-81-322-2710-6_8] *Caption from original*

Morphologic features of Ebstein anomaly	% of patients	Reference(s)

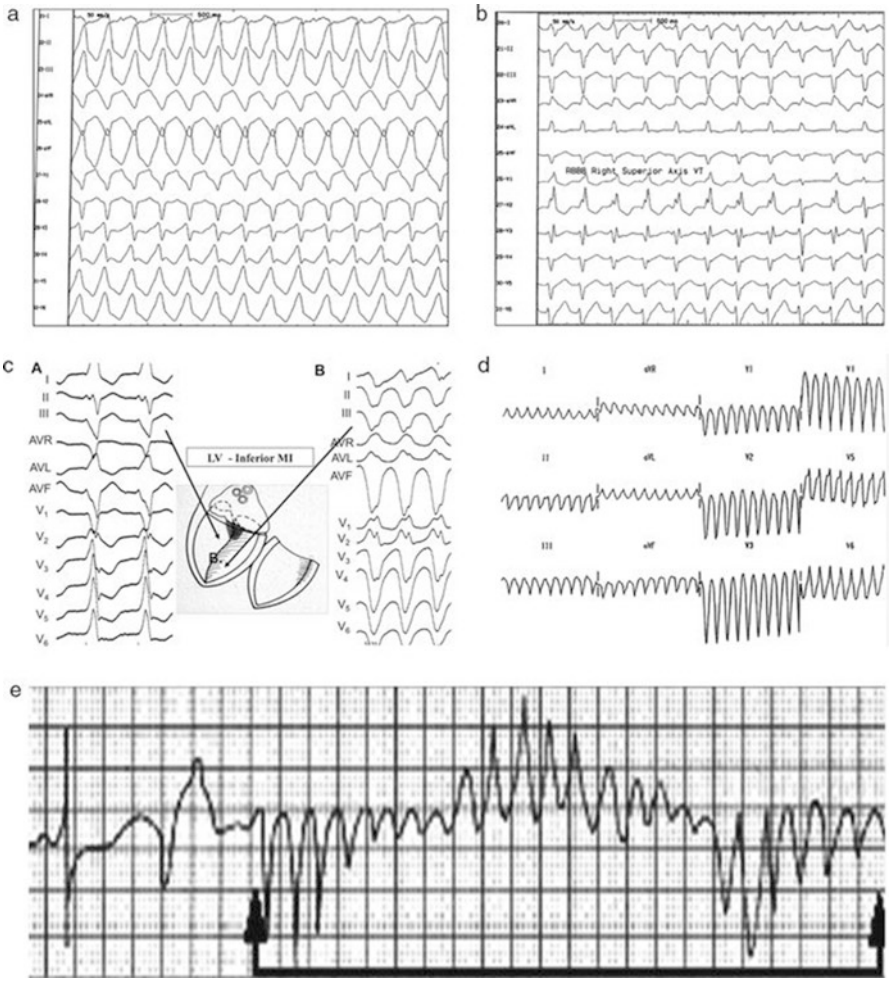
An electrocardiogram (ECG) from a 34-year-old asymptomatic aircrew member showing typical features of the Wolff-Parkinson-White (WPW) syndrome—ie, a short P-R interval and delta waves in multiple leads. [Ferry D, Anholm J, Blomqvist GC, Levine B, Lane L, Buckey J, Wachholz C. Chapter. In: Crawford C, editor. Heart Disease In Presence of Disorders of Other Organ Systems. 1st ed. Philadelphia: Current Medicine; 1996 (Braunwald E, editor. Atlas of heart diseases; vol. 6.)] *Caption adapted from original*

- Ventricular tachycardia is a potentially lethal tachyarrhythmia that is usually associated with structural heart disease, including ischemia. Occasionally it is seen in patients with intoxications, with metabolic derangements, with long QT syndrome, and, rarely, without identifiable precipitant. VT that persists more than 30 seconds is called sustained VT. Because it is driven by a ventricular pacemaker, the QRS complex is wide. VT may or may not generate a palpable pulse.



ECG types of VT and most common causes are shown with characteristic ECG features of selected VTs. LBBB indicates left bundle branch block; RBBB, right bundle branch block; L, left; and R, right. (a) Sustained monomorphic ventricular tachycardia with LBBB and inferior axis suggesting origin from RVOT. This tachycardia is idiopathic in origin. (b) Sustained monomorphic ventricular tachycardia with RBBB and right superior axis, suggesting origin in the left ventricular septum. This type of tachycardia is commonly idiopathic in origin. (c) Two different ventricular tachycardias originating in the left ventricle long after an inferior wall myocardial infarct. This type of VT is related to scars that form after myocardial infarct. (d) Fast ventricular tachycardia with LBBB and left superior axis. Morphology and rate are suggestive of bundle branch reentry ventricular tachycardia. This type of VT is related to nonischemic cardiomyopathy. (e) Polymorphic ventricular tachycardia. This type of tachycardia is frequently related to electrolyte abnormalities,

ischemia, or drug toxicity. [Kocovic D. Ablation for Ventricular Tachycardia. In: Yan G-X, Kowey PR, editors. Management of Cardiac Arrhythmias [Internet]. Humana Press; 2011 [cited 2017 May 24]. p. 257–82. (Contemporary Cardiology). Available from: http://link.springer.com/chapter/10.1007/978-1-60761-161-5_12] *Caption from original*

Presentation

Typical/"Classic"

- Patients with tachyarrhythmias typically present with:
  - Palpitations
  - Chest pain
  - Dizziness
  - Weakness

Atypical

- Patients with tachyarrhythmias, especially atrial fibrillation, may be largely asymptomatic.
- Sometimes the cardinal symptoms of underlying illness (e.g. sepsis, hyperthyroidism, withdrawal syndrome) may overwhelm the patient's perception of tachycardia

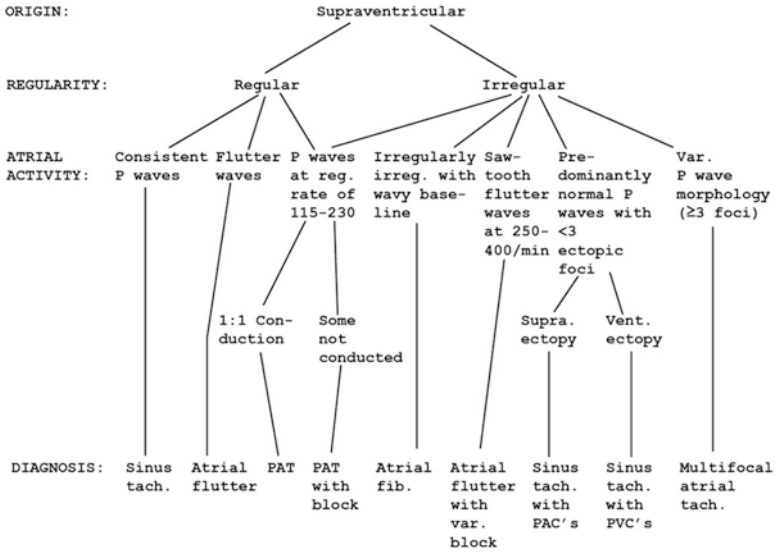
Primary Differential Considerations

- Patients with tachyarrhythmias should be evaluated for type of rhythm abnormality and for underlying cause. Among the important early considerations are:
  - Acute myocardial ischemia/infarction
  - Pulmonary embolism
  - Sepsis
  - Shock
  - Ventricular tachycardia
  - Sustained supraventricular tachycardia

History and Physical Exam

Findings That Confirm Diagnosis

- The ECG confirms the type of arrhythmia and may give clues of myocardial ischemia if present. The clinician should assess the patient's hemodynamic stability while the ECG is being performed. On first review of the ECG, focus on identifying the rhythm and on whether the QRS is narrow or wide.



Flow sheet for supraventricular tachycardia [Petty BG. Arrhythmias. In: Basic Electrocardiography [Internet]. Springer New York; 2016 [cited 2017 May 24]. p. 101–35. Available from: http://link.springer.com/chapter/10.1007/978-1-4939-2413-4_7] *Caption from original*

Factors That Suggest Diagnosis

- Tachypalpitations, weakness, with or without chest pain or shortness of breath.
- ECG should be obtained immediately and will guide the diagnostic process.

Factors That Exclude Diagnosis

- A heart rate (on ECG, monitor, or manual pulse count) of < 100 bpm excludes tachyarrhythmia. A patient with suggestive symptoms, however, should be maintained on a monitor, because the abnormal rhythm may be paroxysmal.

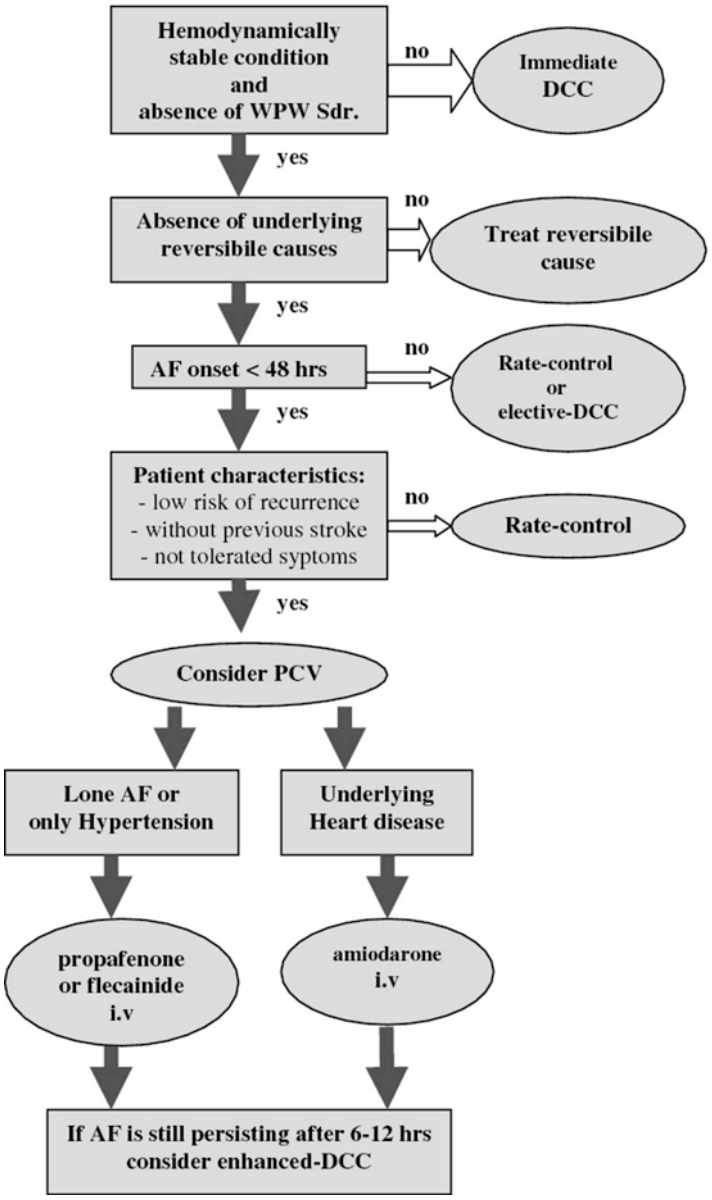
Ancillary Studies

Laboratory

- It is helpful to send routine laboratory studies such as basic chemistries, a complete blood count, and cardiac biomarkers to evaluate for other causes for the patient's symptoms.
- Specialized studies should be ordered as pertinent to the presentation, such as thyroid studies, blood cultures, etc.
- If the patient is taking digoxin or theophylline, check drug levels.

Electrocardiography

- The ECG should be obtained and interpreted promptly.
  - Look first for signs of acute ischemia (in particular, ST-segment elevation).
  - Then look to see if QRS rhythm is regular or irregular.
  - Then evaluate the width of the QRS complex: narrow (normal conduction) or wide (abnormal conduction from above, or ventricular origin).



Key findings of common arrhythmias [Winchester DE, Kaufmann MR, McKillop MS, Miles WM. Pitfalls in the Acute Management of Atrial Fibrillation. In: Peacock WF, Clark CL, editors. Short Stay Management of Atrial Fibrillation [Internet]. Springer International Publishing; 2016 [cited 2017 May 24]. p. 145–73. (Contemporary Cardiology). Available from: http://link.springer.com/chapter/10.1007/978-3-319-31386-3_14] *Caption from original*

Imaging

- The chest x-ray may be helpful in the evaluation of tachyarrhthmias. Other imaging is typically not needed except in specific diagnostic evaluations for underlying problems, such as CT pulmonary angiogram for suspected pulmonary embolism.

Special Populations

Age

- Atrial fibrillation, atrial flutter, MAT, and VT are more likely to occur in older patients.
- PSVT and sinus tachycardia can occur at any age.
- Tachycardia is common in the pediatric age group; etiologies are often benign.
- Parental diagnosis is often accomplished by observing the neck veins or sensing a bounding pulse while holding the child.
- SVT is the most common symptomatic dysrhythmia of infancy and childhood.
- Symptoms of SVT in infancy range from minor to cardiogenic shock.
- In infants, lethargy, feeding problems, or irritability may be manifested.
- In newborns or infants with SVT, the heart rate is often > 220 bpm.

Co-morbidities

- The most important co-morbidities are underlying cardiopulmonary disease, including coronary artery disease, heart failure, structural heart abnormalities, and COPD.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is imperative that all patients be monitored in an ongoing fashion for hemodynamic stability.
- Recognition of ventricular arrhythmia is critical, as VT is an unstable and potentially lethal rhythm.

- Patients with supraventricular arrhythmia (AFib, AFlut, PSVT) often present in relatively stable condition but may not tolerate the ongoing high myocardial oxygen demand for long, so early stabilization and rate control are warranted.

Mimics

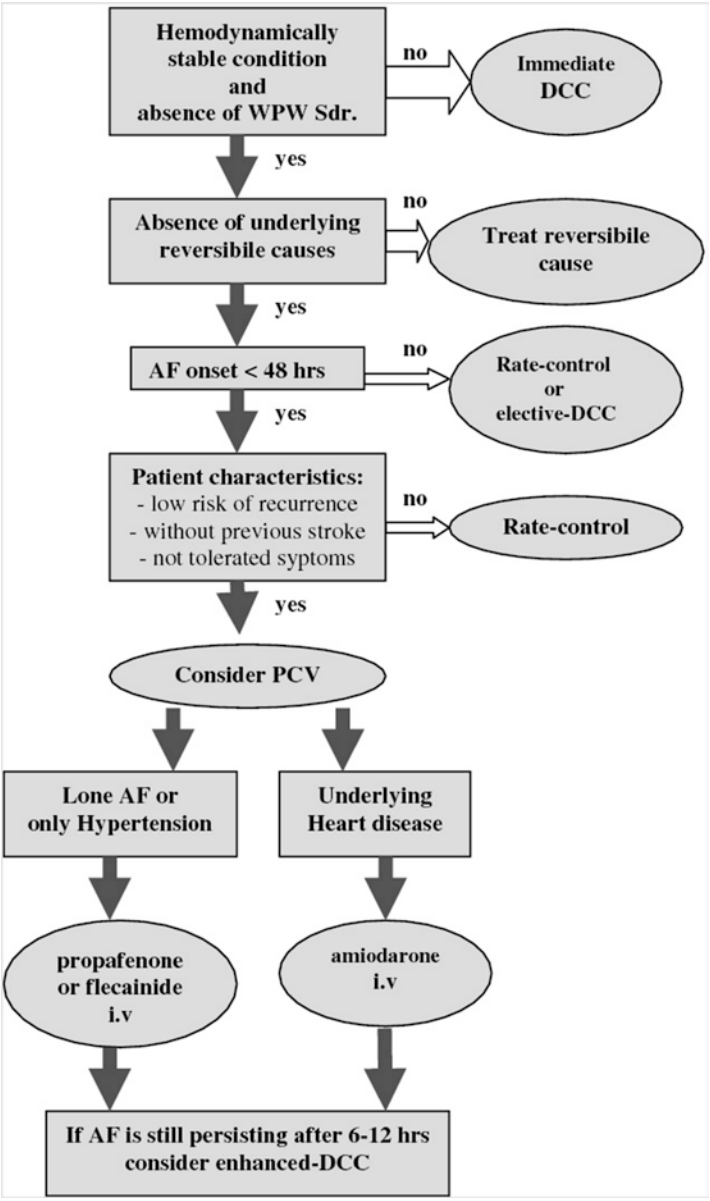
- Palpitations can be caused by anxiety, but sometimes this is not a clear diagnosis, and a prompt ECG should still be obtained.

Time-Dependent Interventions

- The most important intervention is to stabilize patients with hemodynamic instability.
- Recognition of potentially lethal arrhythmias is important.
- Identification and management of underlying illness are important steps and may be life-saving (e.g., PE, sepsis).
- Rate control should be established as soon as possible in order to spare the myocardium ongoing high oxygen consumption that may lead to ischemia.

Overall Principles of Treatment

- Treatment approach is specific to the tachyarrhythmia diagnosis and/or underlying disease. Treatment may be very complex, but first-line actions typically are as follows:
  - Sinus tachycardia: identify and treat underlying cause.
  - MAT: focus on treating underlying pulmonary disease.
  - AFib: consider rate control with diltiazem (if hemodynamically stable) or with cardioversion (if unstable)



Proposed approach to the management of patients with recent-onset AF. Stratify thromboembolic risk and initiate appropriate prophylaxis in all patients. When elective DCC is considered in patients with AF >48 h or after a failed attempt at cardioversion, OAC treatment is required for at least 3 weeks before and 4 weeks after cardioversion [Tampieri A, Rusconi AM, Lenzi T. Cardioversion in atrial fibrillation. Focus on recent-onset atrial fibrillation. Intern Emerg Med. 2012 Oct 1;7(3):241–50.] *Caption from original*

  - AFlutt: consider rate control with diltiazem (if hemodynamically stable) or with cardioversion (if unstable).
  - PSVT: consider rate control with adenosine or diltiazem (if hemodynamically stable) or with cardioversion (if unstable).
  - WPW: if narrow complex QRS, can use adenosine or diltiazem; if wide-complex, treat as VT and avoid these drugs.
  - VT: synchronized cardioversion.
- Patients should be evaluated for any underlying or acute issues that, if treated, can help improve the cardiac function.

Disease Course

- Prognosis is dependent on the specific type of arrhythmia and underlying co-morbidities.
- The mortality of VT is highest within this group of diagnoses.
- Patients with AFib should be evaluated for chronic oral anticoagulation once stabilized.

Berlin, Heidelberg: Springer Berlin Heidelberg; 2010 [cited 2015 Sep 1]. p. 74–7. Available from: http://link.springer.com/10.1007/978-3-540-69837-1_31] *Caption from original*

Incidence/Epidemiology

- Tetralogy of Fallot is seen in 4 per 10,000 live births.
- It accounts for 7–10 % of reported cases of congenital heart disease.
- Repair is usually necessary within the first year of life.

Differential Diagnosis

- Should be considered in the differential diagnosis of cyanotic congenital heart disease, often represented by the "5 T's":
  - Truncus Arteriosus
  - Transposition of the Great Arteries
  - Tricuspid Atresia
  - Tetralogy of Fallot
  - Total Anomalous Pulmonary Venous Return

Pathophysiology and Etiology

- In patients with TOF, the degree of compromise is directly dependent on the severity of the right ventricular outflow obstruction. In most cases, the size of the VSD is generous enough to permit bidirectional blood flow. If left-sided pressures are high enough, the shunting will be "left-to-right," and the patient will be acyanotic. In the converse situation, shunting away from the pulmonary bed will present with cyanosis.
- In the most severe obstructive scenarios, episodes of profound cyanosis may occur (so-called "tet spells" or "hypercyanotic" spells). The etiology of these episodes is unclear.

Presentation

Typical/"Classic"

- As previously mentioned, in situations with severe right-sided outflow obstruction, infants will present with severe cyanosis. This most often occurs during the newborn period.
- In situations where pulmonary and systemic blood flows are equivocal, the infant will often present with a murmur, prompting further investigation.

Atypical

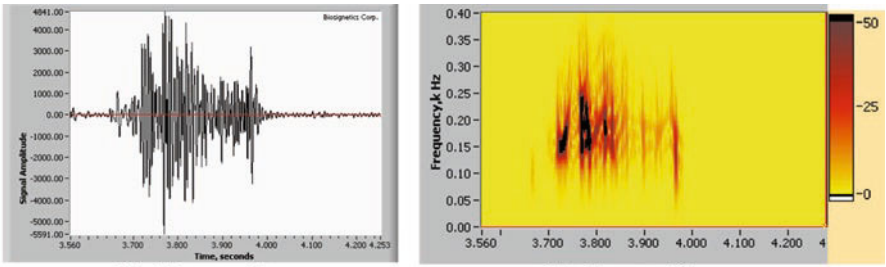
- In cases of minimal right-sided outflow obstruction, shunting across the large VSD will promote the development of congestive heart failure from pulmonary overperfusion.

Primary Differential Considerations

- The other components of the 5 T's (see above) are the most important differential diagnoses to consider.

History and Physical Exam

- Most infants will present with cyanosis in the first few days of life.
- In others, the diagnosis will often be difficult, since most patients with TOF will appear comfortable and in no distress.
- The development of a hypercyanotic (tet) spell will be heralded by the development of cyanosis, hyperpnea, and marked agitation.
- A prominent right ventricular impulse may be palpable.
- The murmur in TOF is secondary to right ventricular outflow obstruction (not from the VSD). As obstruction increases, the murmur will often diminish in intensity, as blood will preferentially be shunted across the VSD.



(A, B). Abnormal heart sound of Severe Tetralogy of Fallot (acyanotic). A) PCG (single heart beat). B) HES (single heart beat). [From article: Heart energy signature spectrogram for cardiovascular diagnosis. BioMed Eng OnLine. 2007 May 4;6(1):1–22. Tetralogy of Fallot murmur. [Congenital Abnormalities: Tetralogy of Fallot; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

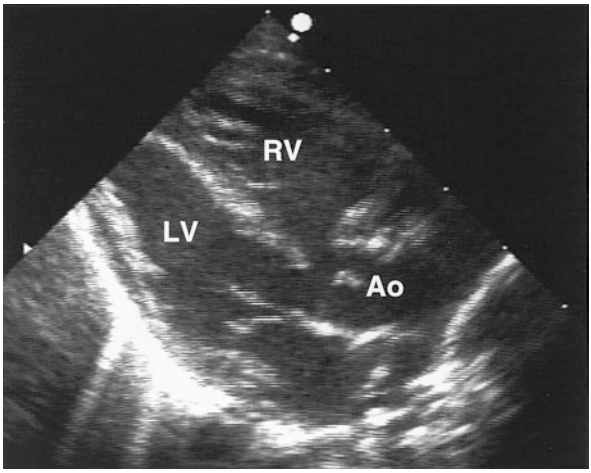
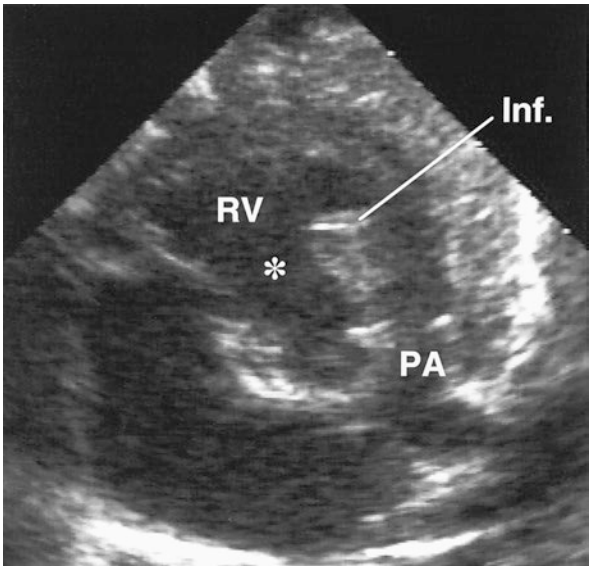
Findings That Confirm Diagnosis

- Echocardiography is the gold standard for establishing the diagnosis of TOF.



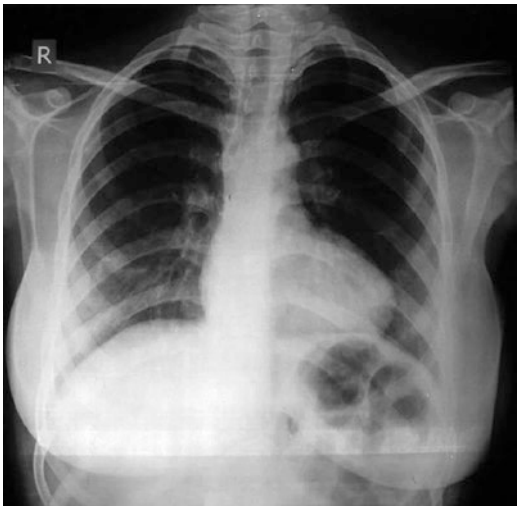
Tetralogy of Fallot. Both subxiphoid and parasternal long- and short-axis images demonstrate the most important aspects of tetralogy of Fallot. A,Parasternal long-axis view demonstrating the large anterior malalignment ventricular septal defect (VSD) with aortic overriding of the crest of the ventricular septum. Ao—aorta; LV—left ventricle; RV—right ventricle. [Hornberger L, Schwartz M. Chapter 2. In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging. Atlas of Heart Diseases, Volume 01, Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption adapted from original*



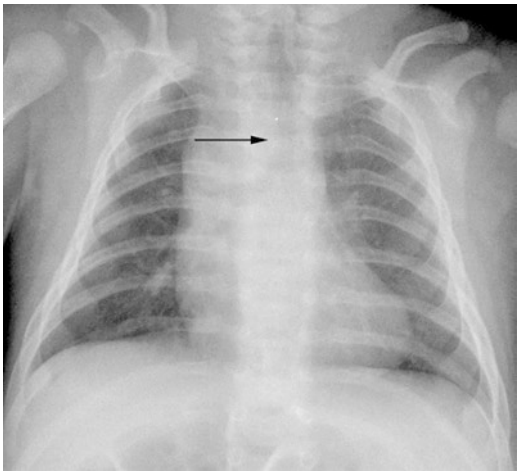
B, Parasternal short-axis view of the right ventricular outflow tract (RVOT) demonstrating anterior malalignment of infundibular septum (Inf). The large subaortic,

malalignment VSD can be seen (asterisk). Other lesions to be excluded in tetralogy of Fallot include additional VSDs, branch pulmonary artery (PA) stenoses, mitral valve abnormalities, and coronary abnormalities, particularly the left anterior descending from the right coronary artery (which crosses over the RVOT) or a single right coronary artery. A prominent conal branch from the right coronary that partially crosses the infundibulum is common in tetralogy of Fallot. RV—right ventricle. [Hornberger L, Schwartz M. Chapter 2. In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging. Atlas of Heart Diseases, Volume 01, Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption adapted from original*

- In more typical scenarios, the presence of cyanosis unresponsive to supplemental oxygen, combined with typical X-ray findings (boot-shaped heart), will point to the diagnosis.

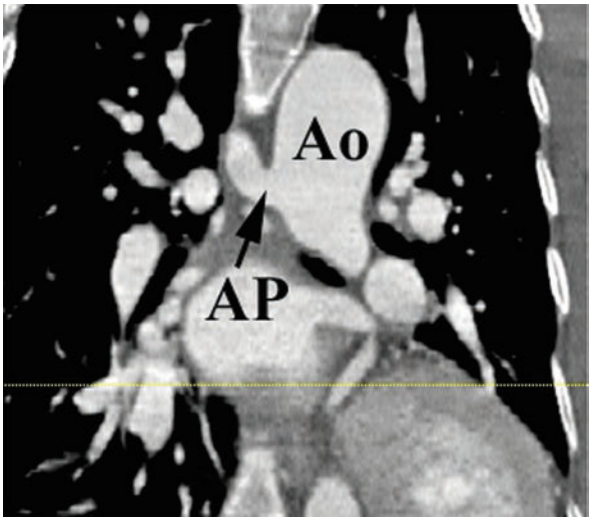


Boot-shaped heart, concave main pulmonary artery segment, and decreased pulmonary vasculature in a tetralogy of Fallot patient [Sadeghpour A, Alizadehasl A, Mahdavi M. Tetralogy of Fallot. In: Sadeghpour A, Kyavar M, Alizadehasl A, editors. Comprehensive Approach to Adult Congenital Heart Disease [Internet]. London: Springer London; 2014 [cited 2015 Sep 1]. p. 237–44. Available from: http://link.springer.com/10.1007/978-1-4471-6383-1_28] *Caption from original*



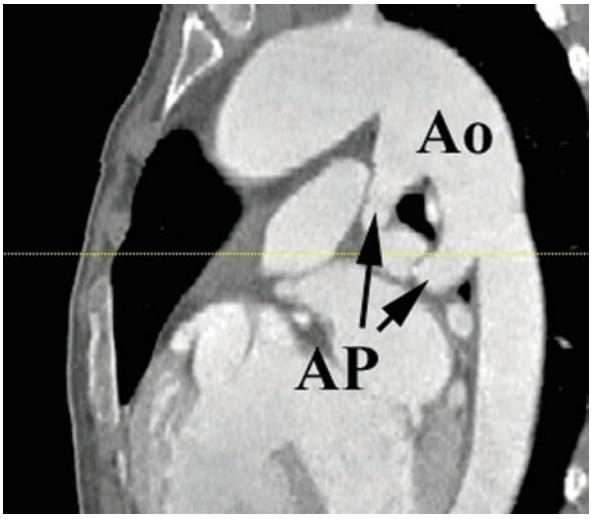
Tetralogy of Fallot. The "boot-shaped" heart is a result of upward tilting of the apex and attenuation of the main pulmonary artery segment. Note the leftward deviation of the trachea (black arrow) indicative of a right aortic arch, which is a common association. [Golding IF, Yoo S, Hamilton R. Cardiology. In: Laxer R, Ford-Jones EL, Friedman J, Gerstle T, editors. The Hospital for Sick Children: atlas of pediatrics. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-188-9] *Caption adapted from original*

- CT scanning may also be helpful.

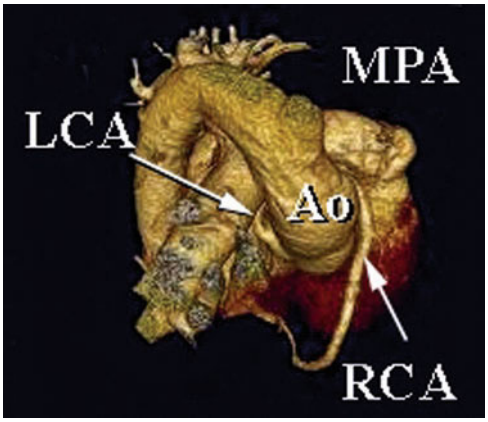


Unrepaired tetralogy of Fallot and pulmonary atresia: CT angiography. Electron beam angiogram of a cyanotic adult with unrepaired tetralogy of Fallot with pulmonary atresia and multiple aortopulmonary (AP) collaterals. A, Coronal slice

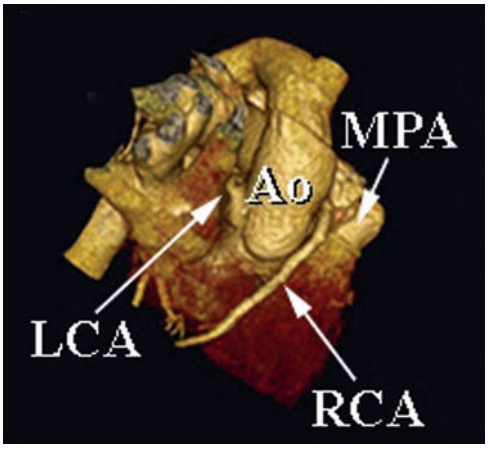
demonstrating large AP collateral emerging rightward from the descending thoracic aorta (Ao). [Aboulhosn J. Chapter 11. In: Budoff MJ, Achenbach S, Narula J, Braunwald E, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption adapted from original*



B, Sagittal slice demonstrating two AP collaterals emerging anteriorly from the descending thoracic aorta (Ao). Delineating the origin, course, and patency of these AP collaterals is challenging and time consuming but imperative to the management of these patients. Depending on anatomic findings patients may be candidates for complete surgical repair, unifocalization, or transcatheter interventions. [Aboulhosn J. Chapter 11. In: Budoff MJ, Achenbach S, Narula J, Braunwald E, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption adapted from original*



Repaired tetralogy of Fallot: CT angiography. Sixteenslice CT angiography with threedimensional volume rendering of a 21-year-old woman with repaired tetralogy of Fallot. A, Right anterior oblique and cranial projection, the right coronary artery (RCA) emerges from the anterior and left facing cusp and courses between the aortic root (Ao) and main pulmonary artery (MPA). The left coronary artery (LCA) emerges from the posterior facing cusp and courses leftward behind the Ao and below the MPA. [Aboulhosn J. Chapter 11. In: Budoff MJ, Achenbach S, Narula J, Braunwald E, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption adapted from original*



B, Right anterior oblique caudal projection. [Aboulhosn J. Chapter 11. In: Budoff MJ, Achenbach S, Narula J, Braunwald E, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption adapted from original*

Factors That Suggest Diagnosis

- A history of repeated cyanotic episodes, which may resolve spontaneously, should alert the clinician to the possibility of TOF.

Factors that Exclude Diagnosis

- The absence of cyanosis essentially rules out TOF except during periods of normal intracardiac shunting (the "pink" tet).

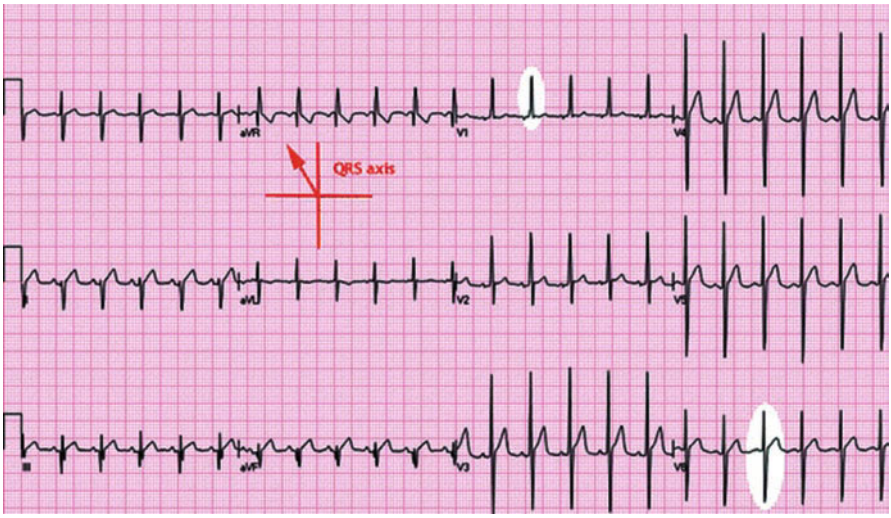
Ancillary Studies

Laboratory

- Basic laboratory tests are rarely indicated.
- As mentioned, arterial blood gas measurements will demonstrate low values for both partial pressures of oxygen and oxygen saturation.

Electrocardiography

- The ECG in TOF will show right ventricular hypertrophy. There will also be right axis deviation, along with varying degrees of R and T wave disruption.



ECG in tetralogy of Fallot. Right ventricular hypertrophy is the dominant feature of ECG in patients with tetralogy of Fallot. RVH may manifest itself in different ways such as tall R in V1 and deep S in V6, rsR′, pure R-wave or qR pattern of QRS complex in right chest leads. In this ECG, RVH is manifested as a pure R in V1, deep S in V6, and right axis deviation [Luxenberg DM, Torchen L. Tetralogy of Fallot. In: Abdulla R, editor. Heart Diseases in Children [Internet]. Boston, MA: Springer US; 2011 [cited 2015 Sep 1]. p. 167–76. Available from: http://link.springer.com/10.1007/978-1-4419-7994-0_13] *Caption from original*

Cardiac Enzymes

- Not indicated,

Special Populations

Age

- The vast majority of patients will present in the neonatal period or early infancy.

Co-morbidities

- About 15–20 % of patients with TOF will present with other syndromes, including Trisomy 21, DiGeorge Syndrome, and velocardiofacial syndrome.

Pitfalls in Diagnosis

- The majority of cyanotic congenital heart defects will present within the first few days of life and be diagnosed during the first few days of life.
- The most common clinical error made when confronted with a cyanotic infant or child is distinguishing between cardiac, pulmonary, and hemoglobin derangements.

Critical Steps Not To Miss

- Clinical paths to follow include:
  - Recognition of central cyanosis.
  - Provision of hyperoxia.
    - If no clinical response is seen, consider cardiac etiologies.
    - If there is measured improvement in oxygenation, pulmonary causes are most likely.

Mimics

- Other causes of cyanosis.

Time-Dependent Interventions

- Immediate consultation with a Pediatric Cardiologist is recommended.
  - Focus is on diagnosis, not treatment, so this is limited.

Overall Principles of Treatment

- Provision of supplemental oxygen.
- In cases of hypercyanotic spells:
  - Placement in the knee-chest position.
  - Sedation with morphine (0.1 mg/kg/dose).
  - Administration of 10–20 cc/kg of normal saline.
  - Immediate consultation with a pediatric cardiologist.

Disease Course

- Short term is excellent after neonatal surgical repair; greater than 90% survival 25 years after neonatal repair.

Chapter 70
Thoracic Aortic Dissection

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Thoracic Aortic Dissection (TAD)

- Occasionally referred to as "aortic syndrome" or "aortic disaster"

Incidence/Epidemiology

- TAD is the admitting diagnosis in 1 per 10,000 hospital admissions. Because TAD may be a rapidly fatal disease and autopsies are performed in very few deaths in the US, the true incidence remains unknown but likely is higher. A 2004 autopsy study found evidence of TAD in 1–3% of cadavers.
- TAD occurs more commonly in men than in women, roughly mirroring the prevalence of hypertension. It is more common in blacks than whites and more common in whites than in Asians.
- Peak age for TAD is 50–65 years. It may occur earlier in patients with Marfan's syndrome, in patients undergoing aortic and mitral valve replacements, in patients undergoing percutaneous coronary intervention, in patients with syphilis, and in those who abuse cocaine.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_70

- The dissection typically occurs either along the right lateral wall of the ascending aorta, where the shear stress of blood flow is highest, or in the ascending aorta just below the ligamentum arteriosum.

Differential Diagnosis

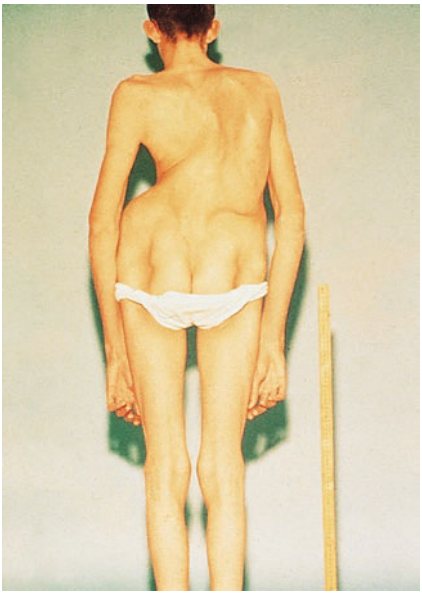
- Because the primary clinical manifestation of TAD is chest pain, the differential is broad. The other life-threatening etiologies of chest pain syndrome—acute myocardial infarction and pulmonary embolism—may present similarly, but because TAD is more often associated with back pain, the differential for this diagnosis may be broader.

Pathophysiology and Etiology

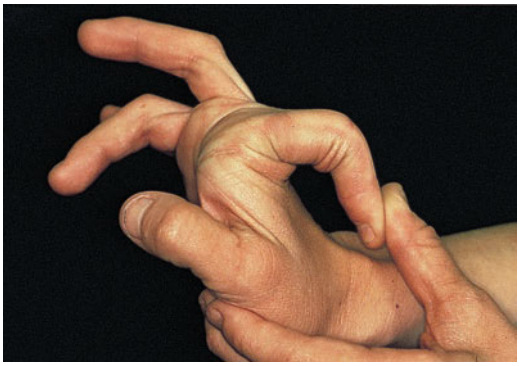
- The pathophysiology of TAD stems from the development of a split in the media of the aortic wall. The innermost layer of the aortic wall, the intima, is torn or interrupted, and blood dissects into the next layer (media) and with the aortic flow pressure behind it, may progress forward, creating a "false lumen." The outermost layer of the aortic wall, the adventitia, prevents the free flow of misdirected blood into the thoracic cavity. The split is usually a circumferential tear that leaves an "intimal flap," but also might result from an aortic ulcer.

Intimal flap seen in the aortic arc. [Niino T, Unosawa S, Shimura K. Stanford type A aortic dissection with intimal intussusception. Gen Thorac Cardiovasc Surg. 2012 Sep;60(9):578-80. https://doi.org/10.1007/s11748-012-0051-1, 2012-09-04] *Caption adapted from original*

- This tearing down the middle of the aortic wall causes pain that is characteristically (but not universally) described by the patient as "ripping." As the false lumen develops and extends, driven by the hydrostatic pressure of continued pulsatile blood flow, it may prevent blood flow through the remaining true lumen into aortic branches that perfuse vital organs, including the heart itself, brain, lung, and kidneys (see Presentation).
- Several problems may predispose the thoracic aorta to dissection. The most important, by far, is hypertension. Problems with the aortic valve (aortic stenosis, bicuspid valve) and the aorta itself (coarctation) are associated with TAD. In addition, several connective tissue diseases are known to increase the risk of TAD, including Marfan's syndrome and Ehlers-Danlos syndrome.

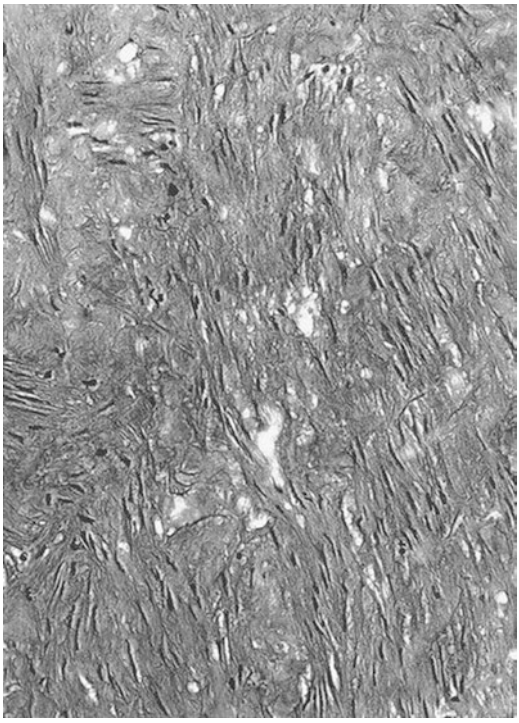


Marfan's syndrome. [Radio S, Godfrey M, Baxter T. Diseases of the aorta. In: McManus B, Braunwald E, editors. Atlas of cardiovascular pathology for the clinician. Philadelphia: Current Medicine; 2000. Chapter 17. ISBN: 1-57340-160-9; 2002-01-21]



Joint hypermobility in Ehlers-Danlos syndrome. [Maricic M, Ko M. Diseases of bone and connective tissue. In Hunder G, editor. Atlas of rheumatology. 4th ed. Philadelphia: Current Medicine; 2005. Chapter 6. ISBN: 1-57340-210-9; 2002-03-07] *Caption adapted from original*

- Hypertension, connective tissue diseases, and the aging process itself may result in cystic medial necrosis, in which degenerative changes occur in the middle layer of the aortic wall. Elastin, collagen, and smooth muscle all start to break down, potentially predisposing to the development of TAD.



Cystic medial necrosis. [Elefteriades JA. Thoracic aortic aneurysm: reading the enemy's playbook. World J Surg. 2008 Mar;32(3):366-74. https://doi.org/10.1007/s00268-007-9398-3, 2008-02-20]

- Other diagnoses associated with TAD are:
  - Congenital
    - Polycystic kidney disease

- Trauma:
    - Sudden deceleration injury
- Toxicologic:
    - Cocaine use
- Iatrogenic:
    - Catheter- or surgery-related aortic injury, especially near the aortic valve

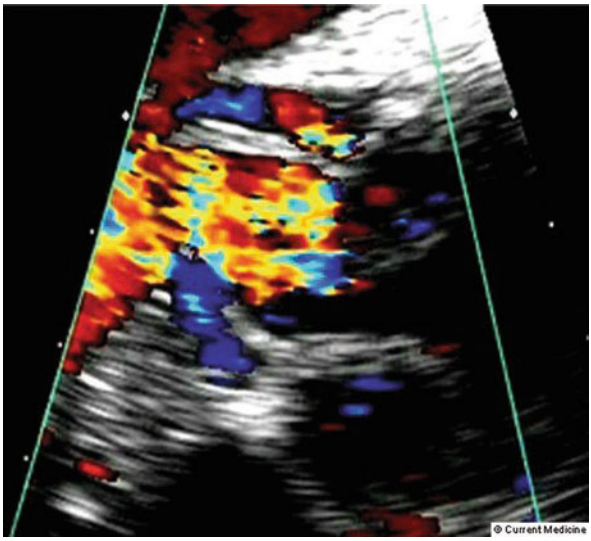
Presentation

Typical/"Classic"

- Chest pain that is often described as "ripping" or "tearing" in nature is the classic presenting symptom in TAD. Less classically, but probably more commonly, the pain is described simply as "sharp." This pain may be felt in the front and/or back of the chest; when the latter, it is classically localized between the scapulae. The pain is usually noted to move with the extension of the dissection. Patients can often identify the exact time the pain started. Other symptoms may result from occlusion of branch arteries and compression of adjacent tissues and therefore are variable. Patients are usually

hypertensive at presentation, although shock may also occur. Related signs and symptoms include:

- Syncope or stroke, when the dissection occludes the carotid arteries
  - Hemiplegia or hemianesthesia may result if just one carotid root is obstructed
- Dyspnea and a clinical picture of heart failure, when the dissection disrupts the aortic root, preventing valve closure and resulting in acute aortic regurgitation

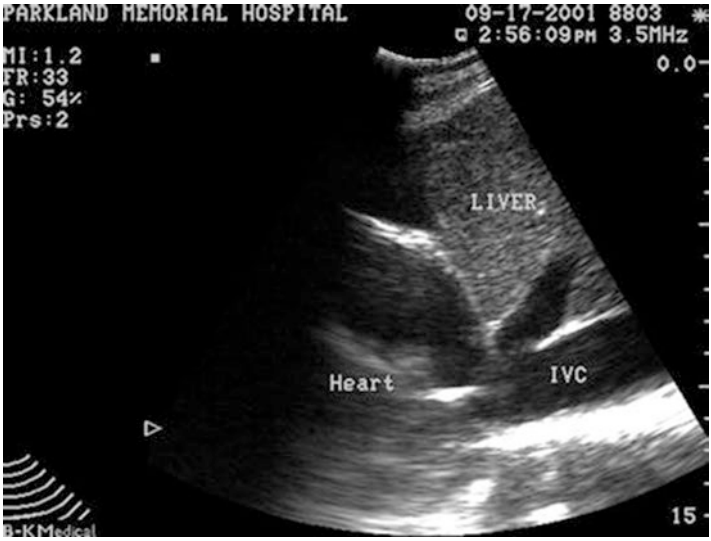


Severe aortic regurgitation from Stanford type A dissection. [Michelena H, Mankad S, Enriquez-Sarano M. Echocardiography in valvular heart disease: aortic valve disease. In: Solomon SD, Braunwald E, editors. Atlas of echocardiography. 2nd ed. Philadelphia: Current Medicine; 2008. Chapter 9. ISBN: 1-57340-217-6, 2008-10-22] *Caption from original*

- Classic signs of aortic regurgitation include a wide pulse pressure, bounding pulses, and a diastolic murmur heard best over the right sternal border.

http://www.easyauscultation.com/cases?coursecaseorder=1&courseid=27
Diastolic murmur. [Aortic Regurgitation – Mild; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- Hypotension, when the dissection spills false lumen blood into the pericardial sac, resulting in pericardial effusion and tamponade



Ultrasound of acute pericardial effusion causing cardiac tamponade. [Tchorz KM. Ultrasound-guided drainage procedures for the intensivist. In: Frankel HL, deBoisblanc BP, editors. Bedside procedures for the intensivist. New York: Springer; 2010. p. 113-37. Book https://doi.org/10.1007/978-0-387-79830-1; Chapter: 6; Chapter https://doi.org/10.1007/978-0-387-79830-1_6, 2010-01-01] *Caption adapted from original*

- Check for jugular venous distension and muffled heart sounds.

- Abdominal pain, from obstruction of mesenteric arteries
- Paraplegia, from obstruction of aortic branches perfusing the spinal cord (such as the great artery of Adamkiewicz)
- Hoarseness, difficulty swallowing, or dyspnea (perhaps with stridor) from pressure on the larynx, trachea, and esophagus caused by the expanding aortic hematoma

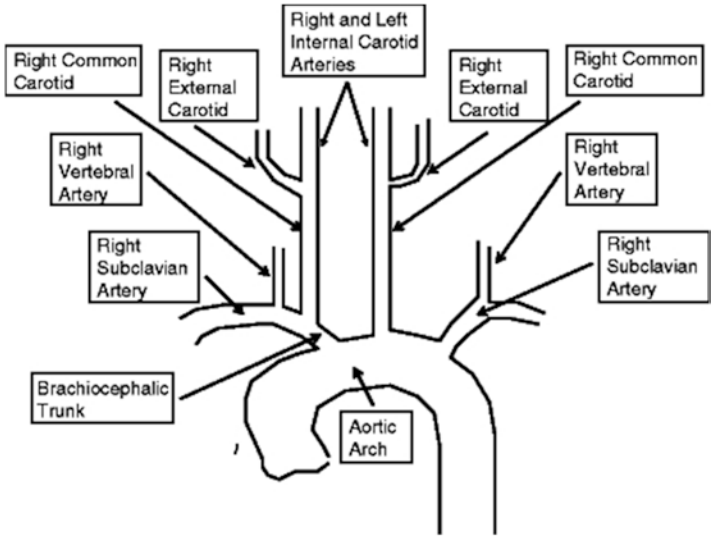
http://www.easyauscultation.com/cases.aspx?coursecaseorder=13&courseid=202
Stridor. [Stridor; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- Horner's syndrome, from compression of the superior cervical ganglia caused by the expanding aortic hematoma

Left ptosis and miosis of Horner's syndrome. [Mutalib M, Vandervelde C, Varghese A, Sallomi DF, Silva P, Hickman CJM, Howlett DC. Horner's syndrome secondary to asymptomatic pneumothorax in an adolescent. Eur J Pediatr. 2007 May;166(5):507–8. https://doi.org/10.1007/s00431-006-0271-4, 2007-03-19] *Caption adapted from original*

- Horner's syndrome manifests as ipsilateral ptosis, miosis, and anhydrosis.

- Physical findings in TAD are highly variable because the location of the dissection and the direction (antegrade or retrograde) in which it extends will determine side branch involvement. If the dissection involves the aortic arch, there may be a difference in the blood pressure measured in each arm. A difference of 20 mm Hg is significant and suggestive of the diagnosis in the right clinical setting.



Anatomy of the aortic arch. [Pelberg RA, Mazur W. Vascular CT angiography manual. London: Springer; 2011. Chapter 5, Carotid and upper extremity CT

angiography; p. 47-90. Book https://doi.org/10.1007/978-1-84996-260-5; Chapter https://doi.org/10.1007/978-1-84996-260-5_5, 2010-01-01]

Atypical

- The most vexing atypical presentation of TAD is a painless presentation. This may occur in elderly people who present with syncope or stroke only. In other cases, the TAD symptoms may simply be overwhelmed by other symptoms or findings, such as stroke, shock, or myocardial infarction (if the dissection extends to the ostium of a coronary artery and causes ST-segment elevation).

Primary Differential Considerations

- Primary differential considerations include pain mimics to TAD and other significant diagnoses (such as stroke) that distract the examiner. The most concerning pain mimics that may share other symptoms associated with TAD include myocardial infarction, pulmonary embolus, aortic aneurysm, and aortic regurgitation without dissection.

History and Physical Exam

Findings That Confirm Diagnosis

- Because there are so many mimics and related multisystem complications of TAD, the diagnosis cannot be confirmed without a definitive imaging study of the thoracic aorta.

Factors That Suggest Diagnosis

- Immediate onset of sharp, ripping, or tearing pain in the presence of ST-segment elevation, syncope, stroke, dyspnea, or weakness should raise suspicion for TAD and prompt consideration of an emergent diagnostic imaging study.
- Suggestive pain with a known diagnosis (or suggestive physiognomy) of Marfan's syndrome, Ehlers-Danlos syndrome, or syphilis should raise suspicion for TAD and prompt consideration of an emergent diagnostic imaging study.

- Suggestive pain and a difference in blood pressure readings between the two arms or between the arms and the legs should raise suspicion for TAD and prompt consideration of an urgent or emergent diagnostic imaging study.
- Any of the related symptoms or findings above *in the absence of suggestive pain in elderly patients with a history of hypertension* should raise suspicion for TAD and prompt consideration of an urgent or emergent diagnostic imaging study.

Factors That Exclude Diagnosis

- A normal imaging study (via CT scan, MRI, or transesophageal echocardiogram) of the thoracic aorta excludes the diagnosis of TAD.

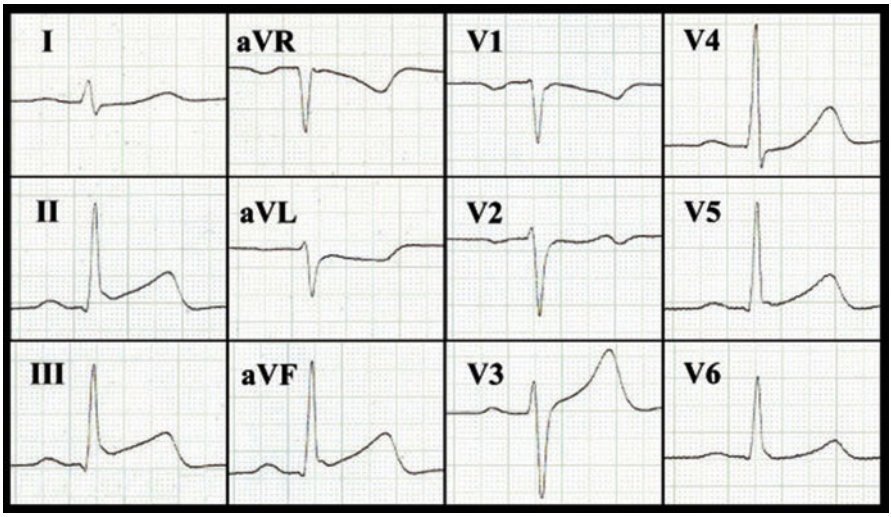
Ancillary Studies

Laboratory

- Lab tests should include CBC; serum electrolyte, blood urea nitrogen (BUN), and creatinine levels; and coagulation studies. Generally, cardiac biomarker measurements are indicated because of the differential consideration of ACS and the possibility of a retrograde dissection that occludes a coronary artery and causes myocardial ischemia.
- If TAD is the presumed or confirmed diagnosis and surgical intervention is anticipated, a type and cross-match specimen should be sent.

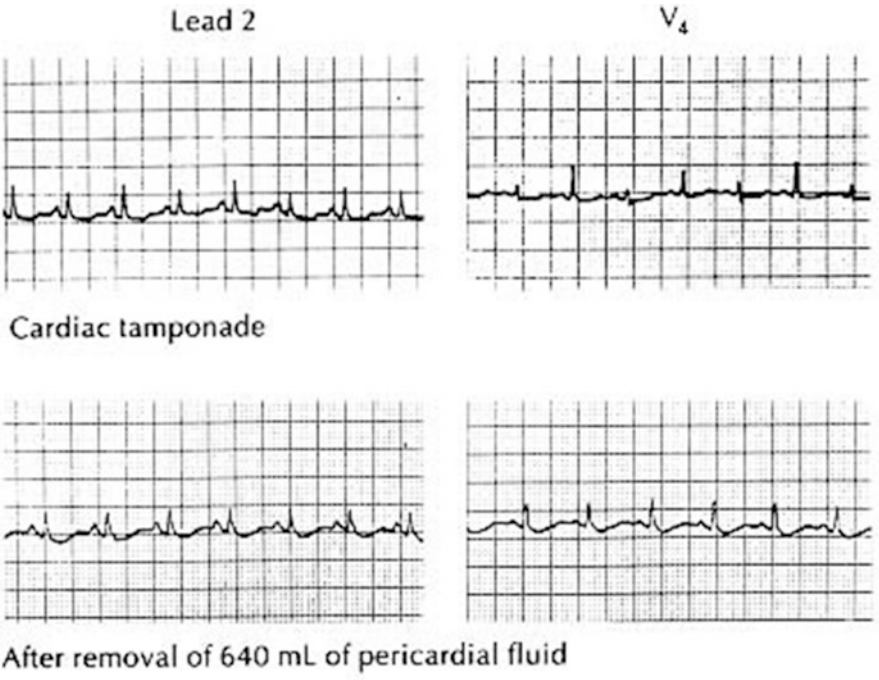
Electrocardiography

- The ECG in most patients with TAD either is normal or shows only nonspecific ST-T changes. Because many patients with TAD have a longstanding history of hypertension, the ECG may show evidence of left ventricular hypertrophy with strain.
- A small minority of patients with TAD will have evidence of STEMI (usually inferior) due to occlusion of the right coronary artery as a complication of TAD.



Twelve-lead ECG demonstrating inferiorly located STEMI with ST-segment elevation in the inferior leads (II, III, aVF) and ST-segment depression in leads I and aVL. [From article: Cardiovascular magnetic resonance of myocardial infarction after blunt chest trauma: a heartbreaking soccer-shot. J Cardiovasc Magn Reson. 2009 Oct;11(1):39. https://doi.org/10.1186/1532-429X-11-39, at http://link.springer.com/article/10.1186/1532-429X-11-39/fulltext.html; by Hannibal Baccouche, Torsten Beck, Martin Maunz, Peter Fogarassy, Martin Beyer, © Baccouche et al; licensee BioMed Central Ltd. 2009; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption adapted from original*

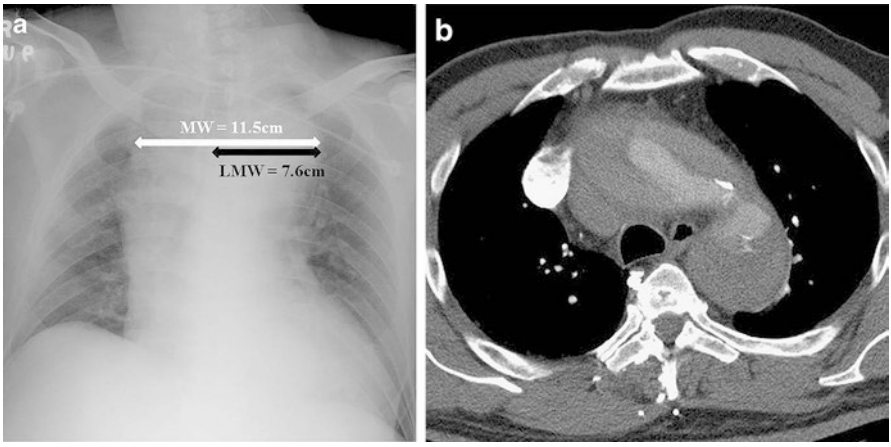
- An even smaller cohort will have ECG changes suggesting pericardial tamponade, such as low voltage or electrical alternans.



Electrical alternans of the QRS complex in a patient with cardiac tamponade. [Fowler N, Abelmann W. Chapter 13. In: Lee RT, Braunwald E, editors. Atlas of cardiac imaging. Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption from original*

Imaging

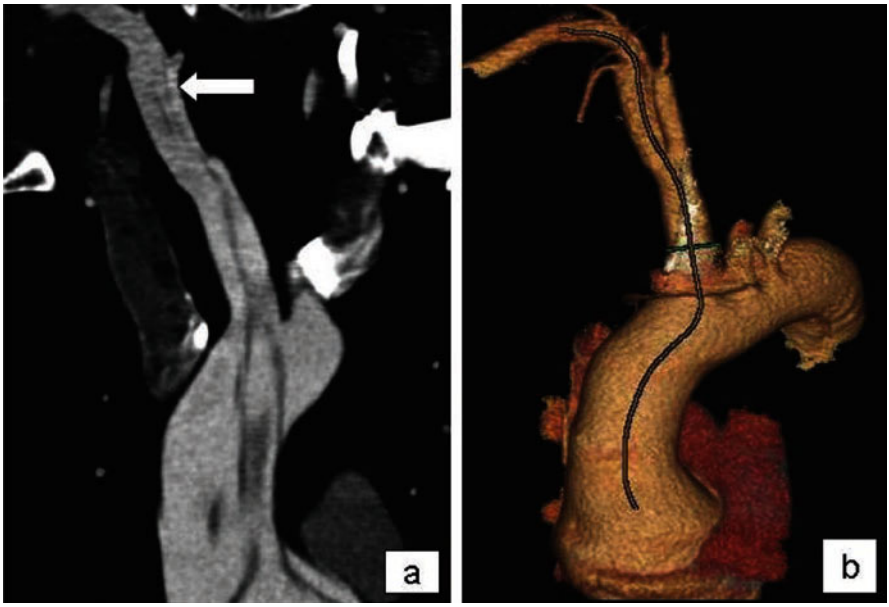
- Imaging studies are used definitively to confirm or refute the diagnosis of TAD.
- The plain chest radiograph (CXR) may suggest TAD but cannot be used to confirm or refute the diagnosis.
    - The most important finding on CXR is a widened mediastinum, which is seen in more than half the patients with TAD. Often these films are recorded with patients in the supine position because of their clinical status; this makes the mediastinum appear wider than on an erect film even in the absence of TAD.



Acute type A aortic dissection in a 46-year-old man. A) AP chest radiograph showing marked widening of the mediastinum with MW and LMW measuring 11.5 and 7.6 cm, respectively. B) Corresponding selected image of CT aortogram confirms type A aortic dissection. [From article: Diagnostic accuracy of mediastinal width measurement on posteroanterior and anteroposterior chest radiographs in the depiction of acute nontraumatic thoracic aortic dissection. Emerg Radiol. 2012 Aug;19(4):309–15. https://doi.org/10.1007/s10140-012-1034-3, at http://link.springer.com/article/10.1007/s10140-012-1034-3/fulltext.html; by Vincent Lai, Wai Kan Tsang, Wan Chi Chan, Tsz Wai Yeung, © The Author(s) 2012; licensed under Creative Commons Attribution License http://creativecommons.org/licenses/by/2.0] *Caption from original*

  - Other findings suggestive of TAD that may appear on CXR include pleural effusion, inward displacement of aortic intimal calcifications, and a double aortic shadow.
  - The CXR is normal in more than 10% of cases of TAD.

- The choice of which definitive imaging study to use in suspected TAD is based on both the efficiency/availability of the test and the clinical stability of the patient. In the past, the diagnosis was made by invasive imaging (aortography). Less invasive modalities (CT, MRI, TEE) are more commonly used today. Of these, CT is the quickest and for the hemodynamically unstable or tenuous patient, is probably the safest approach. It does require iodinated contrast. CT has the additional benefit of potentially identifying another etiology of the patient's pain (such as pulmonary embolism). All three of these modalities allow classification of the TAD (Stanford or DeBakey models; See Overall Principles of Treatment), which directs the choice of medical vs surgical treatment.



A, Contrast-enhanced CT scan showing the intimal flap due to dissection from the aortic root to the ascending aorta, innominate artery and subclavian artery. Special Populations

Age

- TAD most commonly occurs between 50 and 65 years of age. Older patients may have less perception of the pain and more often present with stroke or syncope.
- Within the pediatric population, TAD is associated with Marfan syndrome, Turner syndrome, Ehler-Danlos syndrome, and homocystinuria.

Co-morbidities

- The most important comorbidities in TAD are hypertension and connective tissue disease.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Attributing chest pain to another, potentially less serious etiology may result in loss of valuable treatment time for TAD.
- Focusing on the sequelae of TAD—such as syncope, stroke, weakness, or dyspnea—without considering TAD as the source, may result in loss of valuable treatment time for TAD and further complications from ongoing extension of the false lumen.

Mimics

- The entire constellation of diagnoses that underlies chest pain syndrome can mimic the pain and overall presentation of TAD.

Time-Dependent Interventions

- Control of blood pressure and heart rate (the "pulse-pressure product" that creates shear stress on the aortic wall and may extend the dissection) is critical in stabilizing patients with TAD. Both alpha- and beta-adrenergic blockade is required, as reducing blood pressure alone with a potent agent such as nitroprusside will result in a reflex tachycardia that may be just as harmful as continued hypertension in promoting extension of the dissection.
- Adequate pain control (with attention to iatrogenic hypotension) is also important for reducing shear stress.

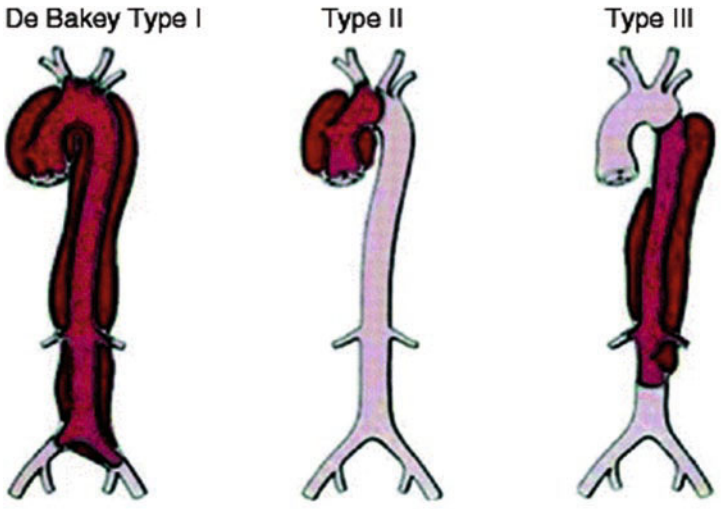
Overall Principles of Treatment

- Stabilization of the patient with control of blood pressure, pulse rate, and pain is critical. The patient may require resuscitation, intubation, and intensive support.
- Definitive treatment approaches for TAD are driven by the anatomic location of the dissection. There are two classification systems for TAD: DeBakey and Stanford. The Stanford system is simpler and more widely used: type A involves the ascending aorta, and type B does not involve the ascending aorta. In the DeBakey classification, there is involvement of the ascending aorta in types I and II but not in type III. Surgical management ordinarily is

indicated for type A (DeBakey I and II) lesions, whereas type B (DeBakey III) dissections may be managed medically or with (percutaneous) endovascular repair.

Steps in the Early Medical Management of a Patient Presenting With Suspected Acute Aortic Dissection
1. Immediate monitoring and stabilization of vital signs
2. Quick assessment: directed history, physical examination, chest radiograph, ECG, lab work
3. Reduce dP/dT with intravenous β-blockers: propranolol, labetalol, metoprolol, or esmolol
4. Treat hypertension to reduce dP/dT: intravenous nitroprusside (use in the presence of a β-blocker, because alone it may increase dP/dT); goal is to reduce systolic blood pressure to 100–120 mm Hg or the lowest level possible while still maintaining cerebral and vital organ perfusion
5. If β-blockers are absolutely contraindicated, consider using intravenous calcium channel blockers or enalaprilat
6. Pain control with morphine as needed
7. Select and proceed promptly to a diagnostic study
8. Decide on medical vs surgical therapy (and determine surgical candidacy as well)

Steps in the early medical management of a patient presenting with suspected aortic dissection. [Creager M. Vascular disease. In Libby P, editor. Essential atlas of cardiovascular disease. Philadelphia: Current Medicine; 2009. Chapter 4. ISBN: 978-1-57340-309-2, 2009-05-21] *Caption adapted from original*



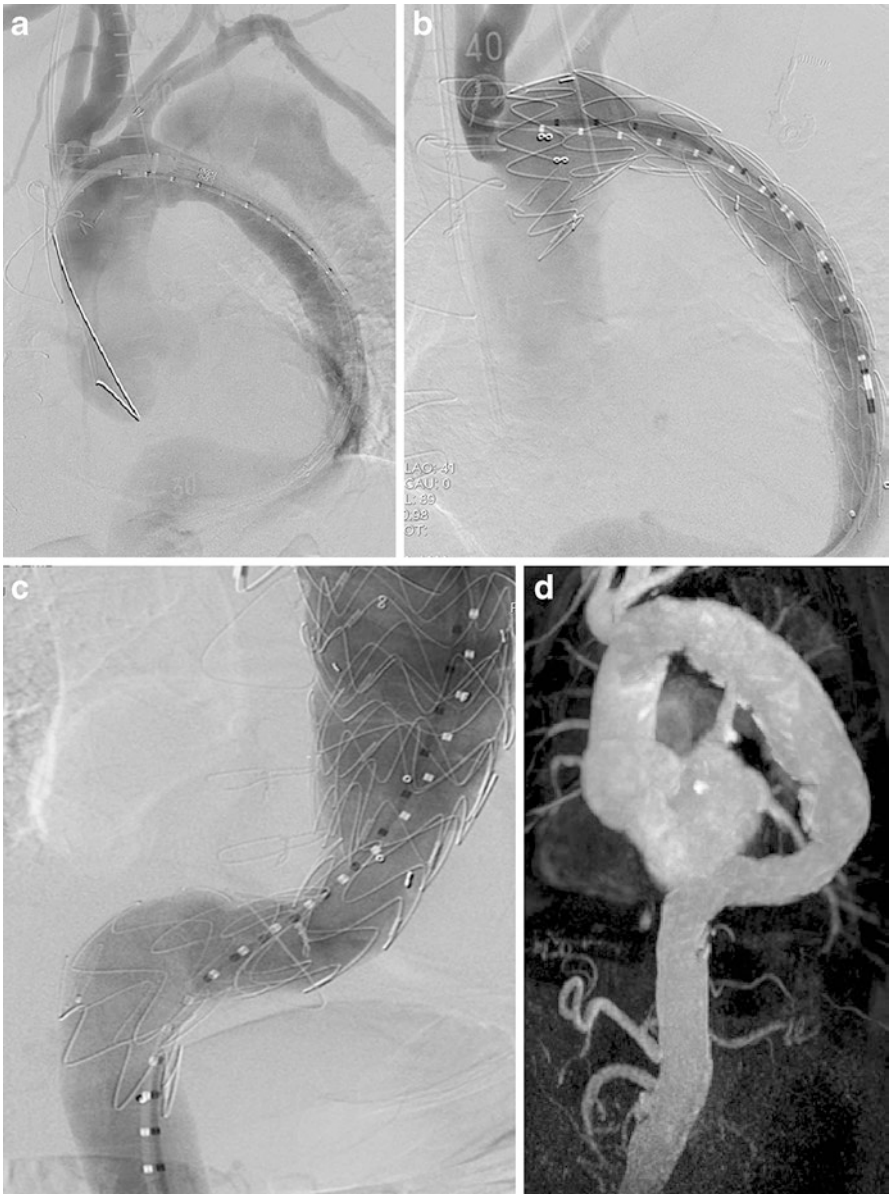
Acuity:	
Acute	<2 weeks after onset
Subacute:	2–8 weeks after onset
Chronic:	>8 weeks after onset

Anatomic location:	
Ascending aorta:	Stanford Type A, DeBakey Type II
Ascending and descending aorta:	Stanford Type A, DeBakey Type I
Descending aorta:	Stanford Type B, DeBakey Type III

Pathophysiology:

Class 1: Classical aortic dissection with initimal flap between true and false lumen
Class 2: Aortic intramural he matoma without identifiable intimal flap
Class 3: Intimal tear without hematoma (limited dissection)
Class 4: Atherosclerothic plaque rupture with aortic penetrating ulcer
Class 5: Iatrogenic or traumatic aortic dissection
(intra-aortic catherterization, high-speed deceleration injury, blunt chest trauma)

Classification of thoracic aortic dissection. [Akin I, Rehders TC, Kische S, Ince H, Nienaber CA. Endovascular treatment of thoracic aorta. In: Lanzer P, editor. Catheter-based cardiovascular interventions. Berlin Heidelberg: Springer; 2013. p. 957-70. Book https://doi.org/10.1007/978-3-642-27676-7; Chapter https://doi.org/10.1007/978-3-642-27676-7_59, 2013-01-01] *Caption from original*



Thoracic endovascular aortic repair (TEVAR) of a type B aortic dissection extending from the arch to the abdominal aorta. (D) MRA at 1 year from the implantation: the true lumen is well expanded at the proximal and middle descending aorta,

while a smaller diameter is observed at the distal part of the vessel. [Midulla M, Moreno R, Baali A, Chau M, Negre-Salvayre A, Nicoud F, Pruvo JP, Haulon S, Rousseau H. Haemodynamic imaging of thoracic stent-grafts by computational fluid dynamics (CFD): presentation of a patient-specific method combining magnetic resonance imaging and numerical simulations. Eur Radiol. 2012 Oct;22(10):2094–102. https://doi.org/10.1007/s00330-012-2465-7, 2012-08-30] *Caption adapted from original*

Disease Course

- TAD carries a high mortality rate. Type A dissections have a 30% mortality even with surgical treatment, and twice that with medical treatment. Thrombotic complications of dissection carry their own risks of morbidity and mortality.

Chapter 71
Total Anomalous Pulmonary Venous Connection

Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Total anomalous pulmonary venous connection (TAPVC) is also commonly referred to as Total Anomalous Pulmonary Venous Return (TAPVR).

The basic anomaly involves a failure of all four pulmonary arteries to normally connect to the left atrium.

Electronic supplementary material The online version of this chapter (https://doi.org/10.1007/978-3-319-63895-9_71) contains supplementary material, which is available to authorized users.

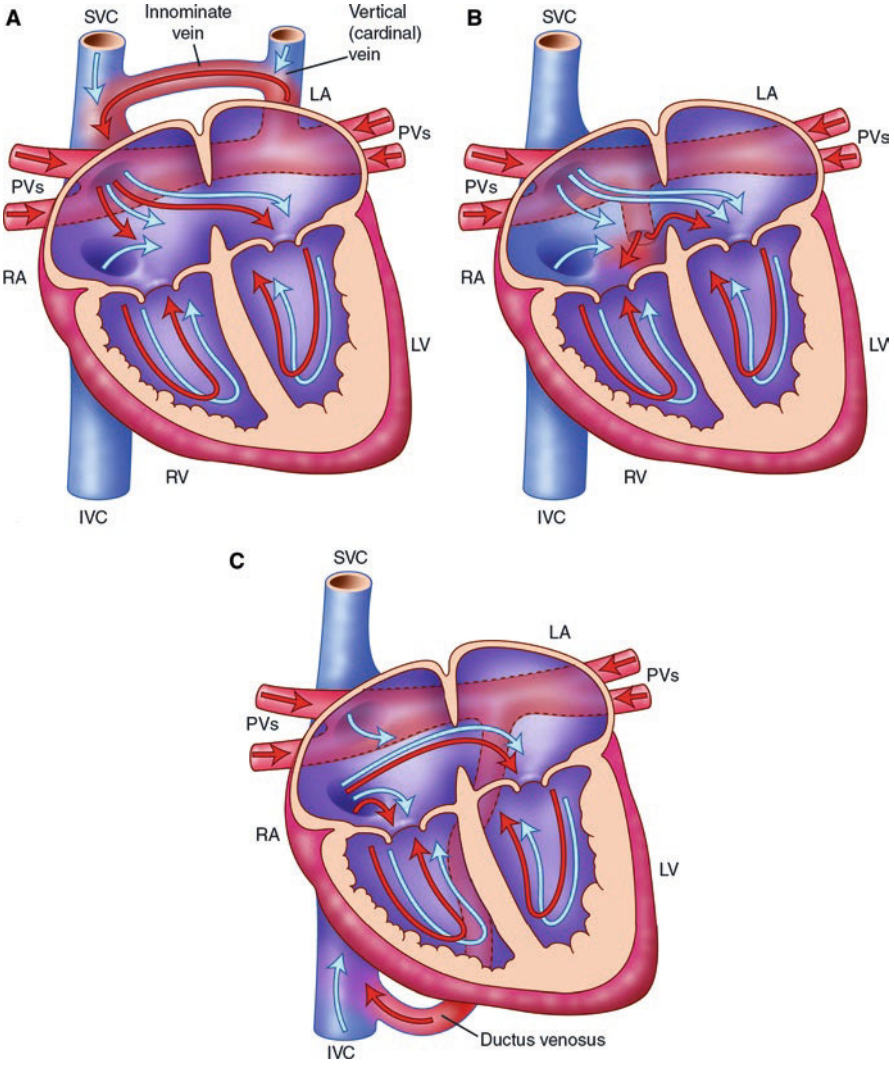

Graphic representation of total anomalous pulmonary venous return. Panel a, supracardiac drainage. In this lesion the path of pulmonary venous drainage is from a vertical vein to the innominate vein into the right atrium (RA). In most defects an associated atrial septal defect is present. Panel b, cardiac drainage. In this pathology, the pulmonary veins (PVs) typically empty into the coronary sinus, draining into the RA. Panel c, infracardiac drainage. In this setting, PVs drain through the ductus venosus to the RA. Frequently this anomaly is associated with pulmonary venous obstruction. IVC inferior vena cava, LA left atrium, LV left ventricle, RV right ventricle, SVC superior vena cava [Miller-Hance WC, Gottlieb EA, Motta P. Anesthesia for Cardiac Surgery in Neonates. Incidence/Epidemiology

- Within the population of infants with congenital heart disease, TAPVR accounts for approximately 1 percent of newborns.
- It is the fifth-most common cause of cyanotic heart disease.

Differential Diagnosis

- Should be considered in the differential diagnosis of cyanotic congenital heart disease, often represented by the "5 T's":
  - Truncus Arteriosus
  - Transposition of the Great Arteries
  - Tricuspid Atresia
  - Tetralogy of Fallot
  - Total Anomalous Pulmonary Venous Return

Pathophysiology and Etiology

- There are four variants of this defect:
  - Supracardiac (nearly 50 %): All blood returns form the pulmonary bed to the right atrium.

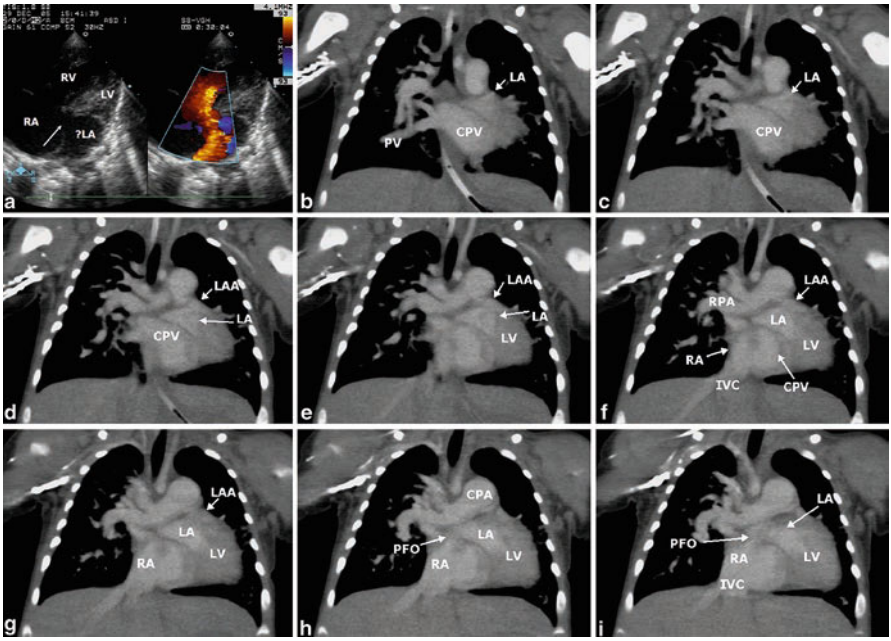
(**a**) Total anomalous pulmonary venous drainage, supracardiac type. Front view of the heart shows RA and RV cut open. At the root of the great vessels, the pulmonary vein is connected to anonymous veins and then to the SVC in front of the ascending aorta. The green probe is placed in the SVC. PI vein means that blood from the pulmonary vein flows through the anonymous vein. Ao aorta, RA right atrium, RV right ventricle, PA pulmonary artery, L lung left lung, R lung right lung. (**b**) View from the left to observe the pulmonary vein. PI vein: The pulmonary vein common trunk is connected to the anonymous vein in front of the aorta. This is the normal great artery relationship. The RV has a coarse moderator band. MB moderate band, PV pulmonary valve, RV right ventricle, AO ascending aorta. (**c**) View from right atrium and right ventricle. The arrow indicates the foramen ovale, RA right atrium, RV right ventricle. (**d**) View from left ventricle outlet tract. The left heart is normal. Red probe is in the aorta (Ao). The pulmonary vein (PI vein) originates from the left and right lungs, then passes by the aorta and returns to the SVC. LV left ventricle, MV mitral valve, PA main pulmonary vein, AV aortic valve. (**e**) Dorsal view of the heart and lung. The left and right pulmonary veins converge, then go forward and return to the SVC. The red arrow indicates the pulmonary artery blood flow. (**f**) Schematic diagram (dorsal view). PI vein means that blood from the pulmonary vein flows through the anonymous vein. LA left atrium, LV left ventricle, AO ascending aorta, SVC superior vena cava and PI vein[Zhu X. Anomalous Pulmonary Venous Drainage. In: Zhu X, editor. Surgical Atlas of Cardiac Anatomy [Internet]. Dordrecht: Springer Netherlands; 2015 [cited 2015 Aug 31]. p. 215–24. Available from: http://link.springer.com/10.1007/978-94-017-9409-1_14] *Caption from original*

- Cardiac (20 %): Pulmonary venous return connects to the coronary sinus.



A 26-day-old boy with cardiac type total anomalous pulmonary venous return (TAPVR) who presented to our hospital for evaluation of progressive dyspnoea. aEchocardiography shows a large septal defect (long arrow) between the right atrium and suspected left atrium. The initial impression was a primum-type atrial septal defect. The paediatric cardiologist also noted the unusually early heart failure and dilated right atrium and right ventricle. MDCT was undertaken for further evaluation. b–i Sequential coronal MIP images from posterior to anterior clearly demonstrate cardiac type TAPVR. The pulmonary veins drain into a large common pulmonary vein and then into the right atrium. The common pulmonary vein and left atrium are separated by a septum. The patent foramen ovale, which is necessary for survival, is also visualized (h, i). After discussion, the paediatric cardiologist believed the misdiagnosis was probably related to the limited spatial resolution of echocardiography. Even on retrospective review, the anatomical detail shown by echocardiography was not as clear as identified on MDCT (?LAechocardiography-proposed LA, but is actually a common pulmonary vein; CPA central pulmonary artery; CPV common pulmonary vein; IVC inferior vena cava; LA left atrium;LAA left atrial appendage; LV left ventricle; PFO patent foramen ovale; PV pulmonary vein; RA right atrium; RPA right pulmonary artery; RV right ventricle) [Lee T, Tsai I-C, Fu Y-C, Jan S-L, Wang C-C, Chang Y, Chen M-C. Using multidetector-row CT in neonates with complex congenital heart disease to replace diagnostic cardiac catheterization for anatomical investigation: initial experiences in technical and clinical feasibility. Pediatric Radiology. 2006 Nov 10;36(12):1273–82.] *Caption adapted from original*

- Infracardiac (30 %): Pulmonary blood return connects to parts of the portal system.
- Mixed (10 %): Return at multilevels.

- Regardless of the anatomic derangement, there is admixing of oxygenated blood with deoxygenated blood, resulting in varying degrees of cyanosis.
- Eventually, right-sided cardiac enlargement will develop in response to volume overload on a chronic basis.

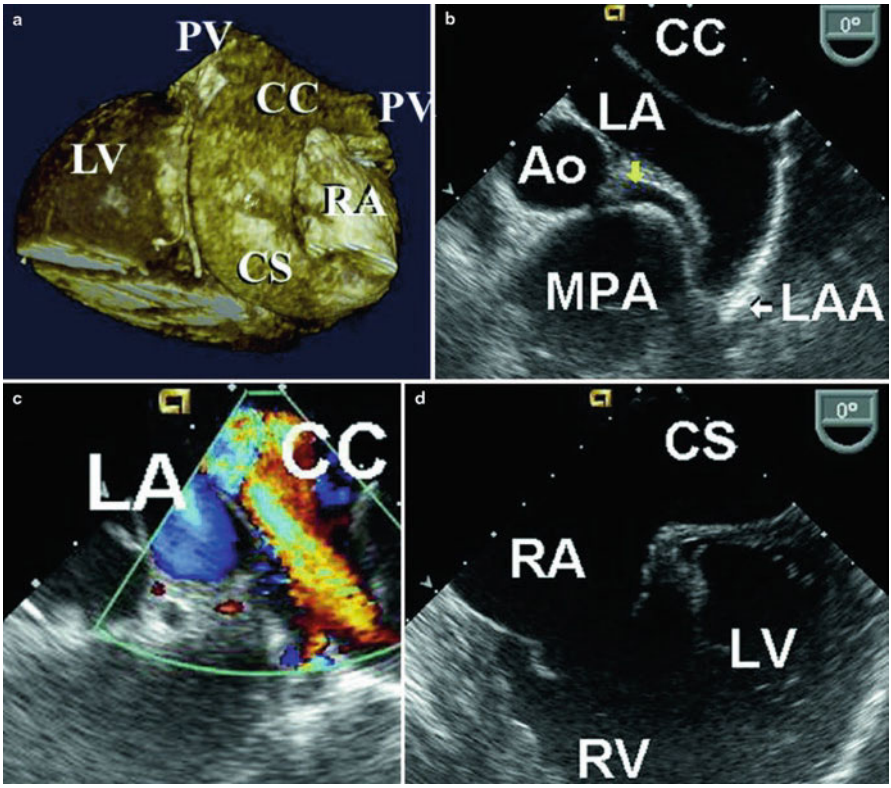
Presentation

Typical/"Classic"

- Presentations vary, depending on the degree of pulmonary venous obstruction.
- Severely obstructed infants present in the early hours after birth, with cyanosis and poor perfusion. Many of these newborns are difficult to diagnose, since premature lung disease is often considered at first.
- In infants with no or mild obstruction, presentations mimic clinical situations encountered in any patient with large volume left-to-right shunts (such as a VSD or ASD). Findings may include poor weight gain, tachycardia, and tachypnea. Oxygen saturations vary, from normal to slightly diminished.

Atypical

- As mentioned, mild cases may not present for months, until right-sided volume overload dominates.
- Older patients may present with TAPVR.



(a) Three-dimensional reconstruction of ECG gated CT angiogram in a 27-year-old cyanotic patient with uncorrected total anomalous pulmonary venous return. Two pulmonary veins (PV) connect to a posterior confluence chamber (CC) that courses inferiorly behind the left atrium (LA) into a dilated coronary sinus (CS) that in turn connects to the right atrium (RA). (b) TEE in the same patient, in the mid esophageal aortic valve short axis view with leftward probe position. Note the posterior CC closely apposing but not connected to the LA. The left main coronary artery (yellow arrow) is seen emerging from the aortic root (Ao) and coursing anterior to the left atrial appendage (LAA) and posterior to a dilated main pulmonary artery (MPA). (c) Color flow Doppler imaging demonstrating low velocity flow towards the transducer from the left sided pulmonary veins to the CC. Note the absence of flow between the CC and LA. (d) Mid esophageal four chamber view with the transducer in a more inferior position at the level of entry of the dilated CS into an enlarged RA. The right ventricle (RV) is also dilated, in comparison to the left ventricle (LV) [Aboulhosn JA, Child JS. Transesophageal Echocardiography in Adults with Congenital Heart Disease. In: Wong PC, Miller-Hance WC, editors. Transesophageal Echocardiography for Congenital Heart Disease [Internet]. London: Springer London; 2014 [cited 2015 Aug 31]. p. 455–73. Available from: http://link.springer.com/10.1007/978-1-84800-064-3_18] *Caption from original*

Primary Differential Considerations

- The other components of the 5 T's (see above) are the most important differential diagnoses to consider.

History and Physical Exam

- Assuming an uneventful neonatal course (i.e., no serious obstruction), these infants will demonstrate the signs and symptoms of progressive heart failure, including, but not limited to, poor weight gain, diaphoresis while feeding, and signs of respiratory distress.
- Heart sounds vary widely. Hepatomegaly will eventually develop.

Findings That Confirm Diagnosis

- Echocardiography remains the gold standard.

The video represents a representative sweep in an infant with total anomalous pulmonary venous connection to the left innominate vein. The exam is initiated at the midesophageal four chamber view. From this window, modified views at the level of the mid esophagus display the right upper and lower pulmonary veins (RUPV, RLPV) and left pulmonary veins (LPVs) are seen returning to a large horizontal confluence. A large vertical vein (VV) arises from the left side of the confluence and travels anteriorly and superiorly, coursing over the left pulmonary artery (LPA) to insert into the left innominate vein (Inn V). The length of the vertical vein is best seen in a sagittal plane, with the midesophageal ascending aortic and upper esophageal aortic arch short axis views, and leftward rotation of the probe. There is no obstruction at any point to pulmonary venous return. A catheter placed in the left internal jugular vein is seen in the vertical vein by two-dimensional imaging. On this video, prominent electrocautery and Doppler mirror image artifacts are seen (MPG 38454 kb) [Tacy TA. Systemic and Pulmonary Venous Anomalies. In: Wong PC, Miller-Hance WC, editors. Transesophageal Echocardiography for Congenital Heart Disease [Internet]. London: Springer London; 2014 [cited 2015 Aug 31]. p. 145–69. Available from: http://link.springer.com/10.1007/978-1-84800-064-3_6] *Caption from original*

- TAPVR should be considered in any infant who presents with cyanosis associated with pulmonary over-circulation.

Factors That Suggest Diagnosis

- TAPVR remains a difficult diagnosis.
- Since eventual echocardiography is often considered in the workup of neonatal cyanosis or CHF, the diagnosis will reveal itself.

Factors That Exclude Diagnosis

- A normal echocardiogram rules out TAPVR diagnosis.

Ancillary Studies

Laboratory

- Laboratory results will demonstrate hypoxia, acidosis, and hypercarbia in severe cases (nonspecific findings).

Electrocardiography

- ECG findings, unfortunately, are nonspecific and cannot be utilized in making the diagnosis of TAPVR.

Cardiac Enzymes

- Not indicated.

Special Populations

Age

- As discussed, most cases are diagnosed in the first few days of life.

Co-morbidities

- TAPVR is associated with asplenia or polysplenia.

Pitfalls in Diagnosis

- Cyanotic variant:
  - Pediatric cardiology consultation is emergently warranted.
- Acyanotic variety:
  - Adherence to strict algorhythmic workups of neonatal CHF or respiratory distress will eventually uncover the lesion.

Critical Steps Not to Miss

- Provision of supplemental oxygen
- Early ventilator support
- Immediate PICU or Pediatric Cardiology consultation

Mimics

- Any congenital cardiac lesion causing cyanosis and/or CHF.

Time-Dependent Interventions

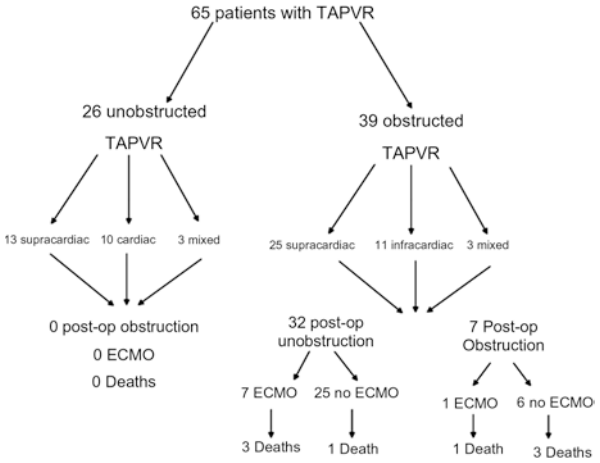
- All interventions are emergent.

Overall Principles of Treatment

- Surgical repair of TAPVR is required; catheter-based treatments have not been shown to be effective. The timing of surgery varies by case.

Disease Course

- Surgical correction is almost always indicated – the earlier the better.



Surgical outcome. The flow chart summarizes the outcome of the cohort presenting for surgical repair of total anomalous pulmonary venous return (TAPVR) at Children's Hospital of Wisconsin from 1991 to 2007 [Frommelt PC, Sheridan DC, Deatsman S, Yan K, Simpson P, Frommelt MA, Litwin SB, Tweddell JS. Unobstructive Total Anomalous Pulmonary Venous Return: Impact of Early Elective Repair on the Need for Prolonged Mechanical Ventilatory Support. Pediatric Cardiology. 2010 Nov;31(8):1191–7.] *Caption from original*

- Long-term outcomes are dramatically improved after full correction (less than 5 %).

Chapter 72
Tracheal Tumors

Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Tracheal Tumors

Incidence/Epidemiology

- Tracheal tumors are very rare. They account for only 2 % of all tumors of the respiratory tract.
- Tracheal tumors account for less than one-half of one percent of all malignant tumors.
- Tumors found in the tracheae are more commonly seen from direct extension of primary lung cancer.
- Metastatic lesions in the trachea arising from non-pulmonary cancers are rare.
- Tracheal tumors have an estimated annual incidence of 0.1/100,000 people per year.
- Tracheal tumors are exceptionally rare in children. Most tracheal tumors in children are benign.
- The majority of tracheal tumors in adults are malignant (80–90 %).

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_72

- Squamous cell carcinoma (SCC) accounts for up to two-thirds of all tracheal malignancies.
  - SCC is more common in older adults (>60), has a significant male predominance, and is almost always associated with cigarette smoking (90 %).
- Adenoid cystic carcinoma (ACC/cylindroma) accounts for 10–15 % of all tracheal malignancies.
  - ACC is more common in younger age groups (40 and up), and has equal distribution between genders.

Differential Diagnosis

- Tracheal tumors are frequently misdiagnosed as adult-onset asthma. Pulmonary function tests (PFTs) in both may show a similar obstruction pattern. The diagnosis of tracheal tumor should be considered in any patient diagnosed with adult-onset asthma who doesn't respond or worsens despite usual treatment with steroids and bronchodilators.
- The most common symptoms of tracheal tumors are cough and dyspnea, so the differential can be very broad, and includes all the causes of cough and dyspnea such as asthma, chronic bronchitis, chronic obstructive pulmonary disease (COPD), pneumonitis, interstitial lung disease (ILD), congestive heart failure (CHF).
- Tracheal tumors can also be initially misdiagnosed as invasive thyroid cancers.

Pathophysiology and Etiology

- Tumors of the trachea can be primary (arising from tracheal tissue), secondary (metastatic from other tissues), or from direct invasion from tumors arising in other contiguous structures.
- The majority (about 80 %) of primary tracheal tumors in adults are malignant.
- Malignant tumors of the trachea include the following cell types.
  - Squamous Cell Carcinoma (SCC). Squamous cell carcinomas account for up to two-thirds of all malignant tracheal tumors. They are pathologically identical to SCC of the lung. They are predominately related to cigarette smoking. There is a male predominance, and most cases occur in those over age 60.

    - SCC are rapid-growing tumors. About half are not amenable to surgical removal when diagnosed.
  - Adenoid Cystic Carcinoma (ACC) has also been called cylindroma. These account for about 10–15 % of malignant tracheal tumors. They arise from bronchial/salivary glandular tissue. These occur about a decade earlier than SCC (in 40's and up), are not associated with cigarette smoking, and occur equally in men and women.
    - ACC grow more slowly than SCC and are usually more amenable to surgical removal.
  - Others. Mucoepidermoid carcinoma, non-small cell bronchogenic cancer, sarcomas, and carcinoid tumors can occur primarily in the trachea, but all are very rare.
- Benign tumors of the trachea also occur. These include chondromas, hemangiomas, hamartomas, neurogenic tumors, granular cell tumors, and squamous papillomas.
  - Chondromas are the most common (but still very rare) non-malignant tracheal tumors. They arise from the tracheal rings. These do have metastatic potential.
  - Papillomas. These are usually associated with infection from human papilloma virus (HPV) types 6 and 11. They commonly arise in areas of prior tracheal injury (tracheotomy sites). They have a tendency to extend down into the lungs, instead of out into the tracheal lumen, making them difficult to diagnose until they are large. Malignant transformation is possible.

Presentation

Typical/"Classic"

- As noted above, tracheal tumors are very uncommon, so there is no "classic" presentation.
- The two most common symptoms of tracheal tumors are cough and dyspnea.
- Other symptoms that can be seen include wheezing, stridor (when the mass is large and nearly obstructing), hoarseness (when the recurrent laryngeal nerve is involved), hemoptysis (more common with SCC) and dysphagia (from external compression of the esophagus).
- As these symptoms are non-specific and frequently seen with much more common diagnoses (asthma, chronic bronchitis, COPD, CHF, etc.), the diagnosis of a tracheal tumor may not have even been considered in the initial differential diagnosis.

- It is important to consider the diagnosis in a patient diagnosed with adult-onset asthma, especially when they are not responding appropriately to usual treatment.
- These tumors are usually large at diagnosis. They don't usually cause symptoms until the tracheal lumen is narrowed by at least 75 %.

Atypical

- As tracheal tumors are uncommon, all presentations could be considered atypical.
- Many patients will have the diagnosis considered only when an imaging study performed for other reasons shows a tracheal mass.

Primary Differential Considerations

- Patients with tracheal tumors may present with symptoms suggestive of other diagnostic considerations, including but not limited to:
  - Tuberculosis and other infectious masses
  - Inflammation
  - Scar tissue

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination findings that can confirm the diagnosis.
- The diagnosis is generally confirmed by imaging or direct visualization by bronchoscopy.

Factors That Suggest Diagnosis

- It is important to consider the diagnosis in a patient diagnosed with adult-onset asthma.
- The diagnosis should also be considered in a patient with a significant smoking history and with cough and dyspnea.
- Inspiratory stridor that worsens with recumbency can be a clue to an obstructing lesion of the trachea.

Factors That Exclude Diagnosis

- There are no historical or physical examination findings that can exclude the diagnosis.
- The diagnosis can only be excluded by a normal bronchoscopic examination.

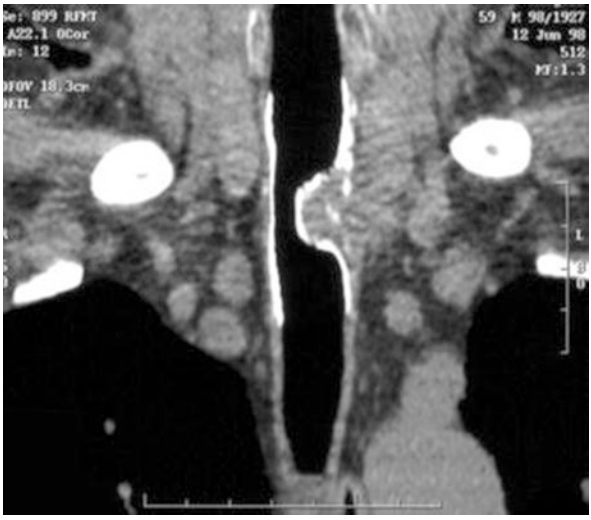
Ancillary Studies

Laboratory

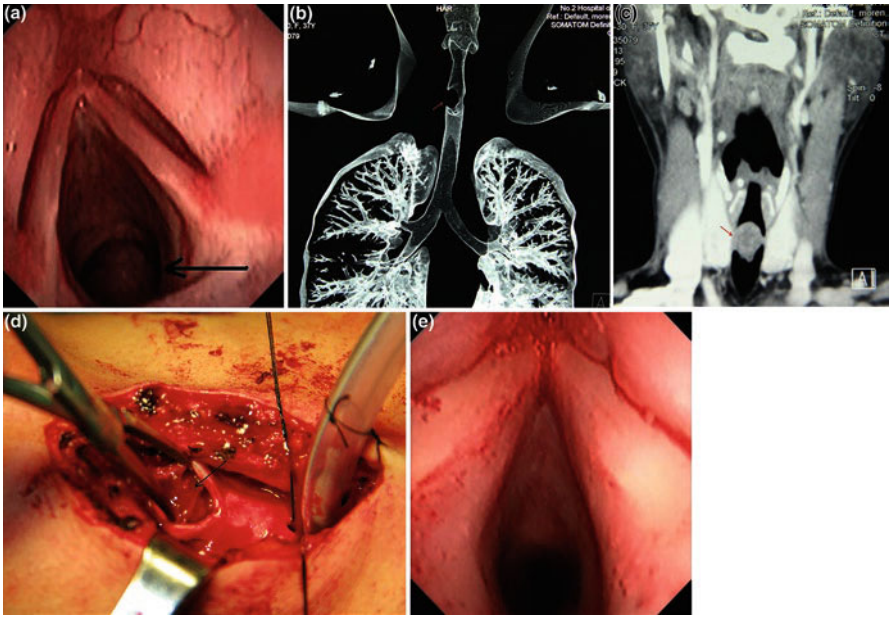
- Laboratory studies are not helpful in the diagnosis of tracheal tumors.

Imaging

- Plain chest x-ray (PA and lateral) will show an abnormality in only about 25 % of cases.
- Computed tomography (CT) of the chest and trachea is the imaging study of choice for the diagnosis of tracheal tumors. Appearance on CT may be able to help distinguish benign from malignant lesions.



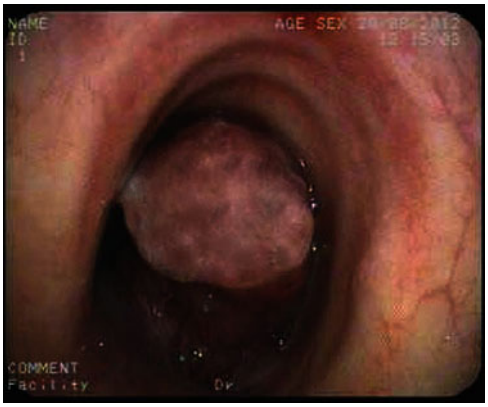
A 59-year-old man with upper tracheal squamous cell carcinoma. [Ferretti GR, Kocier M, Calaque O, Arbib F, Righini C, Coulomb M, Pison C. Follow-up after stent insertion in the tracheobronchial tree: role of helical computed tomography in comparison with fiberoptic bronchoscopy. Eur Radiol. 2003 Feb 7;13(5):1172–8.] *Caption adapted from original.*



a Female, 37 years old, with tracheal adenocystic carcinoma which is located beneath the annular cartilage under tracheobronchoscope (the black arrow). b 3-D CT scan frontal image reconstruction shows there is a tracheal tumor presenting an

irregular filling defect inside the trachea cavity (the red arrow). c 3-D CT scan image reconstruction shows the tracheal tumor is a nodular round tumor protruding inside the tracheal cavity with an even density and a smooth border. Its narrow base is connected to the tracheal wall. There is no increase in the thickness of the tracheal wall (the red arrow). d After the first tracheal rings were incised, there is a tumor protruding into the tracheal cavity from the tracheal wall on the right, and there is no increase in the thickness of the wall (the black arrow). e Electronic fiberoptic bronchoscopy shows that the tracheal wall is smooth and there is no stenosis of the first tracheal rings after postoperative radiotherapy [Li Y, Peng A, Yang X, Xiao Z, Wu W, Wang Q. Clinical manifestation and management of primary malignant tumors of the cervical trachea. European Archives of Oto-Rhino-Laryngology. 2014 Feb;271(2):225–35.] *Caption from original.*

- Bronchoscopy (either flexible or rigid) is currently considered the gold standard test for the diagnosis and evaluation of tracheal tumors. Not only can the tumor be directly visualized, tissue biopsy can be done to allow for pathologic examination and cell typing.



Bronchoscopy showing broad based pedunculated intraluminal tracheal mass which markedly narrow the lumen [Sukumaran R, Nair RA, Jacob PM, Koshy SM, Mathew AP. Extramedullary Plasmacytoma of the Trachea. Head and Neck Pathology. 2014 Jun;8(2):220–4.] *Caption from original.*

- Positron emission tomography (PET/CT). This is often done to help "stage" the disease and to help make treatment decisions.

Special Populations

Age

- Tracheal tumors are very rare in children. When found they are almost universally benign. They can include papillomas, hemangiomas, and granular cell tumors.

Co-morbidities

- A large majority of the patients with SCC of the trachea are smokers, so they often have co-morbidities (COPD, coronary disease, CHF) that can make the diagnosis more difficult. Many of these patients will have the diagnosis considered when an imaging study performed for other reasons shows a tracheal mass.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critical to consider the diagnosis in any patient diagnosed with adult-onset asthma.
- Patients diagnosed with adult-onset asthma should probably have a chest CT as part of their evaluation to exclude competing diagnoses.
- It is important to remember that "all that wheezes is not asthma."

Mimics

- Adult-onset asthma is the most significant mimic of tracheal tumors.
- Chronic bronchitis can also mimic tracheal mass lesions.

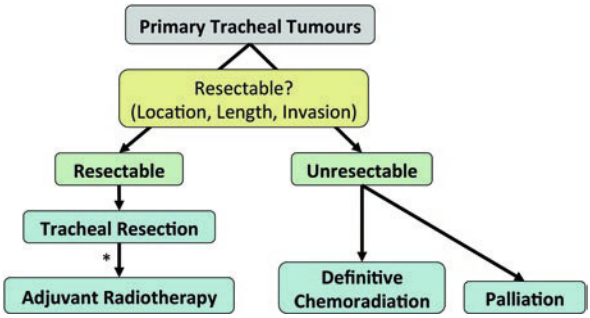
Time-Dependent Interventions

- In patients who present with respiratory distress, it is helpful to start humidified oxygen and avoid the recumbent position. It may be helpful to also use heliox (a mixture of helium and oxygen) to aid with ventilation. Some patients may benefit from tracheal stents or bronchoscopic laser ablation as bridges to surgery or for palliation of symptoms.

Overall Principles of Treatment

- The primary treatment for tracheal tumors is surgical resection.
  - Resectability is decided based upon the physical characteristics of the tumor (such as how much of the trachea is involved, how large the tumor is, and whether there is evidence of spread/metastases.
  - SCC's are usually rapidly growing tumors that metastasize early in their course. Only about one-half of SCC's are amenable to surgical removal when diagnosed.
- As these are rare tumors, there are few clinical trials to help guide treatment; most treatments are guided by expert opinion.
- Because they are so uncommon, there is no validated staging system for any of these tumors.

- Radiation therapy (RT) is often used after surgical resection, especially if the surgical margins were positive, or if the tumor could only be incompletely resected.
- Chemotherapy is often used (usually combined with RT) in unresectable tumors, but there are no good clinical trials documenting benefit.



Management algorithm for primary tracheal tumors. [Sudarshan M, Alamri H, Al-Mahroos M. Lung and Airway Disorders. In: Madani A, Ferri L, Seely A, editors. Pocket Manual of General Thoracic Surgery [Internet]. Cham: Springer International Publishing; 2015 [cited 2015 Dec 4]. p. 35–83. Available from: http://link.springer.com/10.1007/978-3-319-17497-6_3] *Caption adapted from original.*

- Bronchoscopy with laser ablation may be helpful in alleviating symptoms in tumors not amenable to resection, and to control symptoms prior to surgery.
- Non-malignant tumors are also usually treated primarily surgically. Papillomas may respond to bronchoscopic laser ablation, but the treatment may need to be repeated several times. Some papillomas may respond to intralesional injection of cidofovir.

Disease Course

- The five-year survival rate for resectable SCC is about 39 %.
- The five-year survival rate for unresectable SCC is 7 %.
- The five-year survival rate for ACC is about 50 %.
- Benign tumors of the trachea that can be surgically repaired should not recur.
- The only non-malignant tumor associated with long-term complications is the papilloma associated with HPV. It may require numerous endoscopic-guided procedures and treatments and can lead to an increased incidence of tracheal stenosis and tracheomalacia from recurrent "injury" to the trachea. It is important to start treatment only for symptomatic lesions to avoid all unnecessary tracheal injury.

Chapter 73
Tracheomalacia

Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Tracheomalacia/Tracheobronchomalacia

Incidence/Epidemiology

- The incidence and prevalence are unknown.
- Acquired tracheomalacia (TM) seems to be more common in men over the age of 40.
- The estimated incidence of primary TM in children is one in 2,100 births.

Differential Diagnosis

- The predominant symptoms and signs of TM in adults are dyspnea and cough, so the differential includes all diseases associated these complaints.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_73

- This includes asthma, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), cigarette smoking, chronic aspiration, gastroesophageal reflux disease (GERD), interstitial lung disease (ILD), and others.

Pathophysiology and Etiology

- Tracheomalacia (TM) is the term used to describe tracheal weakness. This weakness can be focal/segmental (confined to small lengths of the trachea) or diffuse (involving long portions of the trachea.) When the weakness extends into one or both mainstem bronchi, the term tracheobronchomalacia (TBM) is often used. The disorders are similar and share symptoms, pathophysiology, and treatment, so the following discussion will relate to both, and will be referred to as TM.
- The physiologic result of the tracheal cartilage and surrounding connective tissue weakening is exaggerated luminal narrowing during expiration, and excessive widening during inspiration.
- The trachea can completely collapse during periods of increased expiratory flow, such as coughing and crying (in infants and children).
- The severity appears to be related to the length of the involved segment and the degree of narrowing.
    - TM is generally classified as primary or acquired. Acquired TM is much more common in adults.
        - Congenital TM usually presents in childhood.
            - TM in children more commonly involves the distal third of the trachea and is associated a congenital abnormality.
            - These congenital abnormalities include:
                - Cardiovascular abnormalities (vascular rings, anomalous innominate artery)
                - Developmental delay
                - Severe GERD
                - Tracheoesophageal fistula
                - Esophageal atresia
        - Idiopathic giant trachea is a type of congenital TM that presents in adulthood. It is due to atrophy of the longitudinal elastic fibers and thinning of the muscularis mucosa of the trachea. There is diffuse tracheomegaly. When the process extends into the central bronchi, it is called, Mounier-Kuhn Syndrome. These are exceedingly rare conditions.

- Acquired TM. Acquired TM is more common in adults. There are many causes.
  - Prolonged endotracheal intubation and tracheostomy can lead to tracheal cartilage destruction and usually segmental tracheomalacia.
  - Other causes of direct tracheal injury that can lead to cartilage destruction include direct chest trauma and surgery such as lung transplantation.
  - Chronic compression from extrinsic masses can also lead to cartilage destruction. This can result from vascular compression from aortic aneurysms, vascular rings, malignancies, goiter, and other mediastinal mass lesions.
  - Recurrent cartilaginous inflammation from relapsing polychondritis can cause cartilage injury and destruction leading to tracheomalacia.
  - Recurrent tracheobronchial infections (especially associated with cystic fibrosis and COPD) can lead to tracheomalacia.
  - Prolonged exposure to known airway irritants (tobacco smoke, chronic GERD with aspiration) can also be associated with tracheomalacia.

- Appearance of the trachea: Some patients have predominantly posterior tracheal wall weakness and this results in a crescent-shaped trachea. Other patients have lateral wall tracheal weakness, resulting in a fissure-shaped trachea.
- Distribution: Segmental vs. diffuse distribution of weakness. This classification is important for guiding treatment.

Presentation

Typical/"Classic"

- The predominant symptoms and signs of TM in adults are dyspnea, cough, and sputum retention.
- The disease tends to be slowly progressive and goes through a prolonged asymptomatic period.
- As the disease progresses and symptoms develop, they may only be noticed first during periods of physiologic stress such as infections and while undergoing general anesthesia.
- Dyspnea tends to be less associated with exertion and more with maneuvers that force expiration, such as coughing, valsalva, and a recumbent position.

- Coughing can occur in severe paroxysms and be associated with expiratory wheezing or stridor. The wheezing with asthma and COPD tends to be inspiratory or both inspiratory and expiratory, and the presence of purely expiratory wheezing may be a subtle clue to the diagnosis.
- The symptoms and signs of TM are very nonspecific and can be seen with multiple other diseases, such as asthma, COPD, and CHF.
- Infants with TM are often noted to have expiratory stridor (sometimes called laryngeal crow) within the first few weeks of life. The stridor tends to be worsened and exacerbated by crying, supine position, and feeding.
- Infants may also be noted to have feeding difficulties, e.g., coughing and choking while feeding.

Audio of infant with tracheomalacia.

https://www.youtube.com/watch?v=DFqL3bFQpTE&list=PLRr91eakaLBZvq7dUGWiXlhLRME0SDr3Y
Audio of stridor associated with laryngomalacia, tracheomalacia, and bronchomalacia.

Atypical

- As noted above, the symptoms and signs of TM can be very nonspecific.
- Initial symptoms may be thought to be caused by many other conditions.
- Patients may be noted to have recurrent pulmonary infections due to the inability to clear their sputum.
- When TM develops in the presence of other conditions, the symptoms of dyspnea and cough may seem to be worse than what would be predicted by the severity of the underlying condition.
- Some patients may present with cough syncope.

Primary Differential Considerations

- Patients with tracheomalacia may present with signs and symptoms of other diagnostic considerations, including but not limited to:
  - Laryngomalacia
  - Laryngeal cysts
  - Vocal cord paralysis

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination findings that can confirm the diagnosis.
- The diagnosis can only be confirmed by appropriate findings (airway collapse upon forced expiration) on bronchoscopy.

Factors That Suggest Diagnosis

- The diagnosis can be suspected when a patient presents with a chronic cough or dyspnea that can be related historically or on exam to forced expiratory maneuvers such as coughing and valsalva.
- Predominantly expiratory wheezing should suggest the diagnosis.
- Early symptoms may only be noted during periods of physiologic stress, such as infections, and while undergoing general anesthesia.

Factors That Exclude Diagnosis

- There are no historical or physical examination findings that can completely exclude the diagnosis.

Ancillary Studies

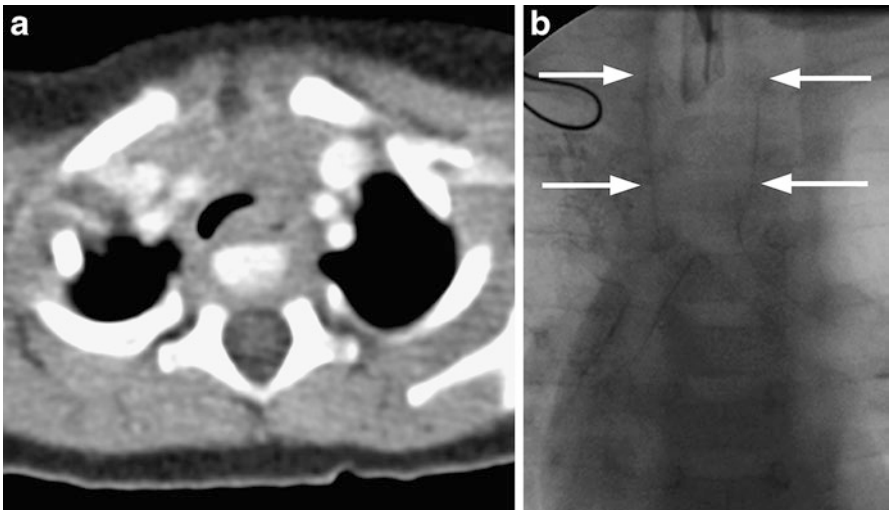
Laboratory

- Laboratory studies are generally not helpful in the diagnosis of TM.

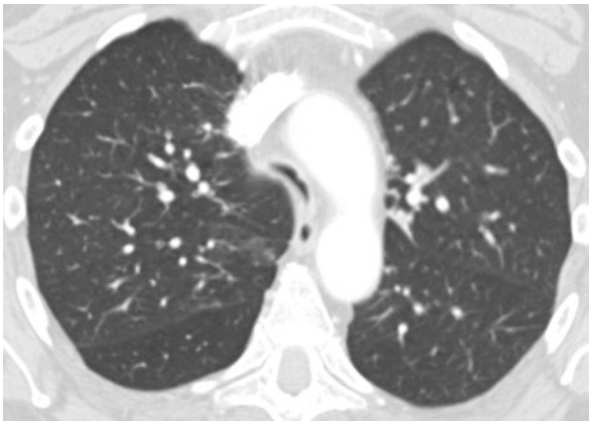
Imaging

- Chest x-ray. Plain chest x-ray is generally not helpful in the diagnosis of TM. The CXR may help if TM is caused by compression from other processes (goiter, mass, aneurysm, etc.).

- Chest CT. Chest CT can be helpful in the diagnosis and evaluation of TM. Ultrafast, multidetector CT performed both normally, and then under forced expiration or cough can document airway collapse. Airway collapse can even be quantified and used to help guide treatment decisions. Chest CT can also help diagnose the cause of acquired TM.

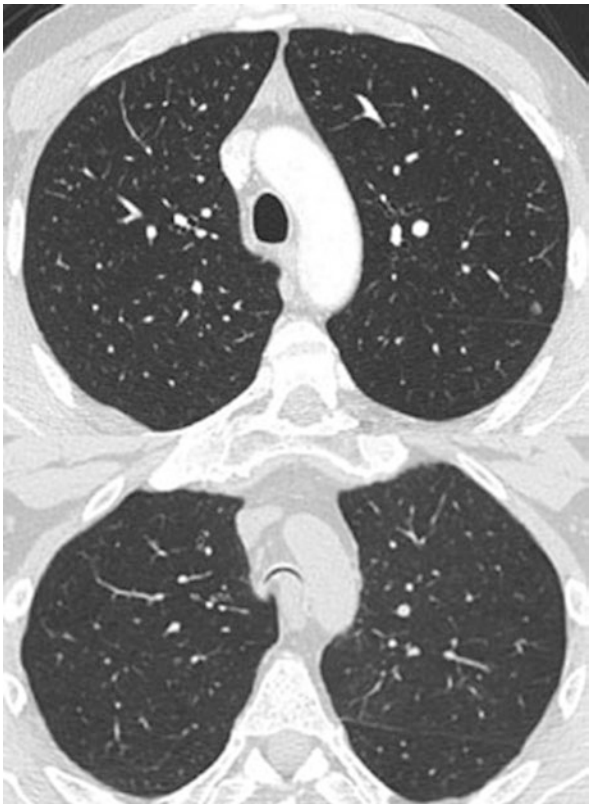


a. Axial CT shows anteroposterior narrowing of the upper trachea suggesting tracheomalacia (W 412, L 55). b. Massive tracheal dilatation is seen at bronchography with only 5 cmH2O CPAP (arrows) [McHugh K, Afaq A, Broderick N, Gabra HO, Roebuck DJ, Elliott MJ. Tracheomegaly: a complication of fetal endoscopic tracheal occlusion in the treatment of congenital diaphragmatic hernia. Pediatric Radiology. 2010 May;40(5):674–80.] *Caption from original.*



CT scan of the chest of a 57-year-old man with severe tracheomalacia demonstrating the "frown sign" [Maldonado F, Tomassetti S, Ryu JH. Orphan Tracheopathies.

In: Cottin V, Cordier J-F, Richeldi L, editors. Orphan Lung Diseases [Internet]. London: Springer London; 2015 [cited 2015 Dec 4]. p. 73–89. Available from: http://link.springer.com/10.1007/978-1-4471-2401-6_6] *Caption from original.*



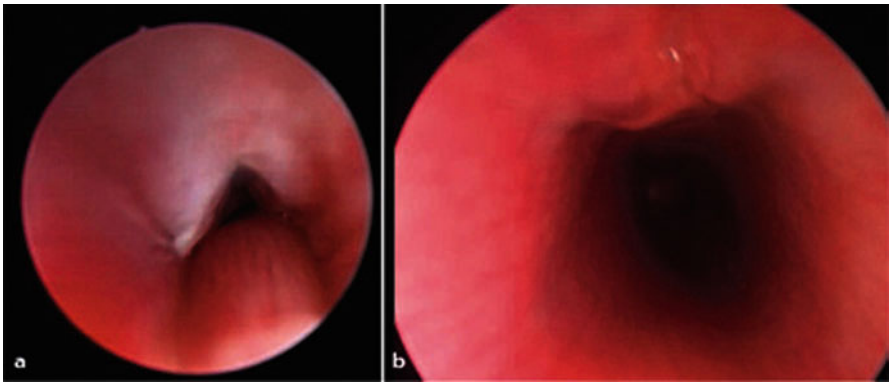
Tracheomalacia. The tracheal lumen has a normal appearance on the inspiratory transverse CT scan (top). This lumen collapses on the expiratory transverse scan (bottom). The posterior tracheal wall bows anteriorly tremendously reducing the airway lumen. [Grenier PA. Airway Disease. In: Baert AL, editor. Encyclopedia of Diagnostic Imaging [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2008 [cited 2015 Dec 4]. p. 57–60. Available from: http://www.springerlink.com/index/10.1007/978-3-540-35280-8_85] *Caption from original.*

Other

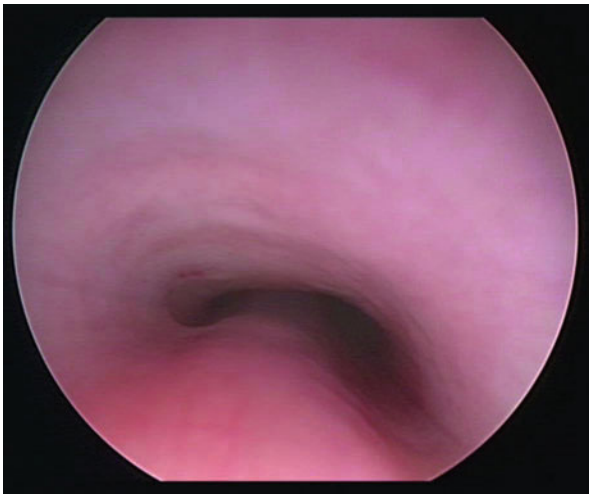
- Bronchoscopy. Currently, the diagnostic gold standard for the diagnosis of TM is direct visualization of dynamic airway collapse during bronchoscopy. Bronchoscopy allows the direct visualization and measurement for grading

the severity of TM. Mild TM is defined as luminal narrowing of less than 50 % during expiration. Moderate TM is defined as narrowing of 25–50 %, and severe TM is diagnosed if the anterior and posterior tracheal walls touch during expiration.

https://www.youtube.com/watch?v=rNADYJySIl4
Video of focal tracheomalacia.



Tracheomalacia. Severe tracheomalacia (a) and after aortopexy (b) [Masciopinto F, Gentili A, Bianchini A, Baroncini S. Airway Endoscopy. In: Lima M, editor. Pediatric Thoracic Surgery [Internet]. Milano: Springer Milan; 2013 [cited 2015 Dec 4]. p. 181–91. Available from: http://link.springer.com/10.1007/978-88-470-5202-4_15] *Caption from original.*



Primary tracheomalacia with soft, collapsible cartilaginous support proximal to the carina [Berg EE, McClay J. Tracheobronchomalacia. In: Lioy J, Sobol SE, editors. Disorders of the Neonatal Airway [Internet]. New York, NY: Springer New York;

2015 [cited 2015 Dec 4]. p. 87–95. Available from: http://link.springer.com/10.1007/978-1-4939-1610-8_11] *Caption from original*.

- Pulmonary Function Tests (PFTs). PFTs can help support a diagnosis of TM, but they cannot make or confirm the diagnosis. PFTs will often show reduction in the expiratory flow rate on a flow volume curve and the expiratory curve will have a "notched" appearance.

Special Populations

Age

- Acquired TM is more common in adults over age 40.
- Congenital TM is more common in children.
- TM in children more commonly involves the distal third of the trachea and is associated a congenital abnormality.
    - These congenital abnormalities include:
        - Cardiovascular abnormalities (vascular rings, anomalous innominate artery)
        - Developmental delay
        - Severe GERD
        - Tracheoesophageal fistula
        - Esophageal atresia
- TM in infants generally disappears spontaneously by the age 0f 18–24 months.
- Infants with TM are often noted to have expiratory stridor (sometimes called laryngeal crow) within the first few weeks of life. The stridor tends to be worsened and exacerbated by crying, supine position, and feeding.
- Infants may also be noted to have feeding difficulties with coughing and choking with feeding.
- Treatment in children is more guided by the pattern (focal or diffuse) of disease.
- Infants and children with mild-to-moderate symptoms can often be managed with conservative measures until the disease spontaneously remits. Conservative treatment includes:
    - Humidified air
    - Chest physiotherapy
    - Slow feedings
    - Meticulous control of secretions
    - Appropriate treatment of infections
- Surgery may be indicated for infants/children with severe disease who do not respond to conservative treatments.
- Infants with reflex apnea should be managed surgically.

Co-morbidities

- Patients with tracheomalacia will frequently have other medical issues that can complicate and worsen TM.
- TM can occur in patients with long-standing asthma and COPD.
- Gastroesophageal reflux disease (GERD) can both cause and worsen TM. Aggressively treating (when present) may prevent worsening.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step.
- TM can coexist with other cardio-pulmonary and laryngeal diseases, so it is important to consider even if a competing/alternative diagnosis has been confirmed.
- TM should be considered if the patients' cough and dyspnea seem out of proportion to the severity of the current diagnosis.

Mimics

- Asthma and COPD can both mimic TM.
- Severe GERD can also cause similar symptoms to TM.

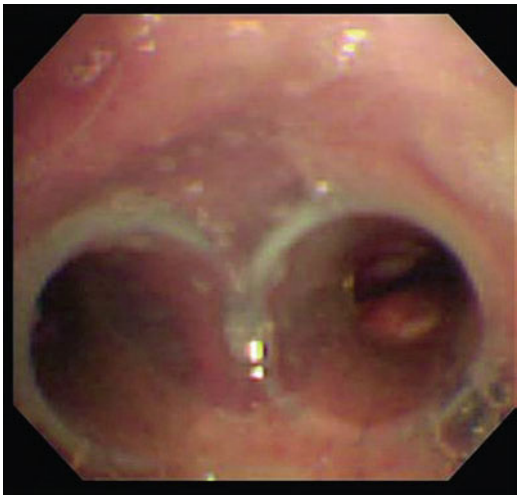
Time-Dependent Interventions

- TM is generally a slowly progressive disease, and as such there are usually no immediately time-sensitive interventions.
- Patients with TM who are admitted to the hospital with another acute illness may benefit from the use of continuous positive airway pressure (CPAP). This can help maintain an open airway and secretion mobilization.

Overall Principles of Treatment

- Treatment is guided by the symptoms and graded severity of TM.
- There is no indication for treatment of asymptomatic patients.

- All patients with suspected TM should have both bronchoscopy and CT chest to help gauge severity and guide therapy.
- The underlying cause of TM should be sought and treated.
- The treatment of contributing, comorbid diseases (COPD, asthma, GERD, CHF) should be maximized.
- If patients remain symptomatic after treatment of all contributing factors, primary therapy for TM should be considered.
- Prior to starting primary therapy, patients should have functional respiratory testing with PFTs, six-minute walk test, and a quality-of-life assessment. This assessment will be used to guide and assess the success of therapy.
- In general, primary therapy for TM can involve stenting and primary surgical repair.
- Many experienced centers will start with stenting and assess response to guide long-term treatment.
    - If patients are not surgical candidates, but they improve with stent insertion, they may be managed with long-term silicone stents. Stents tend to be most helpful in focal, proximal disease.



Silicone Y-stent inserted in a patient with tracheomalacia [Anantham D. Management Principles of Nonmalignant Airway Obstruction. In: Ernst A, Herth FJ, editors. Principles and Practice of Interventional Pulmonology [Internet]. New York, NY: Springer New York; 2013 [cited 2015 Dec 4]. p. 269–83. Available from: http://link.springer.com/10.1007/978-1-4614-4292-9_26] *Caption from original*.

- Patients who are surgical candidates and improve with stenting should be offered definitive surgical repair. Definitive surgical repair generally involves tracheobronchoplasty (the application of a mesh to the posterior tracheal wall, which increases the rigidity of the wall).

- Patients who do not improve with stenting should have the stent removed and be managed with positive airway pressure when needed.

- Future treatments:
  - There is ongoing research on biogenic stents and tracheal replacement.

Disease Course

- In infants, TM usually resolves spontaneously by 18 – 24 months of age
- TM is a slowly progressive disease in adults.
- Almost all patients will worsen over time.
- There have been no reports of spontaneous remission or improvement in adults.

Chapter 74
Tuberculosis

Charles V. Pollack, Jr. and Victoria G. Riese

Name and Synonyms

Tuberculosis, TB

Incidence/Epidemiology

- Tuberculosis is a multisystem disease with many varied presentations, all of which evolve from infection with the atypical pathogen *Mycobacterium tuberculosis*, an acid-fast bacterium that is endemic in some parts of the world, especially underdeveloped regions where living conditions and access to health care are poor.
- Chest pain due to tuberculosis tends to be pleuritic in nature, and may result from lung infection and/or pleural or pericardial involvement.
- In the United States, the current incidence of TB is 3–4/100,000 persons, with the highest incidence in states with the most immigrants—California, Texas, Florida, and New York. The prevalence of HIV disease in those states also may be a contributing factor.
- Globally, the highest incidence of TB is found in India, China, South Africa, Indonesia, and Pakistan.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_74

Differential Diagnosis

- The differential considerations for chest pain due to TB are primarily other pleuritic pain processes, such as pulmonary embolism, pericarditis, pneumonia, pneumothorax, and pleurisy.
- As in all chest pain presentations, immediate life threats such as acute coronary syndrome and aortic dissection should always be considered.
- Acute chest syndrome in sickle cell disease is a differential consideration in at-risk patients.

Pathophysiology and Etiology

- The clinical manifestations of TB result from a variable combination of actual infection and the host's inflammatory response to the infection.
- Chest pain syndrome in patients with TB typically arises from actual pneumonia or from involvement of the pleura or pericardium.
- There may also be chest wall pain from coughing.

Presentation

Typical/"Classic"

- The classic presentation of pulmonary or extrapulmonary thoracic TB that causes chest pain is marked by most or all of the following:
  - Cough
  - Weight loss/anorexia
  - Fever
  - Night sweats
  - Hemoptysis
  - Fatigue
  - Lymphadenopathy
- TB is a more likely presentation in patients with such symptoms if they have risk factors for exposure, such as:
  - Recent travel to an endemic area
  - Recent imprisonment, homelessness, or living in a shelter
  - HIV infection

- Prior TB exposure or infection
- Known positive prior PPD (purified protein derivative) test

Atypical

- TB may affect multiple organ systems, including the spine and other bones, the gastrointestinal and genitourinary (GU) tracts, and the meninges. These types of tuberculous infections are less likely to present with chest pain.

Primary Differential Considerations

Pulmonary TB has protean manifestations. In patients with a history concerning for TB exposure, other diagnoses must still be considered, including:

- Necrotizing bacterial pneumonia
- Fungal pneumonia
- Lung abscess
- Lung cancer
- Bronchiectasis

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination cannot confirm the presence of tuberculosis.

Factors That Suggest Diagnosis

- A history of fever, chills, weight loss, and hemoptysis is suggestive of TB in the patient with chest pain.
- Findings of consolidation on pulmonary exam—such as egophony and percussion dullness, especially in the upper lung fields—are suggestive of TB in the patient with chest pain.

http://www.easyauscultation.com/egophony
Egophony. [Egophony Page; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- Evidence of malnutrition or chronic illness on physical exam should raise suspicion for TB in the patient with chest pain.

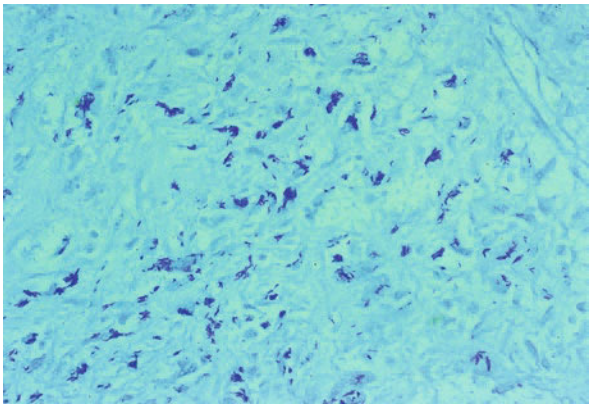
Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude TB in the patient with chest pain.

Ancillary Studies

Laboratory

- Confirmation of TB infection is provided by the finding of acid-fast bacilli (AFB) on smear and/or culture of a bodily fluid, such as sputum



Granulomatous area with acid-fast bacilli in a lung biopsy specimen. Lung biopsy specimen showing a granulomatous area with numerous acid-fast bacilli. Diagnostic fiberoptic bronchoscopy with transbronchial biopsy and bronchial washings is an effective way to obtain diagnostic materials when sputum examination is unrevealing, in the early diagnosis of miliary disease, and in lower lobe tuberculosis when the number of bacilli may be small. (Kinyoun stain.) [Maslow M. Tuberculosis and nontuberculosis mycobacterial infections of the lungs. In: Simberkoff MS, editor. Pleuropulmonary and bronchial infections. Philadelphia: Current Medicine; 1996.

283 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 6). ISBN: 0-443-07740-1] *Caption from original*

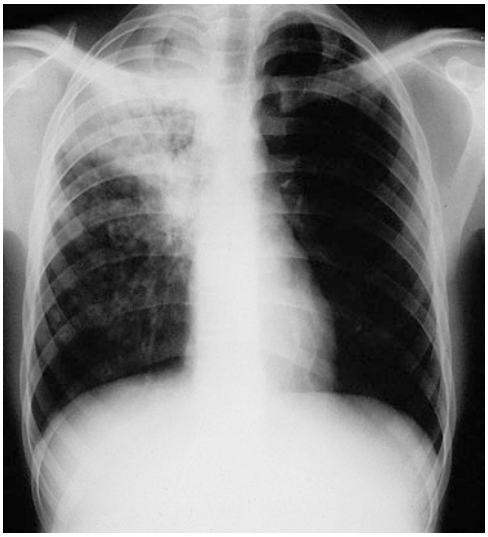
- An HIV test should be obtained in patients with TB and unknown HIV status.
- Basic laboratory tests are of limited clinical value in assessing the patient with chest pain for TB, but they may be appropriate in the evaluation of potential differential considerations.
- Patients suspected of having pulmonary TB should undergo urinalysis; sterile pyuria is a common manifestation of GU TB.

Imaging

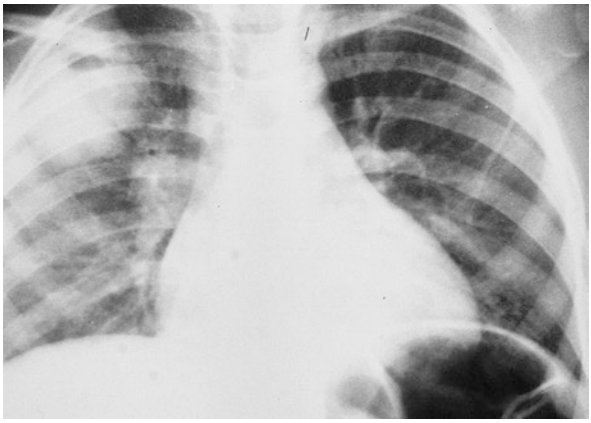
- Chest radiography and CT may strongly suggest pulmonary TB.

Multidrug-resistant tuberculosis (MDR TB). Chest radiograph of a black African man aged 31 years with a CD4 count of 79 cells/mm3 showing bilateral patchy confluent consolidation with cavitatory changes in the left upper lobe. Left apical pleural thickening and features of volume loss suggest previous TB. Tubular lucencies in the left upper lobe suggest underlying bronchiectasis. [Lalloo UG, Ambaram A, Vawda F. Pulmonary complications. In: Mildvan D, editor. International atlas of AIDS. 4th ed. Philadelphia: Current Medicine; 2008. 366 p. ISBN: 1-57340-270-2] *Caption adapted from original*

- The classic findings on x-ray are apical infiltrate(s), often with a cavitary lesion.



Pulmonary tuberculosis (TB) presenting as a right upper lobe infiltrate. [Jacobs R. Tuberculosis. In: Wilfert CM, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1999. 283 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8] *Caption adapted from original*



Pulmonary tuberculosis (TB) presenting as a lung abscess. [Jacobs R. Tuberculosis. In: Wilfert CM, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1999. 283 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8] *Caption adapted from original*

- A normal chest radiograph *does not* exclude TB, but casts doubt on the diagnosis if chest pain features prominently in the patient's presentation.

Special Populations

Age and Gender

- TB occurs in all age, ethnic, and socioeconomic groups. It occurs in both males and females.
- Pulmonary TB often has poorer outcomes at the extremes of age.
- In the United States, foreign-born patients with TB most often are Hispanic or Asian.

Comorbidities

- Comorbidities associated with pulmonary TB include but are not limited to:
  - HIV

TB—Tuberculosis

Transmission
1 of 3 TB cases in HIV patients is recently acquired
Immunity is not conferred by previous exposure to TB organisms
Lack of cavitary disease with HIV may render patients less contagious
Spread of TB facilitated by grouping HIV patients together in health care facilities, homeless shelters, and prisons
Clinical manifestations
Positive purified protein derivative with early stages of HIV only
Usual symptoms (fever, sweats, cough, and weight loss) are usually more exaggerated
Rapid progression from exposure to active disease (from loss of cell-mediated immunity)
Higher rate (40%–89%) of extrapulmonary manifestations
Lymphadenitis with fistula formation and abscesses
Radiographic features
Nonapical distribution
Infiltrates in any lung zone
Cavitation rare late in the disease
Intrathoracic adenopathy in 1 of 3 cases
Miliary infiltrates and pleural effusions
Normal chest radiograph in early stages of pulmonary

Tuberculosis and HIV. All patients with tuberculosis should be screened for HIV, and conversely, all HIV positive patients should have a purified protein derivative (PPD) skin test. The sensitivity of the test is inversely proportional to the degree of immunosuppression. Anergy is common, so a negative PPD should be interpreted

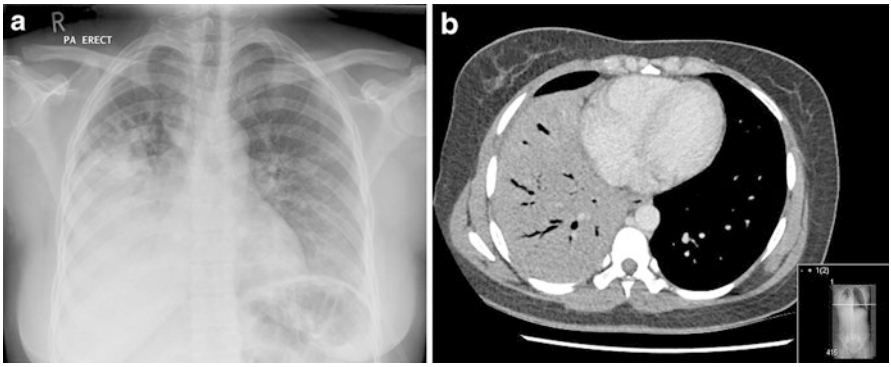
with caution. Prophylactic regimens should be continued for 9 months. Tuberculosis should be considered in any HIV-positive patient with unexplained fevers, cough, infiltrate, adenopathy, meningitis, brain abscess, pericarditis, pleural effusion, or an abscess anywhere in the body. The diagnosis is difficult because the symptoms are nonspecific, the PPD is often negative despite active disease, atypical radiographs are the rule, and extrapulmonary manifestations are common (American Thoracic Society: Targeted tuberculin testing and treatment of latent tuberculosis infection. MMWR Recomm Rep. 2000; 49(RR-6):1 -43.) [Bates JH, Huitt GA. Infections. In: Crapo JD, editor. Bone's atlas of pulmonary medicine. 3rd ed. Philadelphia: Current Medicine; 2005. 338 p. ISBN: 1-57340-211-7] *Caption from original*

- Other immunocompromise
- Cancer
- COPD and chronic respiratory failure
- Chronic hepatic disease
- Alcoholism
- Neurologic disease

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Early consideration of the diagnosis of TB in the patient with chest pain is essential in order to protect other people—family members as well as health-care providers—from possible exposure to the disease.



Case example: a 39-year-old Zambian woman presented with a 4-day history of pleuritic chest pain, cough and breathlessness, and a 6-week history of weight loss and night sweats. She was initially treated with amoxicillin and clavulanic acid, which resulted in symptomatic improvement. Tests on admission demonstrated

HIV-1 infection, with a CD4 count of 192 cells/μL. a Chest radiograph demonstrates right-sided middle and lower zone consolidation. b CT image of the thorax demonstrates nodular shadowing in both upper lobes, with dense consolidation of the right middle and lower lobes. Sputum microscopy was 3+ positive for acid-fast bacilli and culture confirmed Mycobacterium tuberculosis. This emphasizes the importance of testing for HIV and mycobacterial disease in patients with community-acquired pneumonia [Brown J, Lipman M. Community-acquired pneumonia in HIV-infected individuals. Curr Infect Dis Rep [Internet]. 2014 Mar [cited 2015 May 29];16(3)397. Available from: http://link.springer.com/10.1007/s11908-014-0397-x] *Caption from original*

- Accessible, pertinent body fluids (especially sputum in patients with chest pain) should be sent for AFB smear and culture as soon as possible.

Mimics

- The entire constellation of diagnoses underlying pleuritic chest pain, especially those often accompanied by dyspnea and/or fever, can mimic the pain and overall presentation of TB.
- Pericarditis may mimic pleuritic chest pain from TB in presentation. Listen for a pericardial friction rub.

Time-Dependent Interventions

- Anti-infective therapy, usually with empiric antibiotic therapy initially, should be initiated when the diagnosis of pneumonia is strongly considered or confirmed. Consult your local antibiogram for guidance in choosing a specific agent.
- Choice of antimicrobial also is driven by the classification of the pneumonia (community-acquired vs hospital-acquired vs ventilator-associated pneumonia).

Overall Principles of Treatment

- Respiratory isolation should be implemented immediately upon serious consideration of the presence of TB.
- There are several drugs used to treat TB, often in combination. Resistance patterns evolve; therefore, treatment is guided by microbiologic studies.

Categories	Patients	Treatment
Category I	New smear-positive pulmonary TB, smear-negative pulmonary TB with parenchymal involvement, seriously ill pulmonary TB, extrapulmonary TB, severe concomitant HIV disease	2HRZE + 4HR
Category II	Previously treated sputum/smear-positive pulmonary TB relapse, treatment after interruption, treatment failure	2HRZES/1HRZE + 5HRE
Category III	New smear-negative pulmonary TB, less severe form of extrapulmonary TB	2HRZE + 4HR
Category IV	Chronic and MDR-TB	Specially designed/individualized regimens

The number before the letters refers to the number of months of treatment

H isoniazid, *R* rifampicin, *Z* pyrazinamide, *E* ethambutol, *S* streptomycin

Categories of tuberculosis and their treatment regimens as recommended by WHO (Toman K [2004] Toman's tuberculosis case detection, monitoring, treatment, 2nd edn. WHO, Geneva) [Rajasekaran S, Khandelwal G. Drug therapy in spinal tuberculosis. Eur Spine J. 2013 Jun;22(S4):587–93.] *Caption from original*

- Chest pain associated with TB usually improves quickly as the infection resolves. Nonsteroidal anti-inflammatory drugs or narcotics may be given to patients with persistent or severe pain.

Disease Course

- The course of TB is determined by multiple factors, most important of which are:
  - The overall health and immune status of the individual host
  - The number of organ systems involved
  - The extent of infection prior to initiation of treatment
  - Age (older patients have poorer prognoses)
  - Patient adherence to the treatment regimen

Highlights of the 2018 ESC Clinical Practice Guidelines

The European Society of Cardiology revealed 4 new guideline updates developed by expert task forces covering the topics of syncope, cardiovascular diseases during pregnancy, arterial hypertension, and myocardial revascularization, and a consensus document on the fourth universal definition of myocardial infarction. The evidence base supporting the guidelines are summarised, and valuable clinical decision-making tools for practicing clinicians are provided.

ESC
European Society of Cardiology

Dear Colleagues,

In this issue of *ESC Congress 2018 in Review*, we are delighted to share with you peer-reviewed highlights of the European Society of Cardiology Congress 2018 held in Munich, Germany. Over the five days of the congress – in addition to a rich educational programme - 12 Basic & Translational Science Hot Line presentations, 35 Late Breaking Clinical Trial presentations, 15 Clinical Trial Updates, 30 Late-Breaking Registry Results, 4 new ESC Clinical Practice Guidelines, and 4,461 abstracts were presented. The congress spotlight was 'Valvular Heart Disease' to place a special emphasis on the substantial growth in this area over the past decade. Some new features added to the Congress this year included a track called 'Cardiology in 4 Days', which covered the entire field of cardiology with focused lectures given by leading experts; the expansion of the successful 'Expert Advice' sessions; and a dedicated lecture hall, the 'Library Room', which provided a unique forum for discussions.

The articles selected for this issue of *ESC Congress 2018 in Review*, the official highlights report for ESC Congress 2018, will summarise the most newsworthy, cutting-edge, and clinically relevant topics presented in Munich. A typical example would be the ATTR-ACT study, in which tafamidis reduced hospitalisations and improved both survival and quality of life in patients with transthyretin amyloid cardiomyopathy. The results of ATTR-ACT, COMMANDER HF, MITRA-fr, and the numerous other trials presented at ESC Congress 2018 will influence cardiovascular care and allow us to better understand diseases and manage patients.

New ESC Clinical Practice Guidelines were presented on the diagnosis and management of syncope, the management of cardiovascular diseases during pregnancy, myocardial revascularisation (in conjunction with European Association for Cardio-Thoracic Surgery), and management of arterial hypertension (in conjunction with European Society of Hypertension); with dedicated sessions to help attendees understand the underlying science that support the recommendations and the impact of the new guidelines on their own clinical practice.

We are confident that the articles in this edition of *ESC Congress 2018 in Review* will be useful for your clinical practice. Please also be reminded that ESC 365, presenting all congress resources in one online library, provides access to all abstracts, slides and presentations, along with ESC TV interviews and other material from ESC Congress 2018. To access this unique source of up-to-date information, visit us online at www.escardio.org/365.

We hope you will enjoy this issue of *ESC Congress 2018 in Review* and look forward to seeing you in Paris for ESC Congress 2019. For more information, please visit www.escardio.org/ESC2019.

Professor Stephan Achenbach, FESC
Chairman, ESC Congress Programme Committee 2016-2018

Dear Practitioner,

We are pleased to share with you highlights from the European Society of Cardiology (ESC) Congress 2018 held in Munich, Germany.

The featured article provides a topline summary of the 4 new ESC Clinical Practice Guideline updates released during the congress covering myocardial revascularisation, cardiovascular diseases during pregnancy, arterial hypertension, and syncope, as well as the 4th universal definition of MI.

Several highly anticipated clinical trials were presented at ESC Congress 2018. The ATTR-ACT study investigated tafamidis as a treatment for wild-type transthyretin amyloid cardiomyopathy and found that it improved both survival and quality of life, and reduced hospitalisations in these patients for whom the average survival is 3-5 years after diagnosis and there are no currently approved therapies. The CAMELLIA-TIMI 61 study examined the safety and efficacy of a weight-loss drug (lorcaserin) in overweight or obese patients. Results showed that adding lorcaserin to diet and exercise resulted in sustained weight loss compared with placebo without increasing the risk for MACE. Two highly anticipated trials of aspirin for primary CV prevention (ARRIVE and ASCEND) suggest that aspirin may be of benefit in patients with diabetes, but is accompanied by increased gastrointestinal bleeding and its role in moderate risk non-diabetics is uncertain. Results from two studies of rivaroxaban failed to show significant clinical benefits. In MARINER, rivaroxaban 10 mg daily post discharge did not significantly reduce symptomatic venous thromboembolism (VTE) or VTE-related death versus placebo in medically-ill patients, although unexpectedly low event rates reduced the ability to demonstrate a statistical difference given the observed 24% relative risk reduction. In COMMANDER HF, rivaroxaban 2.5 mg twice daily did not significantly reduce the composite of death, MI, or stroke compared with placebo in patients with ischaemic cardiomyopathy in sinus rhythm.

In addition to guideline updates and the results from Hot Line sessions, you will also find information on selected areas of cardiovascular medicine including innovative strategies for secondary prevention and antithrombotic therapy in patients with AF + ACS.

We hope that you find the articles and practical perspectives that are contained in the pages of this issue of *ESC Congress 2018 in Review* helpful in integrating this new information into your clinical practice.

4 Highlights of the 2018 ESC Clinical Practice Guidelines

Late-Breaking Science

13 No Advantage of Early Invasive Strategy in NSTE-ACS
14 Higher Mortality With FFR-Guided Treatment Choice of Multivessel Disease
14 Gastrointestinal and Genitourinary Bleeding May Predict Underlying Cancer
15 Coronary CT Angiography Reduces 5-Year Risk of Myocardial Infarction
16 Ticagrelor Monotherapy Beyond 1 Month No Better Than Standard Dual Antiplatelet Therapy After Stenting
17 Ablation Reduced Recurrent Arrhythmias by Compared With Drug Therapy in AF Patients
18 CAMELLIA-TIMI 61 Established Cardiovascular Safety of Lorcaserin
19 Percutaneous Mitral Valve Repair Is Safe in Patients With Secondary Mitral Regurgitation but Does Not Improve Outcomes
20 Rivaroxaban Does not Reduce the Composite of Death, MI or Stroke in Heart Failure Patients
20 FRANCE-TAVI Registry Results
21 Primary Results From the MARINER Trial
23 Primary Prevention With Aspirin: Effective in Patients with Diabetes, but Role in Moderate-Risk Patients Less Clear
24 Tafamidis Safe and Effective for Patients With Transthyretin Amyloidosis
26 Lowering the Threshold for Diagnosing MI Does Not Improve Patient Outcomes

Selected Content

28 Dual Antithrombotic Therapy Safer and as Efficacious as Triple Therapy in AF patients Undergoing PCI
29 Innovative Strategies for Secondary Prevention

ESC European Society of Cardiology

Highlights of the 2018 ESC Clinical Practice Guidelines

Written by **Lisa Buttle**

The European Society of Cardiology (ESC) revealed 4 new guideline updates developed by expert task forces covering the topics of syncope, cardiovascular diseases (CVD) during pregnancy, arterial hypertension, and myocardial revascularisation, and a consensus document on the fourth universal definition of myocardial infarction (MI). The guidelines summarise the evidence base on these topics, and provide a valuable clinical decision-making tool for practicing clinicians. All guidelines can be accessed from the ESC website (www.escardio.org/guidelines) and the ESC Pocket Guidelines App.

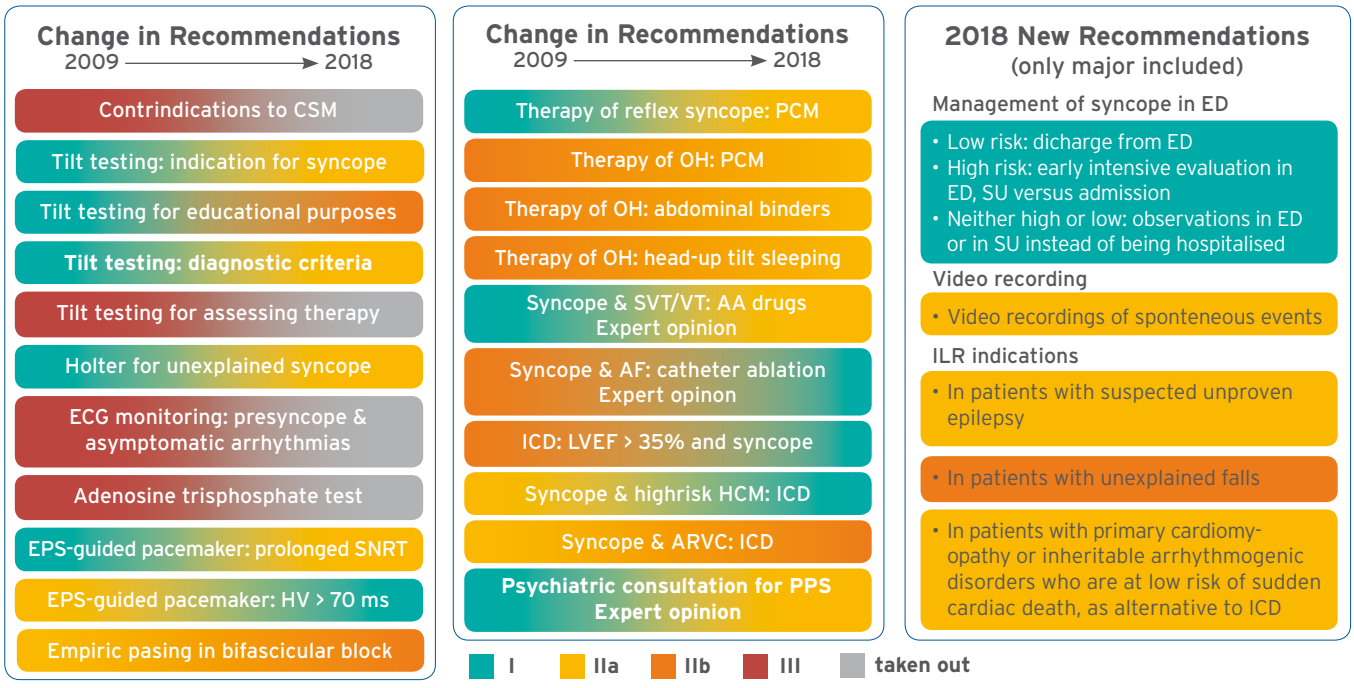
Syncope

The 2018 ESC Guidelines for the Diagnosis and Management of Syncope [Brignole M et al. *Eur Heart J*. 2018] were developed with the special contribution of the European Heart Rhythm Association (EHRA) and presented by Javier Moreno, MD, PhD, Hospital Universitario Ramón y Cajal, Madrid, Spain.

The 2018 guidelines contain a number of updated recommendations and important new and revised concepts, which are summarised in Figure 1, notably with the downgrade of Tilt testing, and the upgrade to class I recommendation for catheter ablation when syncope occurs with atrial fibrillation (AF).

Risk stratification in the emergency department at the initial presentation of syncope is essential to determine whether admission and subsequent investigations are needed, and the revised recommendations for management based upon risk are shown in Figure 2. Examples of high-risk features include new onset of chest discomfort, shortness of breath, headache, abdominal pain, sudden onset of palpitations followed by syncope, or a history of structural or coronary artery disease.

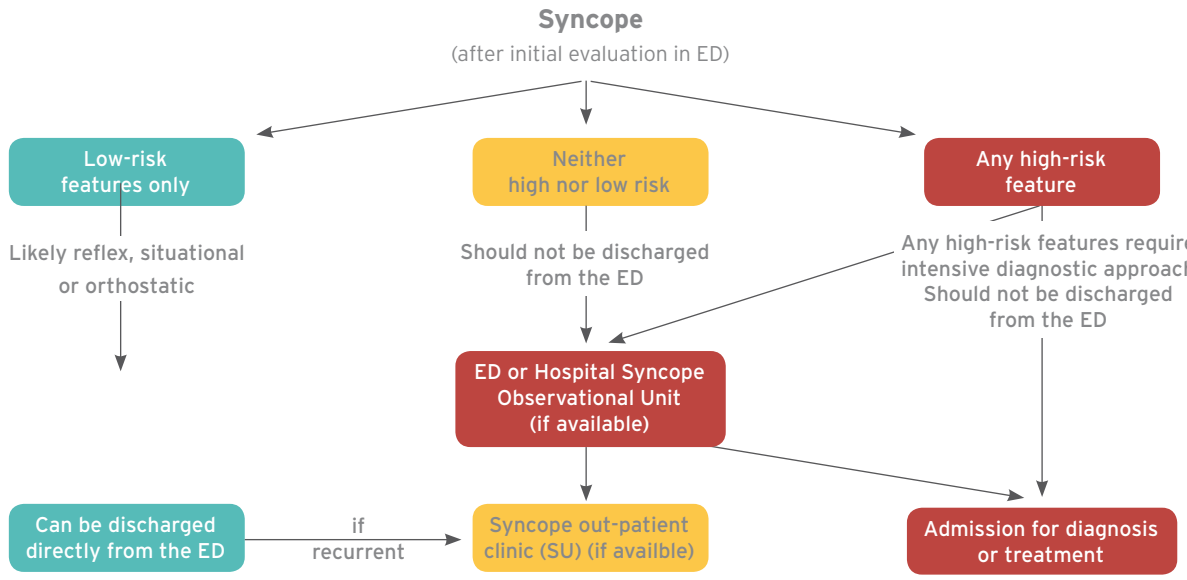
Figure 1. What Is New in the 2018 Syncope Guidelines



AA, antiarrhythmic; AF, atrial fibrillation; ARVC, arrhythmogenic right ventricular cardiomyopathy; CSM, carotid sinus massage; ECG, electrocardiogram; ED, emergency department; LVEF, left ventricular ejection fraction; EPS, electrophysiological study; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter defibrillator; ILR, implantable loop recorder; OH, orthostatic hypotension; PCM, physical counter-pressure manoeuvres; POTS, postural orthostatic tachycardia syndrome; PPS, psychogenic pseudosyncope; SNRT, sinus node recovery time; SU, syncope unit; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Reprinted from Brignole M et al. 2018 ESC Guidelines for the diagnosis and management of syncope. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy037. By permission of Oxford University Press on behalf of the European Society of Cardiology.

Figure 2. Emergency Department Risk Stratification Flow Chart



ED, emergency department; SU, syncope unit.

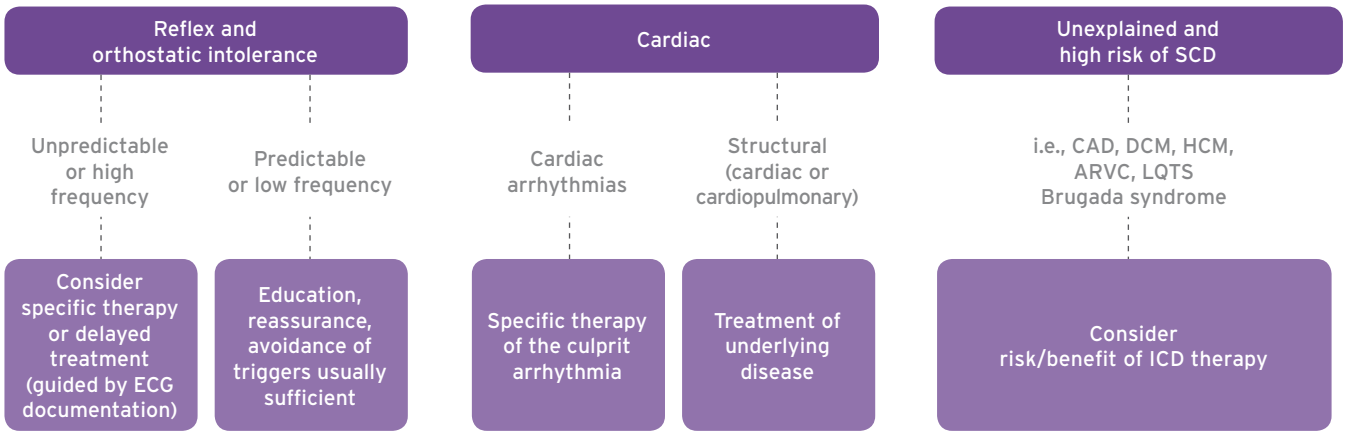
Reprinted from Brignole M et al. 2018 ESC Guidelines for the diagnosis and management of syncope. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy037. By permission of Oxford University Press on behalf of the European Society of Cardiology.

Subsequent investigations of syncope may include prolonged electrocardiographic monitoring, electrophysiology studies, and exercise testing; indications for use of these investigative techniques are included in the full guidelines. A new recommendation suggests the use of video recording of spontaneous events either at home or in hospital; video recording offers pathophysiological insights into syncope and may allow complex events to be diagnosed. Treatment recommendations are based on the identification of specific causes of syncope, wherever possible, and treatment principles are outlined in Figure 3. A new addition to the 2018 guidelines is a chapter focusing on organisational aspects of care, and outlining key drivers for efficient operation of the Syncope Unit.

Cardiovascular Diseases During Pregnancy

The 2018 ESC Guidelines for the Management of Cardiovascular Diseases during Pregnancy [Regitz-Zagrosek V et al. *Eur Heart J*. 2018] were presented by Christi Deaton, PhD, RN, University of Cambridge School of Clinical Medicine, United Kingdom. Since the 2012 guidelines were published, new evidence has accumulated on diagnostic techniques, risk assessment, and the use of CV drugs; full details of these topics are provided in the 2018 update along with new user-friendly summaries in each section highlighting recommendations and remaining 'gaps in the evidence'. New concepts introduced in the 2018 update are listed in Table 1.

Figure 3. General Framework for Treatment of Syncope and the Identification of Specific Mechanisms



ARVC, arrhythmogenic right ventricular cardiomyopathy; CAD, coronary artery disease; DCM, dilated cardiomyopathy; ECG, electrocardiographic; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter defibrillator; LQTS, long QT syndrome; SCD, sudden cardiac death.

Reprinted from Brignole M et al. 2018 ESC Guidelines for the diagnosis and management of syncope. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy037. By permission of Oxford University Press on behalf of the European Society of Cardiology.

Table 1. New Concepts in the 2018 ESC Guidelines on Cardiovascular Diseases in Pregnancy

New concepts
Enforcing mWHO classification of maternal risk.
Introduction of the pregnancy heart team.
More attention for assisted reproductive therapy.
Discussion of the use of bromocriptine in peripartum cardiomyopathy.
Introduction of specific levels of surveillance based on low/medium/high risk for arrhythmia with haemodynamic compromise at delivery.
New information on pharmacokinetics in pregnancy, more detailed information on pharmacodynamics in animal experiments on all drugs.
Perimortem caesarean section is discussed.
Advice on contraception and the termination of pregnancy in woman with cardiac disease is now provided.

mWHO, modified World Health Organization.

Reprinted from Regitz-Zagrosek V et al. 2018 ESC Guidelines for the management of cardiovascular diseases during pregnancy. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy340. By permission of Oxford University Press on behalf of the European Society of Cardiology.

All women with known cardiac or aortic disease who wish to become pregnant should receive prepregnancy counseling to facilitate informed maternal decision making. To assess maternal risk of cardiac complications during pregnancy, the ESC Task Force recommends the modified World Health Organization (mWHO) disease-specific risk classification tool. The general principles of the mWHO classification, and follow-up and management during pregnancy are presented in Table 2. Prepregnancy counseling as well as management during pregnancy and around delivery should be conducted in an expert centre by a multidisciplinary team – the pregnancy heart team – including a cardiologist, obstetrician, anaesthetist, and other specialists.

Peripartum cardiomyopathy (PPCM) is a rare condition that may cause severe complications in pregnancy. PPCM presents with HF secondary to left ventricular (LV)

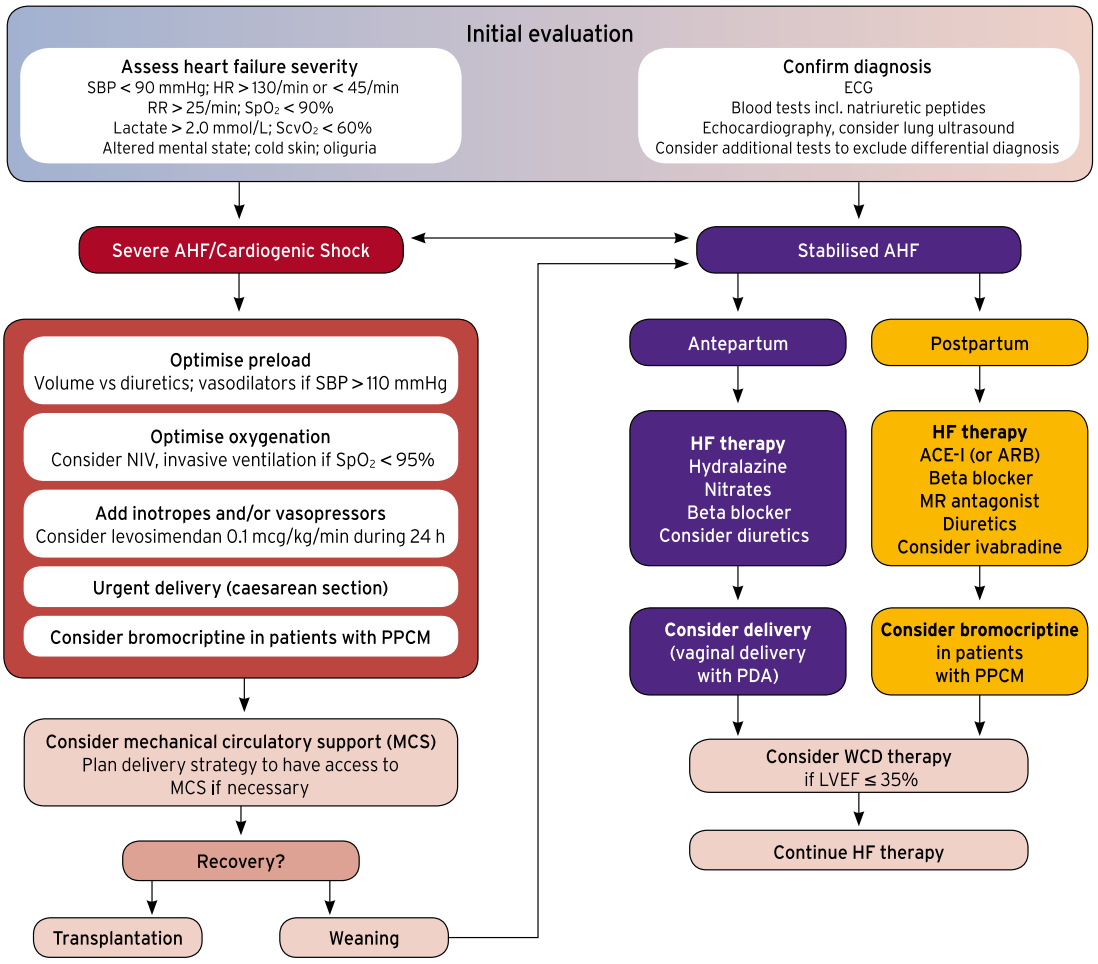
Table 2. Modified World Health Organization Classification of Maternal Cardiovascular Risk

	mWHO I	mWHO II	mWHO II–III	mWHO III	mWHO IV
Diagnosis (if otherwise well and uncomplicated)	Small or mild – pulmonary stenosis – patent ductus arteriosus – mitral valve prolapse Successfully repaired simple lesions (atrial or ventricular septal defect, patent ductus arteriosus, anomalous pulmonary venous drainage) Atrial or ventricular ectopic beats, isolated	Unoperated atrial or ventricular septal defect Repaired tetralogy of Fallot Most arrhythmias (supraventricular arrhythmias) Turner syndrome without aortic dilatation	Mild LV impairment (EF > 45%) Hypertrophic cardiomyopathy Native or tissue valve disease not considered WHO I or IV (mild mitral stenosis, moderate aortic stenosis) Marfan or other HTAD syndrome without aortic dilatation Aorta < 45 mm in bicuspid aortic valve pathology Repaired coarctation Atrioventricular septal defect	Moderate LV impairment (EF 30–45%) Previous peripartum cardiomyopathy without any residual LV impairment Mechanical valve Systemic right ventricle with good or mildly decreased ventricular function Fontan circulation. If otherwise the patient is well and the cardiac condition uncomplicated Unrepaired cyanotic heart disease Other complex heart disease Moderate mitral stenosis Severe asymptomatic aortic stenosis Moderate aortic dilatation (40–45 mm in Marfan syndrome or other HTAD; 45–50 mm in bicuspid aortic valve, Turner syndrome ASI 20–25 mm/m^2, tetralogy of Fallot < 50 mm) Ventricular tachycardia	Pulmonary arterial hypertension Severe systemic ventricular dysfunction (EF < 30% or NYHA class III–IV) Previous peripartum cardiomyopathy with any residual LV impairment Severe mitral stenosis Severe symptomatic aortic stenosis Systemic right ventricle with moderate or severely decreased ventricular function Severe aortic dilatation (> 45 mm in Marfan syndrome or other HTAD, > 50 mm in bicuspid aortic valve, Turner syndrome ASI > 25 mm/m^2, tetralogy of Fallot > 50 mm) Vascular Ehlers–Danlos Severe (re)coarctation Fontan with any complication
Risk	No detectable increased risk of maternal mortality and no/mild increased risk in morbidity	Small increased risk of maternal mortality or moderate increase in morbidity	Intermediate increased risk of maternal mortality or moderate to severe increase in morbidity	Significantly increased risk of maternal mortality or severe morbidity	Extremely high risk of maternal mortality or severe morbidity
Maternal cardiac event rate	2.5–5%	5.7–10.5%	10–19%	19–27%	40–100%
Counselling	Yes	Yes	Yes	Yes: expert counselling required	Yes: pregnancy contraindicated: if pregnancy occurs, termination should be discussed
Care during pregnancy	Local hospital	Local hospital	Referral hospital	Expert centre for pregnancy and cardiac disease	Expert centre for pregnancy and cardiac disease
Minimal follow-up visits during pregnancy	Once or twice	Once per trimester	Bimonthly	Monthly or bimonthly	Monthly
Location of delivery	Local hospital	Local hospital	Referral hospital	Expert centre for pregnancy and cardiac disease	Expert centre for pregnancy and cardiac disease

ASI, aortic size index; EF, ejection fraction; HTAD, heritable thoracic aortic disease; LV, left ventricular; mWHO, modified World Health Organization; NYHA, New York Heart Association.

Reprinted from Regitz-Zagrosek V et al. 2018 ESC Guidelines for the management of cardiovascular diseases during pregnancy. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy340. By permission of Oxford University Press on behalf of the European Society of Cardiology.

Figure 4. Management of Acute Heart Failure During/After Pregnancy



ACE-I, angiotensin-converting enzyme inhibitor; AHF, acute heart failure; ARB, angiotensin receptor blocker; ECG, electrocardiogram; HF, heart failure; HR, heart rate; LVEF, left ventricular ejection fraction; MCS, mechanical circulatory support; MR, mineralocorticoid receptor; NIV, non-invasive ventilation; PDA, peridural analgesia; PPCM, peripartum cardiomyopathy; RR, respiratory rate; SBP, systolic blood pressure; $ScvO_2$, central venous oxygen saturation; SpO_2, peripheral oxygen saturation; WCD, wearable cardioverter-defibrillator.

Reprinted from Regitz-Zagrosek V et al. 2018 ESC Guidelines for the management of cardiovascular diseases during pregnancy. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy340. By permission of Oxford University Press on behalf of the European Society of Cardiology.

systolic dysfunction towards the end of pregnancy and in the months following delivery. The use of bromocriptine has emerged as a new concept for the management of PPCM and HF in pregnancy in the 2018 guidelines. The addition of bromocriptine to standard HF therapy may be considered to stop lactation and improve LV recovery and clinical outcome in women with acute severe PPCM, and should be accompanied by anticoagulation therapy. Patients with symptoms and signs of acute heart failure (AHF) should be evaluated according to AHF guidelines, and the management goals are similar to non-pregnant HF while avoiding fetotoxic drugs during pregnancy (Figure 4).

For all CV drugs used in pregnancy, new and extensive safety data are included in the full 2018 guidelines update. The principles of drug treatment of CV diseases during pregnancy are outlined in Table 3.

Table 3. Recommendations for Drug Use in Pregnancy

Recommendations	Class[a]	Level[b]
Before pharmacological treatment in pregnancy is started, it is recommended to check full guidelines for clinical safety data.	I	C
In the absence of clinical safety data, it is recommended to check the electronic drug table (www.safefetus.com) for pre-clinical safety data.	I	C
In the absence of adequate human safety data, decision-making should be based on individual drug efficacy and safety profiles, and the available animal data, and the decision must be made together with the patient.	IIa	C
Decision-making based on former FDA categories alone is no longer recommended.	III	C

[a]Class of recommendation; [b]Level of evidence. FDA, US Food and Drug Administration.

Figure 5. Classification of Hypertension Stage According to Blood Pressure, Presence of Cardiovascular Risk Factors, Hypertension-mediated Organ Damage, or Comorbidities

Hypertension disease staging	Other risk factors, HMOD, or disease	BP (mmHg) grading			
		High normal SBP 130-139 DBP 85-89	Grade 1 SBP 140-159 DBP 90-99	Grade 2 SBP 160-179 DBP 100-109	Grade 3 SBP ≥ 180 or DBP ≥ 110
Stage 1 (uncomplicated)	No other risk factors	Low risk	Low risk	Moderate risk	High risk
	1 or 2 risk factors	Low risk	Moderate risk	Moderate to high risk	High risk
	≥ 3 risk factors	Low to Moderate risk	Moderate to high risk	High risk	High risk
Stage 2 (asymptomatic disease)	HMOD, CKD grade 3, or diabetes mellitus without organ damage	Moderate to high risk	High risk	High risk	High risk to very high risk
Stage 3 (established disease)	Established CVD, CKD grade ≥ 4, or diabetes mellitus with organ damage	Very high risk	Very high risk	Very high risk	Very high risk

BP, blood pressure; CKD, chronic kidney disease; CV, cardiovascular; DBP, diastolic blood pressure; HMOD, hypertension-mediated organ damage; SBP, systolic blood pressure; SCORE, Systematic Coronary Risk Evaluation.

Reprinted from Williams B et al. 2018 ESC/ESH Guidelines for the management of arterial hypertension. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy339. By permission of Oxford University Press on behalf of the European Society of Cardiology.

Management of Arterial Hypertension

The 2018 ESC/ESH Guidelines for the Management of Arterial Hypertension [Williams B et al. *Eur Heart J*. 2018] were developed in collaboration with the European Society of Hypertension (ESH) and presented by Guy De Backer, MD, PhD, University of Ghent, Belgium. An important shift in the 2018 guidelines is a move away from the sole use of repeat office blood pressure (BP) measurements for diagnosis, with promotion of the use of out-of-office ambulatory or home BP measurements for diagnosis, to detect white coat and masked hypertension, and to monitor BP control.

Global risk stratification is a key message of the 2018 guidelines. The management of hypertension requires formal CV risk assessment, which is recommended with the SCORE model. CV risk can be modified by other risk qualifiers, in particular by the presence of hypertension-mediated organ damage (previously termed 'target organ damage') which should be screened for in hypertensive patients (Figure 5).

For hypertension management, lifestyle adaptations are strongly recommended in all patients and drug treatment is based upon risk assessment and hypertension grade. The 2018 guidelines recommend a more aggressive drug-therapy regimen than the previous guidelines, particularly in the elderly where the biological rather than the chronological age should be considered. The treatment strategy should also take into account fitness, drug tolerance, and total CV risk (Figure 6).

The 2018 Task Force recommends a first treatment target to BP < 140/90 mm Hg in all patients, and if well-tolerated, treated BP should be targeted to ≤ 130/80 mm Hg in most patients, depending on a patient's age and comorbidities, although in some groups the evidence is less compelling. Regarding treatment selection, the 2018 guidelines make two new recommendations: to start treatment in most patients with 2 drugs not 1 (excluding an ACE + ARB combination), and the preferred use of single pill combination therapy to improve adherence to treatment. Detecting poor adherence is

Figure 6. Initiation of Blood Pressure-Lowering Treatment at Different Initial Office Blood Pressure Levels

strongly emphasised in the new guidelines; nurses and pharmacists should play a key role in patient education and support, which will facilitate adherence. More details on treatment and a new chapter on hypertension in specific circumstances can be found in the full 2018 guidelines.

Myocardial Revascularisation

The 2018 ESC/EACTS Guidelines on Myocardial Revascularization [Neumann F-J et al. *Eur Heart J*. 2018] were developed in collaboration with the European Association for Cardio-Thoracic Surgery (EACTS) with the special contribution of the European Association for Percutaneous Cardiovascular Interventions (EAPCI). New recommendations included in the 2018 guidelines are listed in Figure 7.

The guidelines overview was presented by William Wijns, MD, PhD, National University of Ireland, Galway, Ireland, who identified four essential take home messages of the 2018 guidelines:

1) Decision making for stented percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) should be based on combined evaluation of anatomy and physiology (non-invasive or invasive testing; Table 4).
2) Evaluation of the extent of coronary artery disease (CAD) by SYNTAX score (www.syntaxscore.com) is essential when choosing between revascularisation modalities (CABG or PCI).
3) The presence of diabetes is an important decision modifier by itself.
4) The probability of achieving complete revascularisation is of extreme prognostic importance.

Table 4. Aspects to be Considered by the Heart Team for Decision Making Between PCI and CABG Among Patients With Stable Multivessel and/or Left Main Coronary Artery Disease

	Favours PCI	Favours CABG
Clinical characteristics	- Presence of severe co-morbidity (not adequately reflected by scores) - Advanced age/frailty/ reduced life expectancy - Restricted mobility and conditions that affect the rehabilitation process	- Diabetes - Reduced LV function (EF ≤ 35%) - Contraindication to DAPT - Recurrent diffuse in-stent restenosis
Anatomical and technical aspects	- MVD with SYNTAX score 0–22 - Anatomy likely resulting in incomplete revascularisation with CABG due to poor quality or missing conduits - Severe chest deformation or scoliosis - Sequelae of chest radiation Porcelain aorta[a]	- MVD with SYNTAX score ≥ 23 - Anatomy likely resulting in incomplete revascularisation with PCI - Severely calcified coronary artery lesions limiting lesion expansion
Need for concomitant interventions		- Ascending aortic pathology with indication for surgery - Concomitant cardiac surgery

[a]Consider no-touch off-pump CABG in case of porcelain aorta.
CABG, coronary artery bypass grafting; DAPT, dual antiplatelet therapy; EF, ejection fraction; LV, left ventricular; MVD, multivessel coronary artery disease; PCI, percutaneous coronary intervention; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

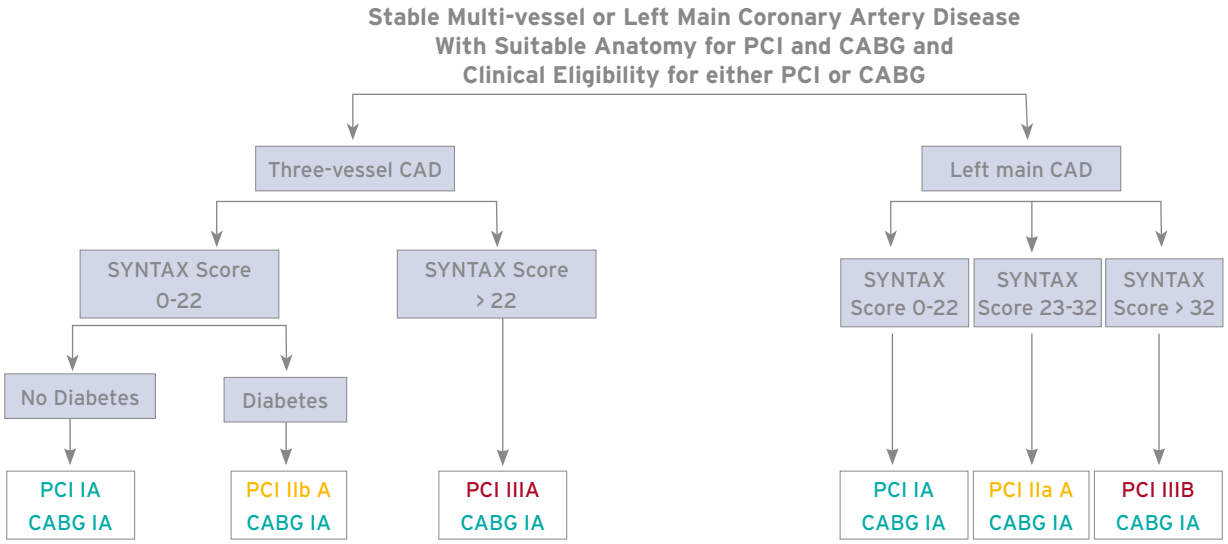
Figure 8. Algorithm to Guide the Choice of Revascularisation Procedure Across Major Categories in Patients With Multivessel or Left Main Coronary Artery Disease



Class recommendations correspond to the 2018 ESC/EACTS Guidelines on Myocardial Revascularization.
CABG, coronary artery bypass grafting; CAD, coronary artery disease; PCI, percutaneous coronary intervention; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

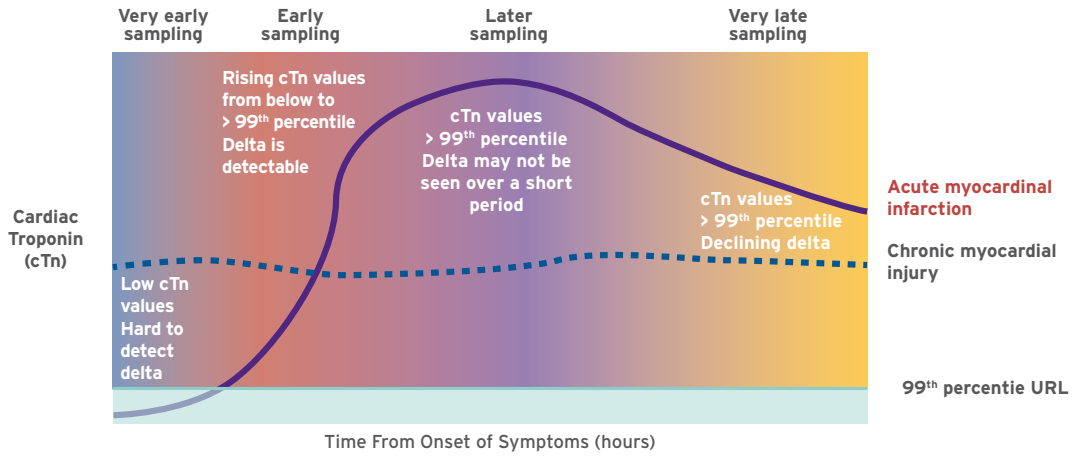
Reprinted from Windecker S et al. Considerations for the choice between CABG and PCI as revascularisation strategies in major categories of patients with stable multivessel coronary artery disease. *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy532. By permission of Oxford University Press on behalf of the European Society of Cardiology.

Considerations for the choice between CABG and PCI as revascularization strategies are further discussed by Windecker et al. in an article accompanying the 2018 guidelines [Windecker S et al. *Eur Heart J*. 2018]. This article expands upon the guidelines chapter on revascularisation in stable CAD and presents an algorithm to guide choice of revascularisation (Figure 8).

Universal Definition of Myocardial Infarction

The Fourth Universal Definition of MI (2018) [Thygesen K et al. *Eur Heart J*. 2018] was developed by a joint Task Force of the ESC, American College of Cardiology (ACC), American Heart Association (AHA), and World Heart Federation (WHF), and was presented by David Hasdai, MD, Rabin Medical Center, Tel Aviv, Israel. One of the key reasons for the Fourth Universal Definition of MI document is the introduction and adoption of high-sensitivity troponin assays to define MI. A chapter identifies strict technical criteria on the use of troponin assays, highlights caveats and advantages of their use, and discusses troponin level kinetics and the influence of timing on assay measurement (Figure 9).

Figure 9. Early Cardiac Troponin Kinetics in Patients After Acute Myocardial Injury Including Acute Myocardial Infarction



cTn, cardiac troponin; URL, upper reference limit.

Reprinted from Thygesen K et al. Fourth universal definition of myocardial infarction (2018). *Eur Heart J*. 2018. doi:10.1093/eurheartj/ehy462. By permission of Oxford University Press on behalf of the European Society of Cardiology.

An important new concept in the Fourth Universal Definition of MI is the differentiation between myocardial injury and MI, which is defined in Table 5. There are many conditions that lead to increased troponin level denoting myocardial injury (e.g., HF, CM). Only when there is clinical evidence of myocardial ischaemia and myocardial injury can MI be diagnosed. Figure 10 provides a model for interpretation of myocardial injury versus MI in clinical scenarios. The Fourth Universal Definition of MI includes further details on the differentiation between type 1 MI and type 2 MI, which is a cause of some confusion in clinical practice. A framework is provided for determining type 2 MI considering the clinical context and mechanisms attributable to acute MI.

The Fourth Universal Definition of MI includes a chapter on the use of imaging techniques that can be employed to diagnose and characterise myocardial injury and MI. For example, magnetic resonance imaging can detect evidence of scarring which is apparent in MI, but can also be used to rule out a diagnosis of MI and identify other causes of myocardial injury (e.g., Takotsubo syndrome, AF); these other scenarios are discussed in new sections in the Fourth Universal Definition of MI.

Table 5. Universal Definitions of Myocardial Injury and Myocardial Infarction

Criteria for Myocardial Injury
The term myocardial injury should be used when there is evidence of elevated cardiac troponin values (cTn) with at least one value above the 99th percentile upper reference limit (URL). The myocardial injury is considered acute if there is a rise and/or fall of cTn values.
Criteria for Acute Myocardial Infarction (types 1, 2 and 3 MI)
The term acute myocardial infarction should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischaemia and with detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL and at least one of the following: • Symptoms of myocardial ischaemia; • New ischaemic electrocardiogram (ECG) changes; • Development of pathological Q waves; • Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology; • Identification of a coronary thrombus by angiography or autopsy (not for types 2 or 3 MIs). Post-mortem demonstration of acute athero-thrombosis in the artery supplying the infarcted myocardium meets criteria for type 1 MI. Evidence of an imbalance between myocardial oxygen supply and demand unrelated to acute athero-thrombosis meets criteria for type 2 MI. Cardiac death in patients with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes before cTn values become available or abnormal meets criteria for type 3 MI.
Criteria for Coronary Procedure-related Myocardial Infarction (types 4 and 5 MI)
Percutaneous coronary intervention (PCI) related MI is termed type 4a MI. Coronary artery bypass grafting (CABG) related MI is termed type 5 MI. Coronary procedure-related MI ≤ 48 hours after the index procedure is arbitrarily defined by an elevation of cTn values > 5 times for type 4a MI and > 10 times for type 5 MI of the 99th percentile URL in patients with normal baseline values. Patients with elevated pre-procedural cTn values, in whom the pre-procedural cTn level are stable (≤ 20% variation) or falling, must meet the criteria for a > 5 or > 10 fold increase and manifest a change from the baseline value of > 20%. In addition with at least one of the following: • New ischaemic ECG changes (this criterion is related to type 4a MI only); • Development of new pathological Q waves; • Imaging evidence of loss of viable myocardium that is presumed to be new and in a pattern consistent with an ischaemic aetiology; • Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or graft, side-branch occlusion-thrombus, disruption of collateral flow or distal embolisation. Isolated development of new pathological Q waves meets the type 4a MI or type 5 MI criteria with either revascularisation procedure if cTn values are elevated and rising but less than the pre-specified thresholds for PCI and CABG. Other types of 4 MI include type 4b MI stent thrombosis and type 4c MI restenosis that both meet type 1 MI criteria. Post-mortem demonstration of a procedure-related thrombus meets the type 4a MI criteria or type 4b MI criteria if associated with a stent.
Criteria for Prior or Silent/Unrecognised Myocardial Infarction
Any one of the following criteria meets the diagnosis for prior or silent/unrecognised MI: • Abnormal Q waves with or without symptoms in the absence of non-ischaemic causes. • Imaging evidence of loss of viable myocardium in a pattern consistent with ischaemic aetiology. • Patho-anatomical findings of a prior MI.

No Advantage of Early Invasive Strategy in NSTE-ACS

Written by **Michiel Tent**

Very early invasive coronary evaluation, within 12 hours, does not improve overall long-term clinical outcomes compared with an invasive strategy conducted within 2-3 days in patients with non-ST-segment elevation acute coronary syndrome (NSTE-ACS). In patients with the highest risk, however, very early invasive therapy improves long-term outcomes.

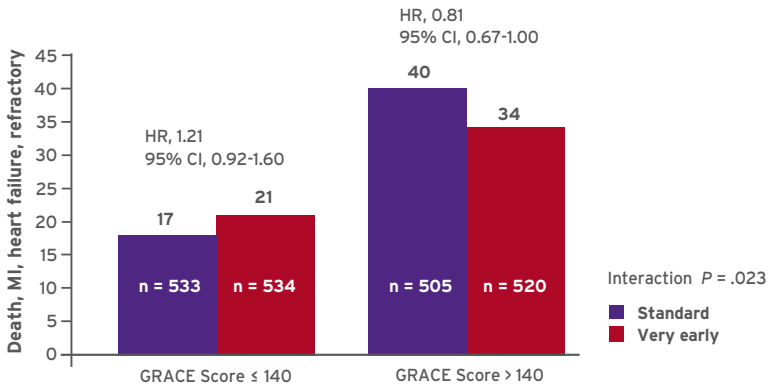
Current guidelines recommend invasive angiography within 24 hours in high-risk patients with NSTE ACS. European Society of Cardiology guidelines define high-risk as a GRACE score > 140, a rise in troponin, or ECG with ischaemia. However, the ideal timing of invasive angiography and revascularisation is unclear. The Very EaRly vs Deferred Invasive evaluation using Computerized Tomography [VERDICT; Kofoed KF et al. *Circulation*. 2018] trial was designed to test the hypothesis that very early invasive coronary angiography (ICA) and possible revascularisation within 12 hours of diagnosis is superior, in terms of clinical outcomes, to an invasive strategy performed within 48-72 hours in patients with NSTE-ACS.

Eligible for inclusion were patients with clinical suspicion of NSTE ACS, electrocardiogram changes indicating new ischaemia, and/or elevated troponin. Excluded were patients with ST-segment elevation myocardial infarction (STEMI) or very high-risk non-STEMI ACS. Participants were randomised 1:1 to coronary angiography within 12 hours of diagnosis (the very early group) or 48-72 hours after diagnosis (the deferred group). Percutaneous coronary intervention (PCI) was the preferred revascularisation strategy; patients not feasible for PCI were allowed coronary artery bypass graft (CABG) surgery. The primary endpoint was a composite of all-cause death, non-fatal recurrent myocardial infarction (MI), hospital admission for refractory myocardial ischaemia, or hospital admission for heart failure.

Thomas Engstrøm, DMSci, PhD, Rigshospitalet, University of Copenhagen, Denmark, presented the results for the 2,147 patients who were randomised. Thirty-two percent had no significant coronary artery disease (CAD). A quarter of patients presented with at least one occluded artery. In the very early group, time to angiography was a median of 4.7 hours compared with 61.6 hours after randomisation in the deferred group. Among patients with significant CAD identified by ICA, revascularisation was performed slightly more often in the very early group (88.4% vs 83.1%).

After a median follow-up of 4.3 years, the composite primary endpoint occurred in 296 patients (27.5%) in the very early group and in 316 (29.5%) in the deferred group (HR, 0.92; 95% CI, 0.78 to 1.08; *P* = .29). Prof. Engstrøm added that in high-risk patients (GRACE score > 140; n = 1,025) a very early invasive treatment strategy lowered the risk of reaching the primary outcome (HR, 0.81; 95% CI, 0.67 to 1.00; *P* for interaction = .023; Figure 1). Risk of nonfatal MI, one of the secondary outcomes, was also significantly lower in the very early group (8.4% vs 11.2%; HR, 0.73; 95% CI, 0.56 to 0.96; *P* = .025); these findings, however, were only hypothesis-generating.

Figure 1. Primary Endpoint Results According to GRACE Risk Score



Reproduced with permission from T Engstrøm, DMSci, PhD.

Prof. Engstrøm observed that very early invasive angiography is feasible, but logistically challenging and possibly not cost effective. It should, however, be performed in patients that present with symptoms of ACS, elevated troponin, and a high GRACE risk score.

Higher Mortality With FFR-Guided Treatment Choice of Multivessel Disease

Written by **Michiel Tent**

Final results of the FUTURE [FUnctional Testing Underlying Revascularization; NCT0188155] trial showed that the use of fractional flow reserve (FFR) to guide treatment choice in all-comer patients with multivessel disease was associated with more than double the risk of mortality after one year despite decreasing the rate of revascularisation.

Gilles Rioufol, MD, PhD, Hospital Louis Pradel, Bron, France, presented the results and noted that the use of FFR is recommended in the current guidelines for guiding percutaneous coronary intervention (PCI) in patients with multivessel disease who are eligible for PCI [Windecker S et al. *Eur Heart J*. 2014]. The trial was conducted to verify whether FFR may aid in the decision between different treatment strategies – PCI, coronary artery bypass grafting (CABG), or optimal medical treatment (OMT) only – and thereby improve clinical prognosis compared with traditional management.

FUTURE was a multicentre, randomised, prospective, open-label, controlled study in 31 French centres. The primary composite endpoint was all-cause mortality, myocardial infarction (MI), repeat revascularisation, or stroke at one year. Patients with either stable angina or stabilised acute coronary syndrome (ACS) and multivessel disease (> 50% stenosis) were eligible for the study. Eligible patients were randomised to either FFR or angiography. A total of 1,728 patients were to be enrolled, but the trial was prematurely halted after 938 patients had been randomised because of higher rates of all-cause mortality in the FFR group.

Of 938 randomised participants, 31% presented with diabetes, 20% with a history of MI, and 46% with ACS, while 52% had three significant lesions. The average SYNTAX score was 19 in the FFR-guided group and 18 in the angiography-guided group. Overall, 470 of 1,090 lesions (43%) evaluated by FFR had a reading above 0.80.

Prof. Rioufol said global results showed that use of FFR resulted in a lower rate of PCI than did angiography (71% vs 79%; *P* = .002) and in a higher rate of OMT alone (17% vs 9%). The rate of ad hoc PCI was 91% and 90%, respectively. CABG was used in only 12% of patients in both arms.

At 1 year, there was no significant difference in the primary composite endpoint of all-cause mortality, MI, repeat revascularisation, or stroke at 1 year between the FFR- and the angiography-guided group (HR, 0.97; 95% CI, 0.69 to 1.36; *P* = .85) or 2 years (HR, 0.99; 95% CI, 0.75 to 1.30; *P* = .93). In a subgroup analysis, the risk of the primary endpoint was higher in patients randomised to FFR-guided strategy who had a Syntax Score > 32 (HR, 3.32; 95% CI, 0.66 to 16.84) or stable angina (HR, 2.31; 95% CI, 1.02 to 5.22). A safety analysis revealed the risk of all-cause mortality at 1 year was significantly higher in the FFR group (HR, 2.39; 95% CI, 1.05 to 5.43; *P* = .038), after which the trial was prematurely halted; notably, this was not procedure-related.

Prof. Rioufol hypothesised that three factors may explain the excess mortality in the FFR-guided group, including the lower-than-expected rate of CABG in a population of multivessel disease patients; the high rate of PCI in severe patients with a SYNTAX score > 32; and the high rate of ad hoc PCI.

Gastrointestinal and Genitourinary Bleeding May Predict Underlying Cancer

Written by **Phil Vinall**

New data from the COMPASS trial indicates that increased gastrointestinal (GI) and genitourinary (GU) bleeding in patients treated with antithrombotic drugs is associated with GI and GU cancer diagnoses.

GI and GU bleeding may be the first sign of an underlying cancer [Jones R et al. *BMC*. 2007; Ford AC et al. *Gut*. 2008]. In the COMPASS trial, treatment with rivaroxaban compared with aspirin was associated with increased GI, but not GU bleeding [Eikelboom JW et al. *N Engl J Med*. 2017]. Using data from COMPASS, John W. Eikelboom, MD, McMaster University, Hamilton, Ontario, Canada, sought to determine whether GI and GU bleeding were associated with increased rates of new cancer diagnoses in patients treated with rivaroxaban.

The COMPASS trial included 27,395 patients with stable coronary or peripheral arterial disease who were randomised to treatment with rivaroxaban 2.5 mg twice daily plus aspirin, 5 mg rivaroxaban, or 100 mg once daily aspirin. Bleeding was defined according to the International Society of Thrombosis and Haemostasis (ISTH) criteria. A new cancer diagnosis was defined as first-ever, or recurrent cancer from a previous diagnosis in patients whose cancer had been thought to have

been eradicated. The proportion of new cancers before and after bleeding, the association between bleeding and new cancer diagnosis, and rates of cancer diagnosis according to randomised treatment were analysed.

In all, 1,082 new cancers were diagnosed during the trial; 257 (23.8%) of these were diagnosed after bleeding (70 were GI cancers and 62 were GU cancers). There was a significant association between GI bleeding and new GI cancers (HR, 12.9; 95% CI, 9.77 to 17.0; *P* < .0001). There was also a significant, but much weaker, association between non-GI bleeding and new GI cancers (HR, 1.77; 95% CI, 1.20 to 2.61; *P* = .004). A highly significant association was also noted between GU bleeding and new GU cancers (HR, 83.4; 95% CI, 58.6 to 118.6; *P* < .0001). The association between non-GU bleeding and new GU cancers was not significant.

The majority of new GI (77.1%) and GU (88.7%) cancers diagnosed after bleeding occurred within 6 months of the bleed. Rivaroxaban-based treatments compared with aspirin increased GI bleeding within the first year, but not in the second or third year, and this was accompanied by an increase in the number of GI cancers diagnosed after bleeding in the first year, but not in the second or third (Table 1).

Table 1. Frequency of GI Cancer After GI Bleeding in Year 1, 2, and 3+

Year	Rivaroxaban 2.5 mg bid + ASA 100 mg od n (%)	Rivaroxaban 5 mg bid n (%)	Aspirin 100 mg bid n (%)
1	22/268 (8.2%)	18/216 (8.3%)	8/114 (7.0%)
2	6/72 (8.3%)	6/81 (7.4%)	5/58 (8.6%)
3+	1/34 (2.9%)	2/29 (6.9%)	2/29 (6.9%)

GI, gastrointestinal.

Among COMPASS patients with vascular disease on long-term antithrombotic therapy, more than 1 in 5 new diagnoses of all cancers were preceded by bleeding and more than 75% of these cancers were diagnosed within 6 months of the bleed. This suggests that GI and GU bleeding are powerful predictors GI and GU cancer diagnosis. An early increase in GI bleeding with antithrombotic treatments appears to be associated with earlier diagnosis of GI cancer.

Prof. Eikelboom suggests that physicians detecting the occurrence of GI or GU bleeding in patients receiving antithrombotic drugs should lead to expedient evaluation for cancer in the same organ. Extended follow-up of COMPASS trial participants may help to determine whether earlier diagnosis of GI cancer in patients with GI bleeding improves cancer outcomes.

Coronary CT Angiography Reduces 5-Year Risk of Myocardial Infarction

Written by **Michiel Tent**

In patients with stable chest pain, coronary computed tomographic angiography (CTA)-guided management reduced 5-year coronary heart disease (CHD) death or non-fatal myocardial infarction (MI) compared with standard care alone in the Scottish Computed Tomography of the Heart trial [SCOT-HEART trial; Newby DE et al. *N Engl J Med*. 2018]. The final clinical outcomes were presented by David E Newby, MD, PhD, University of Edinburgh, United Kingdom.

Coronary CTA improves diagnostic certainty in the assessment of patients with stable chest pain, but its effect on 5-year clinical outcomes was unknown. The SCOT-HEART trial was designed to determine the longer-term effect of CTA on investigations, treatments, and clinical outcomes. The trial had an open-label, multicentre, parallel-group design. Eligible for inclusion were patients aged 18 to 75 years with stable chest pain who had been referred by a primary care physician to an outpatient cardiology clinic. A total of 4,146 patients from 12 Scottish cardiology centres were included. Following routine clinical evaluation, they were randomly assigned to either standard care plus CTA (n = 2,073) or standard care alone (n = 2,073). Clinical endpoints included death (cardiovascular [CV] death, non-CV death, death from CHD, and death from any cause), MI, and stroke. The primary endpoint was death from CHD or nonfatal MI at 5 years.

The median duration of follow-up was 4.8 years, comprising a total of 20,254 patient-years. The rate of the primary long-term endpoint was significantly lower in the CTA group than in the standard-care group (2.3% [n = 48] vs 3.9% [n = 81]; HR, 0.59; 95% CI, 0.41 to 0.84; *P* = .004). This difference was driven primarily by a lower rate of nonfatal MI in the CTA group (HR, 0.60; 95% CI, 0.41 to 0.87). There were no significant differences in non-CV death or deaths from any cause.

The rates of invasive coronary angiography (ICA) and coronary revascularisation were higher in the CTA group than in the standard-care group in the first few months of follow-up. At 5 years however, overall rates were similar. ICA was performed in 491 patients in the CTA group and in 502 patients in the standard-care group (HR, 1.00; 95% CI, 0.88 to 1.13). Coronary revascularisation was performed in 279 patients in the CTA group and in 267 in the standard-care group (HR, 1.07; 95% CI, 0.91 to 1.27). Beyond the first year analysis, patients assigned to CTA had lower rates of ICA (HR, 0.70; 95% CI, 0.52 to 0.95), and of coronary

revascularisation (HR, 0.59; 95% CI, 0.38 to 0.90). In the CTA group, more preventive therapies were initiated (OR, 1.40; 95% CI, 1.19 to 1.65), as well as more antianginal therapies (OR, 1.27; 95% CI, 1.05 to 1.54).

Prof. Newby concluded that, in this trial, CTA in addition to standard care in patients with stable chest pain resulted in a significantly lower rate of death from CHD or nonfatal MI at 5 years than standard care alone, without resulting in a significantly higher rate of coronary angiography or coronary revascularisation. Early increases in ICA and coronary revascularisation were offset by lower rates beyond 1 year. Benefits seem to be attributable to better targeted preventive therapies and coronary revascularisation.

Ticagrelor Monotherapy Beyond 1 Month No Better Than Standard Dual Antiplatelet Therapy After Stenting

Written by **Constance de Koning**

Discontinuing aspirin after 1 month continuing monotherapy with ticagrelor is no better than standard dual antiplatelet therapy (DAPT) in patients undergoing percutaneous coronary intervention (PCI) for acute coronary syndromes (ACS) or stable coronary artery disease (CAD), according to the results of the GLOBAL LEADERS study [Vranckx P et al. *Lancet*. 2018] presented by Patrick W. Serruys, MD, PhD, Erasmus Medical Center, Rotterdam, the Netherlands.

In this multicentre, open-label, superiority trial, a total of 15,968 patients who underwent PCI with a biolimus A9-eluting stent for stable CAD or ACS were randomised to either 75-100 mg aspirin daily plus 90 mg ticagrelor twice daily for 1 month, followed by 23 months of ticagrelor monotherapy (n = 7,988), or standard DAPT with 75-100 mg aspirin daily plus either 75 mg clopidogrel daily (in patients with stable CAD) or 90 mg ticagrelor twice daily (in patients with ACS) for 12 months, followed by aspirin monotherapy for 12 months (n = 7,980). The composite primary endpoint was the cumulative incidence of all-cause death or new Q-wave myocardial infarction (MI) within 2 years; the secondary endpoint was the rate of moderate or severe bleeding (BARC criteria 3 or 5) over the 2-year period.

At 12 months, all-cause mortality or new Q-wave MI was 1.95% in the ticagrelor group versus 2.47% in the standard DAPT group (risk ratio [RR], 0.79; 95% CI, 0.64 to 0.98; *P* = .028; Table 1).

Table 1. Primary and Secondary Outcomes at 12 Months (ITT)

	Experimental group	Reference group	Risk Ratio (95% CI)	*P*-value
Number of patients	n = 7,980	n = 7,988		
All-cause mortality or new Q-wave MI	1.95% (156)	2.47% (197)	0.79 (0.64-0.98)	.028
All-cause mortality	1.35% (108)	1.64% (131)	0.82 (0.64-1.06)	.138
New Q-wave MI	0.60% (48)	0.86% (69)	0.70 (0.48-1.00)	.052

ITT, intent-to-treat; MI, myocardial infarction.

At 24 months, all-cause mortality or new Q-wave MI was 3.81% for ticagrelor versus 4.37% for standard DAPT (RR, 0.87; 95% CI; 0.75 to 1.01; *P* = .073; Table 2).

Table 2. Primary and Secondary Outcomes at 24 Months (ITT)

	Experimental group	Reference group	Risk Ratio (95% CI)	*P*-value
Number of patients	n = 7,980	n = 7,988		
All-cause mortality or new Q-wave MI	3.81% (304)	4.37% (349)	0.87 (0.75-1.01)	.073
All-cause mortality	2.81% (224)	3.17% (253)	0.88 (0.74-1.06)	.18
New Q-wave MI	1.04% (83)	1.29% (103)	0.80 (0.60-1.07)	.14

ITT, intent-to-treat; MI, myocardial infarction.

Major bleeding (BARC 3 or 5) was observed in 2.04% of patients who received aspirin for 1 month and extended ticagrelor and in 2.12% of patients treated with conventional DAPT (RR, 0.97; 95% CI, 0.78 to 1.20; *P* = .767).

Although the rate of serious adverse events did not differ significantly between the two groups, according to Prof. Serruys, adherence may have compromised the assessment of superiority, as in the second year of treatment 78% of ticagrelor patients were adherent versus 93% in the reference group. Investigator reporting was used without central adjudication on the secondary outcomes, so it is possible that bias or misclassification could have occurred. Additionally, the unexpected lower rate of all-cause mortality and the composite primary endpoint limits the predictive power of the study. In conclusion, ticagrelor plus low-dose aspirin for 1 month followed by 23 months of ticagrelor monotherapy was not superior in reducing the 2-year rates of all-cause mortality and non-fatal, new Q-wave MI compared with 12 months of standard DAPT followed by aspirin monotherapy in patients who underwent PCI.

Reproduced with permission from JE Poole, MD.

Ablation Reduced Recurrent Arrhythmias Compared With Drug Therapy in AF Patients

Written by **Michiel Tent**

In the CABANA trial, catheter ablation was associated with a significant relative risk reduction of around 50% in recurrence of atrial arrhythmias in patients with atrial fibrillation (AF) compared with drug therapy. AF was the dominant first recurrent rhythm after the 90-day blanking period during the 5 years of follow-up.

The results of this secondary analysis of the CABANA trial focusing on the recurrence of atrial arrhythmias were presented by Jeanne Poole, MD, University of Washington Medical Center, Seattle, Washington, USA. The single-blind CABANA trial randomised 2,204 symptomatic patients with paroxysmal or persistent AF 1:1 to percutaneous left atrial catheter ablation or medical therapy. Patients aged ≥ 65 years or < 65 years with > 1 risk factor for stroke who were eligible for both ablation and ≥ 2 rhythm or rate controlling drugs were followed for a median of 4 years [Packer DL et al. *Am Heart J*. 2018]. The primary composite endpoint of death, disabling stroke, serious bleeding, or cardiac arrest was not significantly reduced with ablation (HR, 0.86; 95% CI, 0.65 to 1.15; *P* = .30) [Packer DL. HRS 2018 Scientific Sessions].

The current analysis reported rates of recurrent atrial arrhythmias using electrocardiographic monitoring every 3 months (monitoring duration alternated between 24 hours and 96 hours each 3-month period). In CABANA, a 2-channel recording system was used for electrocardiogram monitoring by 86% of enrolling sites, while the remaining centres employed other heart rhythm monitoring systems. Endpoint-determining rhythms (EDR) were defined as: AF, atrial flutter (AFL), or atrial tachycardia (AT) lasting ≥ 30 seconds.

The hazard ratios of a first episode after 90 days of blanking in 1,240 patients with a CABANA recorder in patients randomised to AF ablation versus drug therapy were 0.52 (95% CI, 0.45 to 0.60; *P* < .001) for recurrent AF and 0.53 (95% CI, 0.46 to 0.62; *P* < .001) for the combined outcome of AF, AFL, and AT. In 803 patients without a CABANA recorder, the results similarly favoured the ablation group (HR 0.50 and 0.56, respectively). Ablation was associated with a significant reduction across the 5 years of therapy in cumulative first recurrence event rate, again after 90 days of blanking (Figure 1). There were no reductions in the rates of AFL and AT by treatment strategy (HR, 1.08; 95% CI, 0.83 to 1.39; *P* = .58); only the outcome of recurrent AF was reduced by ablation (HR, 0.53; 95% CI, 0.46 to 0.62; *P* < .001). The average AF burden as assessed by biannual 96-hour Holter monitoring was also found to be significantly lower in the ablation group across all 5 years of treatment (*P* < .0001). These findings were significant regardless of the baseline pattern of AF, paroxysmal or persistent/long-standing persistent AF.

Looking to the future, Prof. Poole noted that this large base of rhythm data provides a foundation for addressing many other important questions with respect to recurrent arrhythmias and treatment of patients with AF.

CAMELLIA-TIMI 61 Established Cardiovascular Safety of Lorcaserin

Written by **Constance de Koning**

Adding lorcaserin to diet and exercise resulted in sustained weight loss compared with placebo without increasing the risk for major adverse cardiovascular events (MACE) in the CAMELLIA-TIMI 61 study [Bohula EA et al. *N Engl J Med*. 2018], presented by Erin A. Bohula, MD, Brigham and Women's Hospital, Boston, Massachusetts, USA.

Weight loss is an important factor when improving cardiovascular (CV) risk factors, but thus far there have been no agents with proven CV safety. In clinical trials, lorcaserin, a selective agonist of the 5HT-2C receptor, has shown efficacy for weight loss, but its CV safety had not been tested.

Twelve-thousand overweight and obese patients were included in this is multicentre, randomised, double-blind, placebo-controlled, parallel-group study. Patients who had established CV disease or CV risk factors, such as type 2 diabetes, and a median baseline body mass index of 35 mg/kg^2 were randomised 1:1 to receive lorcaserin 10 mg twice daily or placebo. Median follow-up was 3.3 years. The primary CV efficacy endpoint was MACE+ (i.e., MACE, hospitalisation for heart failure, unstable angina, or coronary revascularisation). The primary CV safety endpoint was MACE (i.e., CV death, myocardial infarction, or cerebrovascular accident).

A total of 98% of patients in the lorcaserin group and 97% in the placebo group completed the study. Weight loss achieved with lorcaserin was on average 4.2 kg after 1 year versus 1.4 kg for placebo; a between group difference of 2.8 kg (P < .001). At 1 year, 38.7% of patients on lorcaserin had ≥ 5% weight loss compared with 17.4% of those on placebo (OR, 3.01; 95% CI, 2.74 to 3.30; P < .001). Ten percent weight loss or more was achieved by 14.6% and 4.8% of patients, respectively (OR, 3.40; 95% CI, 2.92 to 3.95; P < .001). Weight loss with lorcaserin was sustained over time and remained significant up to 3.3 years.

At 3.3. years, MACE occurred in 6.1% of the lorcaserin-treated patients and 6.2% of patients treated with placebo (HR, 0.99; 95% CI, 0.85 to 1.14; P < .001 for non-inferiority ; Figure 1A). The composite of MACE+ occurred in 707 patients (12.8%, or 4.1% per year) in the lorcaserin group and in 727 (13.3% or 4.2% per year) in the placebo group (HR, 0.97; 95% CI, 0.87 to 1.07; P =.55; Figure 1B).

Adverse events considered to be possibly related to the study drug lead to discontinuation in 7.2% of lorcaserin patients versus 3.7% of placebo patients. The most commonly reported adverse events leading to discontinuation in the lorcaserin group were dizziness, fatigue, headache, diarrhea, and nausea. Lorcaserin seemed to have a favourable effect on glycaemia although it was suggested this may be due to the achieved weight loss.

These findings support using lorcaserin as an adjunct to lifestyle modification for long-term weight management, even in high-risk CV patients. However, whether this new therapy is a cost-effective and sustainable approach to achieving a modest degree of weight loss without additional CV benefit compared with lifestyle changes or bariatric surgery remains to be seen.

Figure 1. Major Adverse Cardiac Outcomes

Percutaneous Mitral Valve Repair Is Safe in Patients With Secondary Mitral Regurgitation but Does Not Improve Outcomes

Written by **Phil Vinall**

Results from the MITRA.fr study show that percutaneous mitral valve repair is as safe as optimal medical treatment (OMT) but does not reduce death or unplanned hospitalisation for heart failure (HF) in patients with secondary mitral regurgitation (MR). The data were presented by Jean-Francois Obadia, MD, PhD, Civils Hospices of Lyon, France [Obadia JF et al. *N Engl J Med*. 2018]

The MITRA.fr study was a national, multicentre, investigator-initiated, open-label, randomised trial. The objective was to evaluate the clinical efficacy and safety of percutaneous mitral valve repair using the MitraClip system plus OMT versus OMT alone in patients with severe symptomatic secondary MR contraindicated for surgical repair. Patients were randomly assigned to receive the MitraClip plus OMT (n = 152) or OMT alone (n = 152). The primary endpoint was a composite of all-cause mortality or unplanned hospitalisations for HF at 12 months after randomisation.

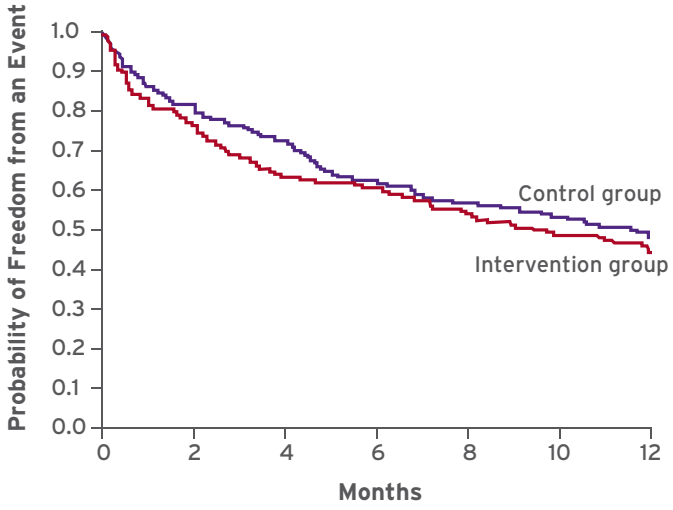
Eligibility requirements included: age > 18 years; NYHA class ≥ II; ≥ 1 hospitalisation for HF within 12 months preceding randomisation; severe secondary MR with an effective regurgitant orifice > 20 mm^2 or regurgitant volume > 30 mL/beat and left ventricular ejection fraction between 15% and 40%. Patients considered eligible for mitral surgery intervention according to the Heart Team and those having a Corelab assessment outside of the predefined parameters were excluded.

The per-protocol analysis includes 109 patients in the MitraClip group and 137 in the OMT group. Participants were a mean age of 70 years (> 75% male). Sixty percent had ischaemic cardiomyopathy and 2/3 were either NYHA Class III or IV. Mean ejection fraction was 33%; mean effective regurgitation orifice area was 31 mm^2; and mean systolic blood pressure was 108.5 mm Hg. The majority of participants were being treated with diuretics, beta blockers, angiotensin-converting enzyme inhibitors/angiotensin receptor blockers and/or a mineralocorticoid receptor antagonist.

The rate of the primary outcome of all-cause death or unplanned rehospitalisation for HF did not differ significantly between the two groups (54.6% for patients who received the MitraClip plus OMT vs 51.3% for those who received OMT only). There were also no differences in the components or within the intention-to-treat or per-protocol analysis (OR, 1.16; 95% CI, 0.73 to 1.84; *P* = .53; Figure 1).

Implantation was successful in 96% of patients. The mortality rate at 1-year was similar for the two groups (24.3% and 22.4%, in the intervention and control groups, respectively). There were no periprocedural incidents of urgent conversion to heart surgery or periprocedural mortality at 3 days. Vascular complications requiring surgery or haemorrhage resulting in transfusion occurred in 3.5% of patients; 1.4% had a cardiac embolism or tamponade. MR grade improved in the

Figure 1. Primary Composite Endpoint



No. at Risk							
Control group	152	123	109	94	86	80	73
Intervention group	151	114	95	91	81	73	67

MitraClip group at discharge and was maintained at 12 months. NYHA class improved significantly in both groups for the majority of patients (from Class II and III at baseline to Class I and II at discharge; $P < .001$).

Percutaneous correction of secondary MR with the MitraClip system is safe but does not improve patient outcomes when compared with OMT. The effectiveness of earlier intervention in a more selected sub-group of patients remains to be explored.

Rivaroxaban Does not Reduce the Composite of Death, MI or Stroke in Heart Failure Patients

Written by **Constance de Koning**

Patients with heart failure are at heightened risk of adverse cardiovascular (CV) events including thromboembolic complications such as stroke [Cleland JGF et al. *Am Heart J*. 2004; Massie BM et al. *Circulation*. 2009; Homma S et al. *N Engl J* Med. 2012; Zannad F et al. *Eur J Heart Fail*. 2015]. Low-dose rivaroxaban (2.5 mg) has been shown to reduce CV death, myocardial infarction (MI), and stroke in patients with acute coronary syndromes (ACS) and in selected high-risk patients with stable coronary artery disease (CAD) when added to antiplatelet agents, according to Faiez Zannad, MD, Université de Lorraine, Nancy, France.

It was hypothesised that the addition of rivaroxaban 2.5 mg twice daily to background antiplatelet therapy would reduce risk of major adverse CV events in patients with recent worsening of congestive heart failure (CHF) and underlying CAD compared with placebo.

The Rivaroxaban in Patients with Heart Failure, Sinus Rhythm, and Coronary Disease trial [COMMANDER HF; Zannad F et al. *N Eng J Med*. 2018] was a randomised, double-blind, parallel-group, event-driven, multicentre study. The primary efficacy outcome was the composite of all-cause mortality, MI or stroke following a HF event. The principal safety outcome was the composite of fatal bleeding or bleeding into a critical space, which could potentially lead to permanent disability. Eligible patients (n = 5,022) were assigned to rivaroxaban 2.5 mg twice daily or placebo added to standard care. Participants had at least a 3-month history of CHF with reduced left ventricular ejection fraction ≤ 40%, CAD, and elevated plasma BNP or NT-proBNP during the index event. Exclusion criteria were a high risk of bleeding, atrial fibrillation (AF), or another condition that required long-term anticoagulation.

The primary endpoint was not significantly different between groups and occurred in 13.4% of rivaroxaban patients and in 14.3% of placebo patients (HR, 0.94; 95% CI, 0.84 to 1.05; $P = .27$). There was also no difference in all-cause mortality between the groups (11.4% and 11.6%, respectively; HR, 0.98; 95% CI, 0.87 to 1.10). There was a nominally significant reduction in stroke with rivaroxaban compared with placebo (1.08% vs 1.62%: HR, 0.66; 95% CI, 0.47 to 0.95) and a trend for MI (HR, 0.83; 95% CI, 0.63 to 1.08). The principal safety outcome occurred in 0.7% of rivaroxaban patients and 0.9% of placebo patients (HR, 0.80; 95% CI, 0.43 to 1.49; $P = .48$).

Low-dose rivaroxaban as an addition to guideline-based treatment does not improve the composite of all-cause mortality, MI, or stroke in patients with recent worsening of CHF and reduced ejection fraction, and CAD without AF. Prof. Zannad noted that as this study included HF patients who were at high risk after recent HF hospitalisation, it opened the possibility that HF deaths made up a substantial proportion of all deaths in this population instead of deaths due to atherothrombotic events. Trends for reduction in MI and stroke support the hypothesis that more potent antithrombotic strategies may reduce thrombotic risk in patients with HF. However, rates of death are high and may occur from predominantly non-thrombotic causes attenuating benefit for the primary composite endpoint of this trial. Future studies focused on outcomes modifiable with antithrombotic therapies may demonstrate efficacy.

FRANCE-TAVI Registry Results

Written by **Michiel Tent**

Male gender, renal failure, and atrial fibrillation (AF) predicted mortality at 3 years of follow-up in patients who underwent successful transcatheter aortic valve replacement (TAVR). Primarily for AF, anticoagulation was associated with a lower risk of bioprosthetic valve dysfunction (BVD) after TAVR but a higher risk of long-term mortality.

The results from FRANCE-TAVI, a prospective, multicentre, nation-wide French registry were, presented by Jean-Philippe Collet, MD, Sorbonne University and Pitie Salpetriere Hospital, Paris, France [Overtchouk P et al. *J Am Coll Cardiol*. 2018]. Prof. Collet explained that the optimal antithrombotic treatment after TAVR is still unknown. Dual antiplatelet therapy (DAPT) is used most frequently but single antiplatelet therapy or oral anticoagulation (OAC) are also used. The objectives of the French research group were two-fold: to investigate whether antithrombotic treatment influences long-term mortality and early BVD, and to explore independent correlates of long-term mortality and early BVD after TAVR. BVD was defined as increased prosthetic gradient ≥ 10 mm Hg or new gradient ≥ 20 mm Hg, and was identified by multislice computed tomography (MSCT).

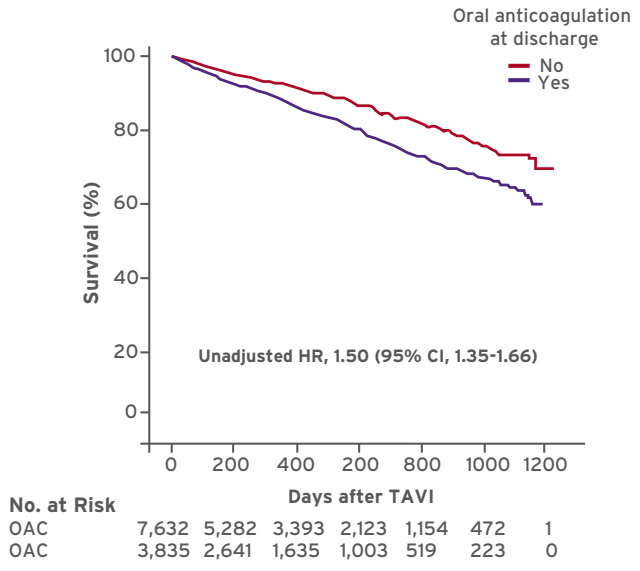
Between 1 January 2013 and 31 December 2015, 12,804 patients were included. Of these, 11,469 were alive at discharge with known antithrombotic treatment and were analysed for mortality. Mean age was 82.8 years, mean logistic Euroscore was 17.8, and mean follow-up was 495 days. A total of 2,555 patients had at least two echocardiographic evaluations and were eligible for BVD assessment. The prevalence of BVD post-TAVR in the registry was 5.5% (n = 140). One third of patients had a history of AF; the same proportion had OAC at discharge (n = 3,836), primarily for the prevention of cardioembolic stroke. The results showed that neither aspirin nor clopidogrel were independently associated with mortality (Table 1).

Table 1. Independent Correlates of Mortality

	Adjusted HR (95% CI)	*P*-value
Male gender	1.63 (1.44-1.84)	.001
History of AF	1.41 (1.23-1.62)	.001
Chronic renal failure	1.37 (1.23-1.53)	.001

Prof. Collet noted that anticoagulation at discharge remained a correlate of mortality (unadjusted HR, 1.50; 95% CI, 1.35 to 1.66; Figure 1) independent of AF, despite the strong correlation between AF and mortality.

Figure 1. Kaplan-Meier Survival Curves According to Anticoagulation at Discharge



OAC, oral anticoagulation.

Reprinted from Overtchouk P et al. Long-Term Mortality and Early Valve Dysfunction According to Anticoagulation Use: The FRANCE-TAVI registry. *J Am Coll Cardiol*. 2018; DOI: 10.1016/j.jacc.2018.08.1045. Copyright 2018. With permission from Elsevier.

Anticoagulation at discharge was also independently associated with lower rates of BVD (adjusted OR, 0.54; 95% CI, 0.35 to 0.82; *P* = .005). The same was true for a non-femoral approach (adjusted OR, 0.53; 95% CI, 0.28 to 1.02; *P* = .049). A higher risk of BVD was yielded by chronic renal failure (adjusted OR, 1.46; 95% CI, 1.03 to 2.08; *P* = .034); and by a prosthesis size of ≤ 23 mm (adjusted OR, 3.43; 95% CI, 2.41 to 4.89; *P* < .001). Prof. Collet noted that antithrombotic treatment is driven not by the procedure but by patient characteristics. Of the patients in this study, 70% used OAC therapy to manage their AF and use of OAC was associated with lower risk of BVD.

Limitations of the study include its non-randomised, observational nature, which means unknown confounders cannot be excluded; the declarative clinical outcome reporting; treatment cross-over, which could not be assessed; and the identification of BVD with MSCT, which may have led to different correlates.

Primary Results From the MARINER Trial

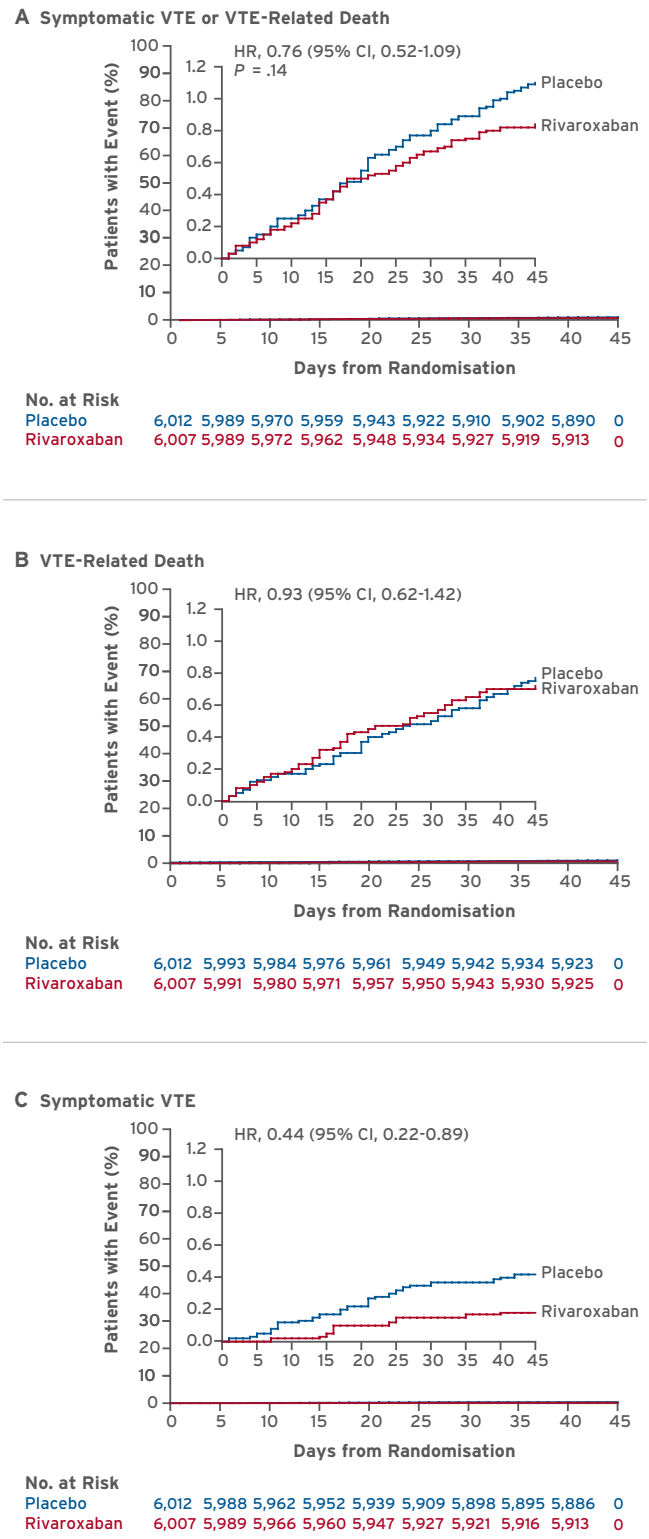
Written by **Constance de Koning**

Primary results from the MARINER trial [Spyropoulos AC et al. *N Engl J Med*. 2018] showed that treatment with rivaroxaban did not significantly reduce the risk of symptomatic venous thromboembolism (VTE) and VTE-related death in medically ill patients after hospital discharge.

Hospitalised patients run a substantial risk of developing VTE after discharge. According to Alex C. Spyropoulos, MD, Lennox Hill Hospital, New York, USA, the role of extended thromboprophylaxis has been investigated but has either shown excess bleeding or beneficial effects from reducing mostly asymptomatic deep vein thrombosis (DVT). MARINER was designed to compare rivaroxaban with placebo for the prevention of symptomatic VTE and VTE-related death in medically ill patients at heightened risk of VTE after discharge from the hospital. The principal safety objective was major bleeding.

The trial was a randomised, double-blind, placebo-controlled, event-driven study that included a total of 12,024 patients aged ≥ 40 years who had been hospitalised with an acute medical illness for 3-10 consecutive days and had an elevated VTE risk, defined as a modified IMPROVE score ≥ 4 or a score of 2 or 3 plus a plasma D-dimer level more than twice the upper limit of normal. The rivaroxaban regimen consisted of 10 mg once daily or 7.5 mg for patients with a creatinine clearance of 30 to < 50 ml/min. The first dose was given on the day of discharge and the last dose at Day 45. Patients were followed up for an additional 30 days. Baseline characteristics were similar between groups.

Figure 1. Primary Efficacy Outcome up to Day 45



Reprinted from *The New England Journal of Medicine*. Spyropoulos AC et al. Rivaroxaban for Thromboprophylaxis after Hospitalization for Medical Illness. EPub 26 August 2018. Copyright © 2018 Massachusetts Medical Society.

The results showed that symptomatic VTE and VTE-related death up to Day 45 occurred in 66 patients receiving placebo versus 50 patients receiving rivaroxaban. This represented a 24% relative risk reduction or a 0.27% absolute risk reduction (HR, 0.76; 95% CI, 0.52 to 1.09; *P* = .136 ; Figure 1A).

There was a slight benefit in the patients who received the full 10 mg rivaroxaban dose (0.65% vs 0.98%; *P* = .075), with no such signal in the patients with moderate renal insufficiency who received the lower 7.5 mg dose. Exploratory, prespecified secondary outcomes showed a nominally significant 56% reduction in symptomatic VTE (*P* = .023) and a 27% reduction in the composite of symptomatic VTE and all-cause mortality (*P* = .033) with rivaroxaban. Major bleeding was low in both groups (0.28% for rivaroxaban and 0.15% for placebo; HR, 1.88; 95% CI, 0.84 to 4.23; *P* = .124).

Rivaroxaban in this trial did not significantly reduce the composite of symptomatic VTE and VTE-related death in at-risk patients post-discharge (Figure 1B). The number of major bleeding events with rivaroxaban was low, with no significant increase in major, critical or fatal bleeding. These differences in risk suggest that the number needed-to-treat (NTT) to prevent one symptomatic VTE is 430 while the NTT to cause one major bleed is 856.

The event rate for the primary endpoint in the population selected was low (1.1% over 45 days in the placebo group) relative to that estimated in the design (2.5%) and even lower for the endpoint of symptomatic VTE (0.42%, 25 of 6,012 randomised to placebo). The trial was powered estimating a 40% relative risk reduction requiring 161 primary endpoint events. However, the observed relative risk reduction was 24% with only 116 events, raising the question of whether the trial was adequately powered. That no effect was observed with rivaroxaban on VTE-related death raises the question whether the definition used in the trial, which included sudden and unexplained death, was specific enough to capture true thrombotic related causes of death.

It should be noted that the observed event rate in the placebo group was 1.1% – less than half the estimate in the original protocol (2.5%). Although a protocol amendment increased the enrolment from 8,000 to 12,000 patients to allow more primary endpoint events to accrue, the final number was fewer than anticipated (116 vs 161 events). These results indicate that either a higher risk population and/or larger trial with a greater number of events would be needed to determine whether low-dose oral anticoagulation may significantly reduce recurrent VTE events in medically ill patients.

Primary Prevention With Aspirin: Effective in Patients with Diabetes, but Role in Moderate-Risk Patients Less Clear

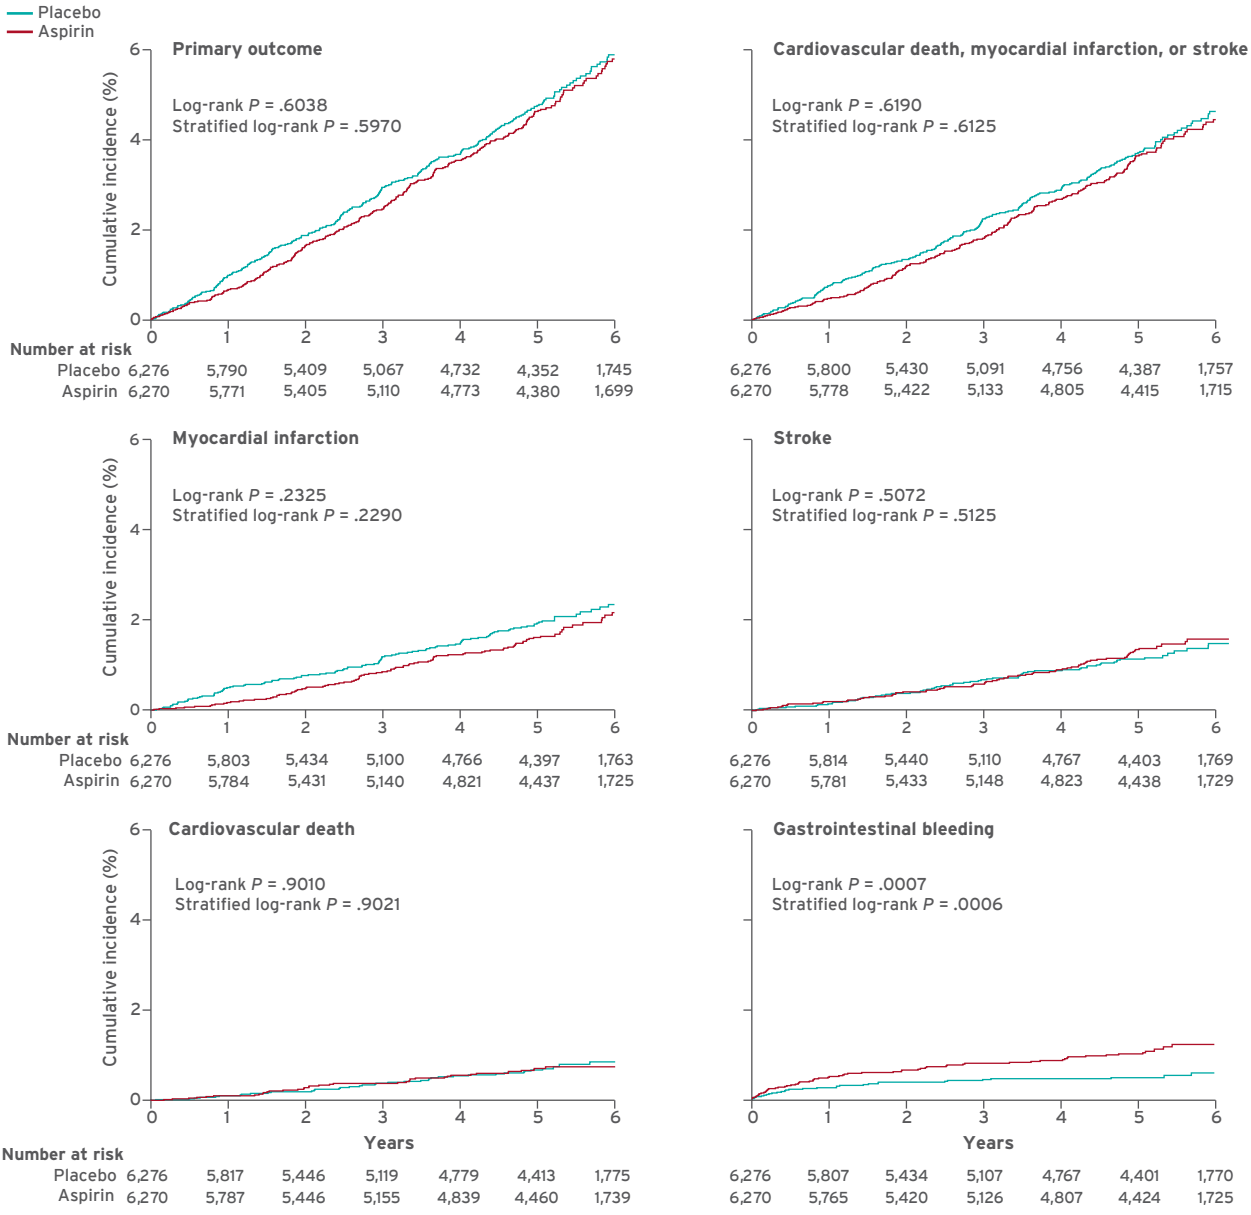
Written by **Constance de Koning**

Prevention of cardiovascular (CV) events plays a key role in achieving optimal patient outcomes, especially in high-risk groups. Although aspirin did not reduce CV risk in moderate-risk patients, it did prevent serious vascular events (SVE) in diabetic patients without CV disease (CVD), although major bleeding was increased.

No Clear Role for Aspirin in CV Risk Reduction in Moderate-Risk Patients

Findings from the Aspirin to Reduce Risk of Initial Vascular Events trial [ARRIVE; Gaziano JM et al. *Lancet*. 2018] showed that aspirin does not reduce the long-term risk of CV events in patients at moderate risk. This randomised, double-blind, placebo-controlled, multicentre trial assessed the efficacy and safety of aspirin in patients at moderate estimated risk of a CV event (men age ≥ 55 years with ≥ 2 CV risk factors and women age ≥ 60 years with ≥ 3 CV risk factors). Patients had no known history of CVD or diabetes plus an estimated 10-year risk of major coronary heart

Figure 1. Key outcomes



Reprinted from *Lancet*. Gaziano JM et al. Use of aspirin to reduce risk of initial vascular events in patients at moderate risk of cardiovascular disease (ARRIVE): a randomised, double-blind, placebo-controlled trial; http://dx.doi.org/10.1016/S0140-6736(18)31924-X. Copyright 2018. With permission from Elsevier.

disease events of 10-20% corresponding to a 10-year 20-30% CVD risk were randomised to 100 mg enteric-coated aspirin daily (n = 6,270) or placebo (n = 6,276). Statins were used by 43% of patients in this study. The primary efficacy endpoint was time of first occurrence of composite endpoint (CVD death, myocardial infarction [MI], stroke, unstable angina, transient ischaemic attack [TIA]). Researchers found that 4.3% of patients taking aspirin and 4.5% of patients taking placebo experienced the primary endpoint over a mean of 5 years (HR, 0.96; 95% CI, 0.81 to 1.13; *P* = .60). The primary safety endpoints were haemorrhagic events and incidence of other adverse events; gastrointestinal bleeding (GI) events occurred in 0.97% of patients taking aspirin and in 0.46% of patients on placebo (HR, 2.11; 95% CI, 1.36 to 3.28; *P* = .0007). Rates of severe GI bleeding were extremely low (0.06% for aspirin and 0.03% for placebo) The mortality rates were 2.55% in the aspirin group and 2.57% in the placebo group (HR, 0.99; 95% CI, 0.80 to 1.24; *P* = .95). Other findings included a lower risk of fatal or non-fatal MI for patients on aspirin if they were at least 60% compliant with treatment: 1.52% versus 1.78% in the placebo group (HR, 0.85; 95% CI, 0.64 to 1.11; *P* = 0.23; Figure 1) but not reduction in stroke (1.2% vs 1.07%; HR, 1.12; 95% CI, 0.80 to 1.55; *P* = .507).

J. Michael Gaziano, MD, Brigham and Women's Hospital, Boston, Massachusetts, USA, added that despite a lack of overall reduction in CV events, these results emphasised the ability of aspirin to reduce the risk of a first non-fatal MI without affecting the risk of total stroke, while providing more insights into the efficacy and safety of aspirin in the primary prevention of CVD in older individuals and women.

Aspirin Prevented SVE in Diabetic Patients Without CVD but Caused Major Bleeding

The risks and benefits of aspirin to prevent a first CV event in patients with diabetes was evaluated in the Effects of Aspirin for Primary Prevention in Persons with Diabetes Mellitus trial [ASCEND; ASCEND Study Collaborative Group. *N Engl J Med*. 2018]. A total of 15,480 patients with diabetes (94% type 2, median duration 7 years) and no prior CVD were randomised to aspirin 100 mg daily or placebo, with a mean follow-up of 7.4 years. The primary efficacy outcome was the first SVE (i.e., MI, stroke or TIA, or vascular death, excluding any confirmed intracranial haemorrhage). The primary safety outcome was the first major bleeding event. Secondary outcomes included GI cancer. Statins were used by approximately 75% of participants. Aspirin significantly reduced the risk of a SVE (non-fatal MI, stroke or TIA, or vascular death; 8.5% vs 9.6%; rate ratio, 0.88; 95% CI, 0.79 to 0.97; *P* = .01). A breakdown of the outcomes per separate SVE is shown in Table 1.

Table 1. Components of Primary Efficacy Outcome Plus Revascularisation

Type of event	Aspirin (n = 7,740)	Placebo (n = 7,740)
	no. of participants with events (%)	
Any SVE	658 (8.5)	743 (9.6)
Any arterial revascularisation	340 (4.4)	384 (5.0)
Any SVE or revascularisation	833 (10.8)	936 (12.1)

SVE, serious vascular event.

However, these outcomes came with an increased risk of major bleeding (4.1% vs 3.2%; HR, 1.29; 95% CI, 1.09 to 1.52; *P* = .003), of which 41% were GI, 21% were sight-threatening events, 17% were intracerebral haemorrhage (ICH), and 20% were bleeding events at other sites. No significant effect of the use of aspirin on mortality from all vascular causes combined (representing ~30% of all deaths) was observed when compared with placebo. There were no between-group differences in the rates for any type of cancer after more than 7 years (11.6% in the aspirin group vs 11.5% in the placebo group; RR, 1.01; 95% CI, 0.92 to 1.11), but longer-term follow-up is ongoing.

These trials of aspirin for primary prevention suggest that aspirin may be of benefit in high-risk, compliant patients, although GI bleeding is increased.

Tafamidis Safe and Effective for Patients With Transthyretin Amyloidosis

Written by **Phil Vinall**

Transthyretin amyloidosis (ATTR) is an underdiagnosed life-threatening disease that causes restrictive cardiomyopathy (CM) and progressive heart failure. Median survival is 2.5 to 3.6 years after diagnosis and the only treatment currently available is supportive care. Tafamidis is a novel non-NSAID benzoxazole derivative that binds to the thyroxine-binding sites of both variant and wild-type transthyretin (TTR). It then inhibits dissociation of tetramers into monomers, the rate limiting step in the formation of TTR amyloid leading to CM.

Claudio Rapezzi, MD, University of Bologna, Italy, presented the results of the Transthyretin Amyloid Cardiomyopathy Clinical Trial [ATTR-ACT], a multicentre, international, double-blind, placebo-controlled, Phase 3 trial [Maurer MS et al. *Circ Heart Fail*. 2017; Maurer MS et al. *N Engl J Med*. 2018].

The primary objective of ATTR-ACT was to compare the efficacy, safety, and tolerability of 80 or 20 mg tafamidis meglumine oral daily dose with placebo plus standard of care in patients with hereditary or wild-type

ATTR-CM. After screening, patients (n = 441) were randomly assigned (2:1:2) to tafamidis 80 mg, tafamidis 20 mg, or placebo for the 30-month treatment phase. Patients were stratified for genotype (wild-type or variant) and disease severity (NYHA class).

The primary efficacy analysis was the hierarchical combination of all-cause mortality and frequency of cardiovascular (CV)-related hospitalisations. Secondary endpoints included change in the 6-minute walk test (6MWT) and the Kansas City Cardiomyopathy Questionnaire-Overall

Figure 1. Primary Analysis and Components

A Primary Analysis, with Finkelstein-Schoenfeld Method

	No. of Patients	*P* Value from Finkelstein-Schoenfeld Method	Win Ratio (95% CI)	Patients Alive at Month 30 *no. (%)*	Average Cardiovascular-Related Hospitalisations during 30 Months among Those Alive at Month 30 *per patient per year*
Pooled Tafamidis	264			186 (70.5)	0.30
		< .001	1.70 (1.26-2.29)		
Placebo	177			101 (57.1)	0.46

Summary (KCCQ-OS) score. Data were pooled from the two tafamidis treatment groups.

Patients were a mean age of 74 years (90% male; about 80% white); 76% had the wild-type genotype. Disease severity was mostly NYHA class II and III. N-terminal pro b-type natriuretic peptide (NT-proBNP) were ~3,000. In the primary analysis, the combined endpoint of all-cause mortality and rates of CV-related hospitalisations were less frequent among the 264 patients who received tafamidis than among the 177 patients who received placebo (Win Ratio, 1.70; 95% CI, 1.26 to 2.29; $P < .001$; Figure 1A). Tafamidis was associated with lower all-cause mortality than placebo (78 of 264 [29.5%] vs 76 of 177 [42.9%]; HR, 0.70; 95% CI, 0.51 to 0.96; Figure 1B) and a lower rate of CV-related hospitalisations, with a relative risk ratio of 0.68 (0.48 per year vs 0.70 per year; 95% CI, 0.56 to 0.81; Figure 1C). At Month 30, tafamidis was also associated with a lower rate of decline in distance for the 6MWT ($P < .001$) and a lower rate of decline in KCCQ-OS score ($P < .001$). Using the more traditional Cox model, the reduction in the risk of all-cause mortality with tafamidis compared with placebo was 30% ($P = .0259$) with divergence of the event curves noted at 18 months of treatment.

Across prespecified subgroups including etiology wild-type (ATTR vs hereditary ATTR), NYHA class (I/II vs III), and tafamidis dose (80 vs 20 mg), the reduction in all-cause mortality and frequency of CV-related hospitalisations favoured tafamidis over placebo, except for patients in NYHA class III at baseline in whom CV-related hospitalisations were higher in tafamidis-treated patients, which may be a consequence of longer survival during a more severe period of disease.

Tafamidis was well tolerated with a safety profile comparable to placebo. In particular, permanent discontinuation due to adverse events, dose reductions, diarrhoea, and urinary tract infections were less common with tafamidis than with placebo.

These findings provide strong evidence that tafamidis is an effective therapy for patients with ATTR-CM and underscore the importance of early diagnosis and treatment in this disease.

Lowering the Threshold for Diagnosing MI Does Not Improve Patient Outcomes

Written by **Phil Vinall**

Improvements in assay sensitivity have allowed for highly precise quantification of very low levels of troponin, a critical factor when diagnosing myocardial infarction (MI). The 4th Universal Definition of MI now recommends use of high-sensitivity cardiac troponin (hs-cTnI) and a sex-specific 99th centile upper reference limit as the diagnostic threshold. Nicholas L. Mills, MD, PhD, Edinburgh University, United Kingdom, presented the results from the High-Sensitivity Troponin in the Evaluation of Patients With Acute Coronary Syndrome trial showing that such strict classification does not improve outcomes [High-STEACS; Shah ASV et al. *Lancet*. 2018].

High-STEACS was a stepped-wedge, cluster-randomised, controlled trial designed to test the hypothesis that the new definition would reduce subsequent MI or cardiovascular (CV) death at one year in patients who had been hospitalised with suspected acute coronary syndrome.

Both the contemporary and high-sensitivity assays were measured in all patients throughout the trial. During the 6 to 12-month validation portion of the trial, care was guided by the contemporary assay and the results of the high-sensitivity assay were suppressed. After validation, sites were randomised to either early or late implementation during which time the high-sensitivity assay was used to guide care and the results of the contemporary testing was suppressed. Using the assay results, patients likely to benefit from high-sensitivity troponin were stratified into 3 groups: those without myocardial injury (hs-cTnI concentrations within the reference range); those with myocardial injury that had already been identified for some time by the contemporary assay (any cTnI concentration greater the diagnostic threshold of this assay); and patients reclassified by the high-sensitivity cardiac troponin assay (increased hs-cTnI concentration, > 16 ng/L for women, > 34 ng/L for men, cTnI concentrations below the diagnostic threshold on the contemporary assay). The primary endpoint was a composite of MI or CV death at one year.

In all, 48,282 consecutive patients were enrolled (mean age 61 years; 47% female) of whom 10,360 had myocardial injury (8,589 identified by contemporary assay and 1,771 reclassified by high sensitivity assay). Patients with myocardial injury were similar except that reclassified patients were older (mean age 75 years) and more likely to be female (83%).

The primary outcome of MI or death from CV causes occurred in 2,586 patients. Patients with no myocardial injury had excellent outcomes with only 2% experiencing the primary outcome in both phases of the trial. Patients identified by contemporary assay had worse outcomes with 19% experiencing an event in the validation phase and 17% in the implementation phase. Reclassified patients, those with evidence of injury not disclosed by contemporary assay, had intermediate outcomes that did not improve with the implementation of

high sensitivity assay (15% of patients in the validation phase and 12% in the implementation phase; Figure 1).

Implementation of hs-cTnI and the 99th percentile threshold reclassified 1 in 6 patients, but only one-third had a diagnosis of type 1 MI, and the rate of subsequent MI or CV death at one year was unaffected. The results of this trial led Prof. Mills to question the recommendations by the Global Task Force for the Universal Definition of MI to base the diagnostic threshold for MI on the 99th percentile from a normal reference population.

Dual Antithrombotic Therapy Safer and as Efficacious as Triple Therapy in AF patients Undergoing PCI

Written by **Michiel Tent**

In patients with atrial fibrillation (AF) and presenting with acute coronary syndrome (ACS) or undergoing percutaneous coronary intervention (PCI), presenters agreed that dual antithrombotic therapy (DAT: oral anticoagulant + clopidogrel) is equally effective as, and safer than triple antithrombotic therapy (TAT: oral anticoagulant [OAC] + dual antiplatelet therapy).

Kurt Huber, MD, Sigmund Freud University Medical School, Vienna, Austria, provided an update on the use of DAT and TAT for AF patients undergoing PCI. He argued that choosing DAT or TAT should be done on an individual basis. Positive outcome studies have shown safety benefits for DAT in patients with AF and PCI in cases of increased bleeding risk [Hansen ML et al. *Arch Intern Med*. 2010; Dewilde WJ et al. *Lancet*. 2013].

The current European Society of Cardiology guidelines [Valgimigli M et al. *Eur Heart J*. 2018] state that in patients with ACS treated with coronary stent implantation, dual antiplatelet therapy (DAPT) with a $P2Y_{12}$ inhibitor on top of aspirin is recommended for 12 months (class I, level A), unless there are contraindications such as excessive risk of bleeding (e.g., PRECISE-DAPT score ≥ 25). In patients with an indication for oral anticoagulation undergoing PCI, TAT should be considered for 1, 3, or 6 months (class IIa, level B) followed by up to 6 months of DAT (class IIa, level A) if concerns about ischaemic risks are prevailing. If concerns for bleeding risk are prevailing, TAT may be considered for 1 month (class IIa, level B), followed by DAT for up to 12 months (class IIa, level A); and if bleeding risk is very elevated, up to 12 months of DAT may be appropriate, in the form of clopidogrel and a non-vitamin K antagonist oral anticoagulant (NOAC; class IIa, level A).

Prof. Huber argued that drug-eluting stents (DES) with a low stent thrombosis rate may make the choice for DAT or for the duration of TAT easier. The Biofreedom™ drug-coated stent almost halved the risk of clinically driven target lesion revascularisation at 2 years compared with a bare-metal stent (BMS; HR, 0.54; 95% CI, 0.41 to 0.72; $P < .0001$) [Garot P et al. *J Am Coll Cardiol*. 2017]. The Synergy™ DES also significantly lowered the incidence of major adverse cardiac and cerebrovascular events at 1 year (12% in the DES group vs 16% in the BMS group; RR, 0.71; 95% CI, 0.52 to 0.94; $P = .02$) [Varenne O et al. *Lancet*. 2018].

Observational Trials of AF in ACS or Stenting

Andrea Rubboli, MD, Cardiology Division, Ospedale Maggiore, Bologna, Italy, discussed lessons from observational studies of AF in ACS or stenting. These studies show a high variability in the choice of antithrombotic therapy; an increased risk of bleeding with newer $P2Y_{12}$ inhibitors in TAT; and an efficacy of DAT at least equal to TAT, with a superior safety profile.

Over 170,000 patients were included in observational studies. According to Prof. Rubboli the results are difficult to compare and analyse because of overall differences in design and other aspects. There is a high variability in use of antithrombotic regimens, which is largely irrespective of the patient's risk profile: TAT ranged from 8.5 to 85%; DAT from 5 to 81%; and DAPT from 10 to 22%.

Temporal trends in Italy (2001 to 2014) in non-ST elevation (NSTE) ACS patients show a significant and progressive decrease in the use of single therapy with either antiplatelets or oral anticoagulants [De Luca L et al. *Int J Cardiol*. 2017]. The use of DAPT and of DAT was stable, while the use of TAT increased. Compared with clopidogrel, the newer $P2Y_{12}$ inhibitor prasugrel as part of TAT more than doubled the bleeding risk in NSTEMI/STEMI patients undergoing PCI (adjusted incidence rate ratio, 2.37; 95% CI, 1.36 to 4.15; $P = .003$) [Jackson LR 2nd et al. *JACC Cardiovasc Interv*. 2015]. However, the same may not be true for DAT. In registration trials of AF patients, the absolute incidence rate of major bleeding averages 4-5% for up to 12 months of TAT, which favourably compares with approximately 3.5% observed for OAC monotherapy in registration trials of non-vitamin K antagonist OACs in AF patients.

Observational studies also suggest DAT to be at least as effective as TAT, with a superior safety profile. According to Prof. Rubboli, there is no room for DAPT, except in AF patients undergoing PCI with a CHA_2DS_2-VASC score of 1, in whom adding an OAC does not decrease stroke risk, while increasing the bleeding risk, as opposed to patients with a score of ≥ 2.

Additional variables can play a role in establishing a reduced risk of bleeding, notably a high quality of OAC (reflected by being a long time in therapeutic range) when vitamin K antagonists (VKAs) are used in TAT; and use of chronic anticoagulation at the time of PCI; while a shorter (> 1 month) duration of TAT does not worsen net clinical outcomes and thus may be optimal.

TAT Versus DAT in Clinical Trials

Jean-Philippe Collet, MD, PhD, Pitié-Salpêtrière Hospital, Paris, France, weighed the benefits of triple versus dual therapy in major clinical trials in AF with ACS or stenting. He concluded that DAT is safer than TAT; patients who use TAT have a high risk of bleeding; and the most appropriate combination for DAT remains unknown.

In the open-label WOEST trial, DAT (with a VKA + clopidogrel) was associated with significantly lower rates of bleeding (19.4% vs 44.4%; HR, 0.36; 95% CI, 0.26 to 0.50; $P < .0001$) and overall mortality than TAT (VKA + clopidogrel + ASA), with similar rates of thrombotic events [Dewilde WJ. *Lancet*. 2013]. There were 573 participants, 69% of whom had AF. First generation DES and a femoral approach were the most common procedural aspects, and left main disease was an exclusion criterion. Ischaemic and bleeding risk should be weighed when choosing the duration of antiplatelet therapy, as there were significantly fewer BARC type 2 – 5 bleedings in DAT versus TAT (HR, 0.68; 95% CI, 0.47 to 0.98) in the landmark analysis at Week 6.

In the PIONEER AF-PCI trial [Gibson CM et al. *N Engl J Med*. 2016] 2,124 AF patients undergoing PCI with stent placement were randomised to one of three groups after PCI: Group 1: DAT, comprised of low-dose rivaroxaban (15 mg once dialy) plus a $P2Y_{12}$ inhibitor for 12 months; Group 2: very-low-dose rivaroxaban (2.5 mg twice daily) plus DAPT for 1, 6, or 12 months; Group 3: standard TAT therapy with a VKA (INR 2.0 to 3.0) plus DAPT for 1, 6, or 12 months. DAPT duration was prespecified and no power calculation was made. The rates of clinically significant bleeding were lower in the groups who received rivaroxaban than in the group who received standard TAT therapy with VKA + DAPT (6.8% in Group 1, 18.0% in Group 2, and 26.7% in Group 3; HR for Group 1 vs Group 3, 0.59; 95% CI, 0.47 to 0.76; $P < .001$; HR for Group 2 vs Group 3, 0.63; 95% CI, 0.50 to 0.80; $P < .001$; Figure 1). The three groups had similar efficacy rates.

In the REDUAL-PCI multicentre trial [Cannon CP et al. *N Engl J Med*. 2017], 2,725 AF patients who had undergone PCI were randomly assigned to TAT with warfarin plus a $P2Y_{12}$ inhibitor (clopidogrel or ticagrelor) plus aspirin (for 1 to 3 months; triple-therapy group), or DAT with dabigatran (110 mg or 150 mg twice daily) plus a $P2Y_{12}$ inhibitor (clopidogrel or ticagrelor) and no aspirin (110-mg and 150-mg dual-therapy groups). The risk of bleeding was lower among those who received DAT (HR, 0.52; 95% CI, 0.42 to 0.63; $P < .001$ for noninferiority; $P < .001$ for superiority for 110 mg dabigatran; HR, 0.72; 95% CI, 0.58 to 0.88; $P < .001$ for noninferiority for 150 mg dabigatran) than among those who received TAT. DAT was noninferior to TAT with respect to the risk of thromboembolic events.

The most favourable duration of DAPT has yet to be determined, and is the subject of ongoing trials, such as the AUGUSTUS trial. The new ESC/EACTS Guidelines on Myocardial Revascularization [Neumann FJ et al. *Eur Heart J*. 2018.] present a list of strategies to avoid bleeding complications in patients with oral anticoagulants (Table 1), as well as a practical table with information on high-risk features for ischaemic events.

Table 1. Strategies to Avoid Bleeding Complications of OAC in Myocardial Revascularisation Patients

Assess ischaemic and bleeding risks using **validated risk predictors** (e.g., CHA_2DS_2-VASC, ABC, and HAS-BLED) with a focus on modifiable risk factors.
Keep **triple therapy duration as a short as possible**; dual therapy after PCI (OAC and clopidogrel) to be considered instead of triple therapy.
One should consider the **use of a NOAC instead of a VKA** when NOACs are not contraindicated.
Consider a **target INR in the lower part of the recommended target** range and maximise time in the therapeutic range (i.e., > 65%) when a VKA is used.
Clopidogrel is the $P2Y_{12}$ inhibitor of choice.
Use **low-dose (≤ 100 mg daily) aspirin**.
Routine use of **PPIs**.

Innovative Strategies for Secondary Prevention

Written by **Constance de Koning**

Secondary cardiovascular (CV) prevention remains a highly dynamic field, in which new strategies are continuously being developed and tested in contemporary trials. Novel approaches include proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibition, anti-cytokine therapy, $P2Y_{12}$ inhibition, and targeting residual inflammatory, lipid, and thrombotic risk.

Residual Inflammatory, Lipid, and Thrombotic Risk in CAD

Despite optimum medical therapy, the recurrent event rate in post-acute coronary syndrome (ACS) in trials remains high (about 10% in the first year). This is even higher in clinical practice, with up to one-third of elderly, high-risk patients having a recurrent event in the first year post-ACS. The protective role of high density lipoproteins (HDL) has been questioned based on human genetic studies and negative clinical trial results of various HDL raising therapies. In contrast, recent genetic analyses support the causality of triglyceride-rich lipoproteins in CV risk. According to Peter Libby, MD, Brigham & Women's Hospital, Boston, Massachusetts, USA, the dependent and independent variable in adjusting the CV risk of triglycerides for HDL may have been confused [Libby P et al. *Eur Heart J*. 2014]; it may be the case that HDL is in fact a marker for triglycerides. These findings may aid in achieving biomarker-guided personalisation of the management of risk in secondary prevention by targeting residual low-density lipoprotein (LDL) risk, residual inflammatory risk, and residual risk due to triglyceride-rich lipoproteins.

Role of PCSK9 Inhibition Still Evolving

Inhibition of PCSK9 is effective in reducing LDL, in patients with familial hypercholesterolemia and in very high-risk patients. PCSK9 monoclonal antibodies may also be useful in managing ACS, as ACS induces increased PCSK9 levels, which in turn may influence plaque vulnerability of the coronary vessels [Navarese EP et al. *Ann Int Med*. 2016]. The FOURIER study [Sabatine MS et al. *N Engl J Med*. 2017] showed a 1.5% absolute risk reduction (RR) with evolocumab on time to CV death, myocardial infarction (MI), stroke, hospitalisation for unstable angina, or coronary revascularisation in very high-risk patients who used the highest tolerated dose of statins (HR, 0.85; 95% CI, 0.79 to 0.92; $P < .001$). The ODYSSEY trial [Steg PG et al. ACC Conference 2018], which assessed alirocumab, also showed a reduction in LDL-cholesterol (LDL-C) and CV endpoints. The study included an even higher-risk group of patients and longer follow-up than the FOURIER study, demonstrating a 15% RR in major adverse cardiovascular events (MACE; HR, 0.85; 95% CI, 0.78 to 0.93; $P = .0003$) and a 1.6% absolute risk reduction. The EVOlocumab study for early reduction of LDL-C levels in patients with ACSs [EVOPACS; NCT03287609] is currently investigating the safety and efficacy of evolocumab in ACS patients.

Other methods to reduce LDL-C are being investigated, including inclisiran, a RNA interference therapeutic inhibiting the synthesis of PCSK9, which was found to lower PCSK9 and LDL-C levels in patients at high CV risk with elevated LDL cholesterol levels [Ray KK et

Figure 1. Clinically Significant Bleeding in PIONEER AF-PCI

al. *N Engl J Med*. 2017]. However, there are still some unanswered questions, according to François Mach, MD, Geneva University Hospital, Switzerland. These include the need for more data regarding inclisiran and other silencing drugs, whether PCSK9i could be of use in patients with chronic kidney disease, and the clinical effect of PCSK9i on Lp(a) reduction. The benefits of PCSK9 inhibitors are clear, Prof. Mach stated, they offer the possibility of treating patients 1 or 2 times a month, with most patients (95%) reaching target levels with minimal side effects. However, long-term follow-up data is still needed and cost is an issue. Nevertheless, PCSK9 inhibition is a promising therapy.

Preventing CV Events by Targeting Residual Inflammatory Risk

Paul M. Ridker, MD, Brigham and Women's Hospital, Boston, Massachusetts, USA, presented data from the CANTOS trial, which included more than 10,000 patients. First presented at the European Society of Cardiology Congress 2017, CANTOS demonstrated large dose-dependent reductions in C-reactive protein (CRP) with no change in LDL-C and high-density lipoprotein cholesterol [Ridker PM et al. *N Engl J Med*. 2017]. In the secondary endpoint analysis, it was found that those with greater high-sensitivity (hs)CRP reduction had a greater risk reduction of MACE [Ridker PM et al. *Lancet*. 2018]. Interestingly, the reduction of MACE in patients with moderate chronic kidney disease (n = 1,875) was also significant (HR, 0.82; 95% CI, 0.68 to 1.00; *P* = .05) [Ridker PM et al. *J Am Coll Cardiol*. 2018]. New data suggest that residual inflammatory risk is still present irrespective of on-treatment LDL-C (including patients with LDL-C < 20 mg/dL) and is associated with increased rates of adverse events (Figure 1) [Bohula EA et al. *Circulation*. 2018].

Figure 1. Presence of Residual Inflammatory Risk in Patients with hsCRP < 1, 1-3, and > 3

		LDL-C at 1 month (mg/dL)				
		< 20	20-49	50-69	70-99	≥ 100
Incidence rate at 3 years	hsCRP < 1 mg/L	9.0%	9.8%	10.4%	10.9%	12.3%
	hsCRP 1-3 mg/L	10.8%	12.0%	12.6%	13.2%	14.9%
	hsCRP > 3 mg/L	13.1%	14.7%	15.4%	16.4%	18.2%

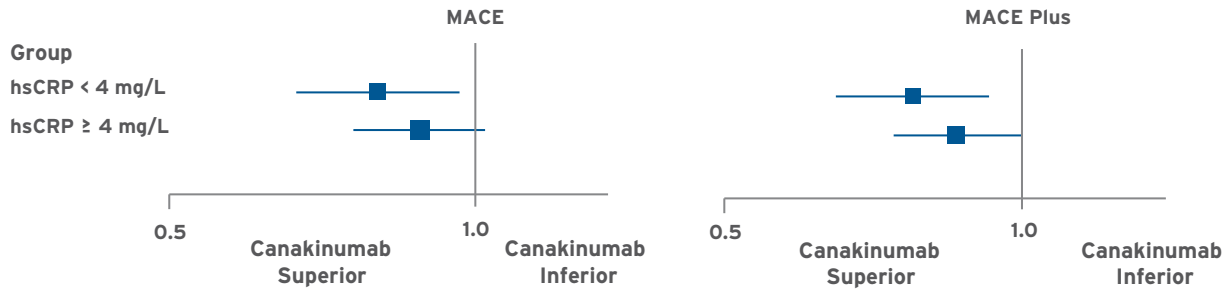
LDL-C, low-density lipoprotein cholesterol

Profound LDL reduction without inflammation effects is very effective, as is profound inflammation effects without LDL reduction, Dr Ridker stated. There are two important questions to answer for evidence-based guidelines: is there consistent evidence that the biomarker independently predicts risk, and is there randomised trial proof that lowering the biomarker lowers the risk? The confirming answer to the first question concerns many biomarkers, whereas the second answer only applies to LDL-C/ApoB and hsCRP/IL-6 [Ridker PM et al. *J Am Coll Cardiol*. 2018; in press].

Optimised Antithrombotic Strategy Post-ACS: Which Option?

When optimising antithrombotic strategy in high-risk, post-ACS patients, two periods can be distinguished: the time between discharge and 1 year post-ACS, and the time beyond 1 year post-ACS. For the early post-ACS period, dual antiplatelet therapy (DAPT; aspirin plus clopidogrel) is the gold standard. Optimisation may be achieved by using stronger $P2Y_{12}$ inhibition; providing an ischaemic benefit, but also a higher bleeding risk [Wiviott SD et al. *N Engl J Med*. 2007; Wallentin L et al. *N Engl J Med*. 2009]. A second option is to add Factor Xa inhibition to standard of care [Mega JL et al. *N Engl J Med*. 2012]. As Thomas Cuisset, MD, CHU TIMONE,

Figure 1. CANTOS: Consistency of Effect



Adapted from Ridker PM et al. Relationship of C-reactive protein reduction to cardiovascular event reduction following treatment with canakinumab: a secondary analysis from the CANTOS randomised controlled trial. *Lancet*. 2018;391:319-28.

Marseille, France, pointed out, the gold standard as of August 2018 is to use more potent $P2Y_{12}$ inhibitors (e.g., prasugrel, ticagrelor). Current guidelines state that triple therapy with aspirin plus clopidogrel and low-dose rivaroxaban is possible in patients with low bleeding risk.

Beyond the first year post-ACS, the gold standard has been lifelong single antiplatelet therapy after discontinuation of DAPT. Clinicians now have two options to add to aspirin; the PEGASUS trial [Bonaca MP et al. *N Engl J Med*. 2015] investigated ticagrelor and the COMPASS trial [Eikelboom J et al. *N Engl J Med*. 2017] assessed rivaroxaban in patients with stable coronary artery disease or peripheral arterial disease.

The first option to optimise antithrombotic strategy is prolonged $P2Y_{12}$ inhibition, which in itself consists of various options. The second option is to add Factor Xa inhibition to aspirin. Prof. Cuisset explained that a 2-step approach is required, although this can be challenging. Firstly, candidates for an optimised strategy would need to be identified (i.e., high/low bleeding risk), and secondly, the best strategy should be selected for each patient based on individual patient characteristics. Still, a number of issues may arise, such as the risk of nonadherence in case of multiple treatment changes, the duration of the chosen optimised strategy (30 months, 3 years or lifetime?), the choice of long-term DAPT and whether monotherapy with new $P2Y_{12}$ blockers is feasible.

Introduction

There is considerable overlap of the current document with other guidelines, specifically with those on "Stable Coronary Artery Disease", "Non-ST-Elevation Myocardial Infarction", "ST-Elevation Myocardial Infarction", "Heart Failure" and "Valvular Heart Disease" and the "Focused Update on Dual Antiplatelet Therapy".

Unless supported by new evidence, the recommendations of the current guidelines follow these guidelines.

A summary of the key changes in comparison with the previous guideline is provided in Figure 1 and Figure 2.

Figure 1 New recommendations

Calculation of the Syntax Score, if left main or multivessel revascularization is considered	Completeness of revascularization prioritized, when considering CABG vs PCI
Radial access as standard approach for coronary angiography and PCI	NOAC preferred over VKA in patients with non-valvular AF requiring anticoagulation and antiplatelet treatment
DES for any PCI	No-touch vein technique, if open vein harvesting for CABG
Systematic re-evaluation of patients after myocardial revascularization	Annual operator volume for left main PCI of at least 25 cases per year
Stabilised NSTE-ACS patients: revascularization strategy according to principles for SCAD	Pre- and post-hydration with isotonic saline in patients with moderate or severe CKD, if expected contrast volume is >100 mL
Use of the radial artery grafts over saphenous vein grafts in patients with high-degree stenosis	
Myocardial revascularization in patients with CAD, heart failure, and LVEF ≤35% CABG preferred PCI as alternative to CABG	
Routine non-invasive imaging surveillance in high-risk patients 6 months after revascularization	Dabigatran 150-mg dose preferred over 110-mg dose when combined with single antiplatelet therapy after PCI
Double-kissing crush technique preferred over provisional T-stenting in true left main bifurcations.	De-escalation of $P2Y_{12}$-inhibitor guided by platelet function testing in ACS patients
Cangrelor in $P2Y_{12}$-inhibitor naïve patients undergoing PCI	Routine revascularization of non-IRA lesions in myocardial infarction with cardiogenic shock
GP IIb/IIIa inhibitors for PCI in $P2Y_{12}$-inhibitor naïve patients with ACS undergoing PCI	Current generation BRS for clinical use outside clinical studies

	Class I		Class IIa
	Class IIb		Class III

The figure does not show changes compared with the 2014 version of the Myocardial Revascularization Guidelines that were due to updates for consistency with other ESC Guidelines published since 2014.

ACS = acute coronary syndromes; AF = atrial fibrillation; BRS = bioresorbable scaffolds; CABG = coronary artery bypass grafting; CAD = coronary artery disease; CKD = chronic kidney disease; DES = drug-eluting stents; GP = glycoprotein; IRA = infarct-related artery; LVEF = left ventricular ejection fraction; NOAC = non-vitamin K oral anticoagulants; NSTE = non-ST-elevation; PCI = percutaneous coronary intervention; SCAD = stable coronary artery disease; VKA = vitamin K antagonists.

= chronic kidney disease; DES = drug-eluting stents; GP = glycoprotein; IRA = infarct-related artery; LVEF = left ventricular ejection fraction; NOAC = non-vitamin K oral anticoagulants; NSTE = non-ST-elevation; PCI = percutaneous coronary intervention; SCAD = stable coronary artery disease; VKA = vitamin K antagonists.

Figure 2 Changes in Class of Recommendations

UPGRADES
For PCI of bifurcation lesions, stent implantation in the main vessel only, followed by provisional balloon angioplasty with or without stenting of the side branch
Immediate coronary angiography and revascularization, if appropriate, in survivors of out-of-hospital cardiac arrest and an ECG consistent with STEMI
Assess all patients for the risk of contrast-induced nephropathy
OCT for stent optimization

DOWNGRADES
Distal protection devices for PCI of SVG lesions
Bivalirudin for PCI in NSTE-ACS
Bivalirudin for PCI in STEMI
PCI for MVD with diabetes and SYNTAX score <23
Platelet function testing to guide antiplatelet therapy interruption in patients undergoing cardiac surgery
EuroSCORE II to assess in-hospital mortality after CABG

The figure does not show changes compared with the 2014 version of the Myocardial Revascularization Guidelines that were due to updates for consistency with other ESC Guidelines published since 2014.

	Class I		Class IIa
	Class IIb		Class III

CABG = coronary artery bypass grafting; MVD = multivessel coronary artery disease; NSTE-ACS = non-ST-elevation acute coronary syndromes; OCT = optical coherence tomography; PCI = percutaneous coronary interventions; STEMI = ST-elevation myocardial infarction, SVG = saphenous vein grafts.

Objective evidence of myocardial ischaemia by non-invasive stress imaging and intravascular assessment of the functional relevance of coronary artery stenoses are key to clinical decision making for myocardial revascularization. Because of the low sensitivity of stress ECG and its inability to gauge the extent and distribution of ischaemia, non-invasive stress imaging is recommended as the first line test.

Recommendation for non-invasive imaging in patients with coronary artery disease and heart failure with reduced ejection fraction

Recommendation	Class[a]	Level[b]
Non-invasive stress imaging (CMR, stress echocardiography, SPECT, or PET) may be considered for the assessment of myocardial ischaemia and viability in patients with HF and CAD (considered suitable for coronary revascularization) before the decision on revascularization.	IIb	B

CAD = coronary artery disease; CMR = cardiac magnetic resonance; HF = heart failure; PET = positron emission tomography; SPECT = single photon emission computed tomography.

[a] Class of recommendation.

[b] Level of evidence.

Recommendations on functional testing and intravascular imaging for lesion assessment

Recommendations	Class[a]	Level[b]
When evidence of ischaemia is not available, FFR or iwFR are recommended to assess the haemodynamic relevance of intermediate-grade stenosis.	I	A
FFR-guided PCI should be considered in patients with multivessel disease undergoing PCI.	IIa	B
IVUS should be considered to assess the severity of unprotected left main lesions.	IIa	B

FFR = fractional flow reserve; iwFR = instantaneous wave-free ratio; IVUS = intravascular ultrasound; PCI = percutaneous coronary intervention.

[a] Class of recommendation.

[b] Level of evidence.

Decision making and patient information

The Heart Team should provide a balanced, multidisciplinary decision-making process. For common case scenarios, interdisciplinary institutional protocols should be developed. However, complex cases—defined by the protocols—should be discussed individually. Ad hoc meetings of the Heart Team should facilitate efficient clinical workflows.

Active patient participation in the decision-making process should be encouraged.

Patient information needs to be unbiased and evidence-based. Short-term, procedure-related and long-term risks and benefits should be thoroughly discussed. The patient's right to decline the treatment option recommended by the Heart Team has to be respected. Patient refusal of a recommended treatment should be acknowledged in a written document after the patient has received the necessary information by the Heart Team members. In this case, the patient may be offered an alternative treatment option by the Heart Team.

Table 3 Multidisciplinary decision pathways, patient informed consent, and timing of revascularization

	ACS	
	Shock	**STEMI**
Multidisciplinary decision making	Not mandatory during the acute phase. Mechanical circulatory support according to Heart Team protocol.	Not mandatory during the acute phase.
Informed consent	Witnessed verbal informed consent or family consent if possible without delay.	Witnessed verbal informed consent may be sufficient unless written consent is legally required.
Time to revascularization	Emergency: no delay.	Emergency: no delay.
Procedure	Proceed with intervention based on best evidence/ availability. Ad-hoc treatment of culprit lesion, staged treatment of non-culprit lesions according to institutional protocol or Heart Team decision.	Proceed with intervention based on best evidence/ availability. Non-culprit lesions treated according to institutional protocol or Heart Team decision.

Table 3 Multidisciplinary decision pathways, patient informed consent, and timing of revascularization (continued)

	ACS
	NSTE-ACS
Multidisciplinary decision making	Not mandatory during the acute phase. After stabilization, recommended as in SCAD.
Informed consent	Written informed consent[a]. In emergency cases witnessed verbal informed consent may be sufficient.
Time to revascularization	Urgency: within 2 hours to within 72 hours depending on the risk criteria.
Procedure	Proceed with intervention based on best evidence/ availability. Non-culprit lesions treated according to institutional protocol or Heart Team decision.

Decision making and patient information

Table 3 Multidisciplinary decision pathways, patient informed consent, and timing of revascularization (continued)

	SCAD without ad-hoc PCI indication according to Heart Team protocol	SCAD with ad-hoc PCI indication according to Heart Team protocol
Multidisciplinary decision making	Required.	Not required.
Informed consent	Written informed consent[a].	Written informed consent[a].
Time to revascularization	Within 2 weeks for high-risk patients[b] and within 6 weeks for all other patients	Ad hoc.
Procedure	Allow for enough time from diagnostic catheterization to decide on the appropriate intervention.	Proceed with intervention according to institutional protocol defined by Heart Team.

[a] This may not apply to countries that are not legally required to ask for written informed consent. ESC and EACTS advocate documentation of patient consent for all revascularization procedures.

[b] Severe symptoms (CCS class 3), anatomy (left main disease or equivalent, three-vessel disease or proximal left anterior descending artery), or depressed ventricular function.

ACS = acute coronary syndromes; CCS = Canadian Cardiovascular Society; ESC = European Society of Cardiology; EACTS = European Association for Cardio-Thoracic Surgery; NSTE-ACS = non-ST-segment elevation acute coronary syndrome; PCI = percutaneous coronary intervention; SCAD = stable coronary artery disease; STEMI = ST-segment elevation myocardial infarction.

Recommendations for decision-making and patient information in the elective setting

Recommendations	Class[a]	Level[b]
It is recommended that patients undergoing coronary angiography are informed about benefits and risks as well as potential therapeutic consequences ahead of the procedure.	I	C
It is recommended that patients are adequately informed about short- and long-term benefits and risks of the revascularization procedure with information about local experience and allowed enough time for informed decision making.	I	C
It is recommended that institutional protocols are developed by the Heart Team to implement the appropriate revascularization strategy in accordance with current Guidelines.	I	C
In PCI centres without on-site surgery, it is recommended that institutional protocols are established with partner institutions providing cardiac surgery.	I	C

CABG = coronary artery bypass grafting; PCI = percutaneous coronary intervention.

[a] Class of recommendation.

[b] Level of evidence.

Myocardial revascularization is performed for relief of symptoms of myocardial ischaemia and improvement of prognosis. In stable coronary artery disease, the prognostic benefit is dependent on the extent of myocardium subject to ischaemia. With the exception of subtotal stenoses in a major coronary vessel, angiography alone does not suffice to establish the indication for PCI, but documentation of ischaemia or haemodynamic relevance is required. Indications for revascularization in patients with stable angina or silent ischaemia are shown in the Table here.

Whether conservative therapy, PCI or CABG is preferred should depend on the risk– benefit ratios of these treatment strategies, weighting the risks of peri-procedural complications against improvements in health-related quality of life, as well as long-term freedom from death, MI or repeat revascularization. Predicted surgical mortality, anatomical complexity of CAD, and the anticipated completeness of revascularization are important criteria for decision making with respect to the type of revascularization (see Table here).

Individualized treatment decisions should respect the range of predicted surgical risks in the major RCTs which inform the choice of revascularization modality (Table 5). Apart from these issues of individual operative risk and technical feasibility, diabetes mellitus (see Chapter) and anatomical complexity of CAD, as assessed by the SYNTAX score (calculator at http://www.syntaxscore.com), determine the relative benefits of PCI and CABG. Moreover, the ability to achieve complete revascularization is a key issue when choosing the appropriate treatment strategy. The prognostic and symptomatic benefit of myocardial revascularization critically depends on the completeness of revascularization.

Indications for revascularization in patients with stable angina or silent ischaemia		
Recommendations	**Class[a]**	**Level[b]**
For prognosis		
Left main disease with stenosis >50%[c].	I	A
Proximal LAD stenosis >50%[c].	I	A
Two- or three-vessel disease with stenosis >50%[c] with impaired LV function (LVEF ≤35%).	I	A
Large area of ischaemia detected by functional testing (>10% LV) or abnormal invasive FFR[d].	I	B
Single remaining patent coronary artery with stenosis >50%[c].	I	C
For symptoms		
Haemodynamically significant coronary stenosis[c]in the presence of limiting angina or angina equivalent, with insufficient response to optimized medical therapye.	I	A

CAD = coronary artery disease; FFR = fractional flow reserve; iwFR = instantaneous wave-free ratio; LAD = left anterior descending coronary artery; LV = left ventricular; LVEF = left ventricular ejection fraction. [a] Class of recommendation - [b] Level of evidence - [c] With documented ischaemia or haemodynamically relevant lesion defined by FFR ≤0.80 or iwFR ≤0.89 or >90% stenosis in a major coronary vessel - [d] Based on FFR <0.75 indicating a prognostically relevant lesion - [e] In consideration of patient compliance and wishes in relation to intensity of antianginal therapy.

Recommendations on criteria for the choice between coronary artery bypass grafting and percutaneous coronary intervention		
Recommendations	**Class[a]**	**Level[b]**
Assessment of surgical risk[c]		
It is recommended that the STS score is calculated to assess in- hospital or 30-day mortality, and in-hospital morbidity after CABG.	I	B
Calculation of the EuroSCORE II may be considered to assess in- hospital mortality after CABG.	IIb	B
Assessment of CAD complexity		
In patients with LM or multivessel disease, it is recommended that the SYNTAX score is calculated to assess the anatomical complexity of CAD and the long-term risk of mortality and morbidity after PCI.	I	B
When considering the decision between CABG and PCI, completeness of revascularization should be prioritized.	IIa	B

CABG = coronary artery bypass grafting; CAD = coronary artery disease; LM = left main; PCI = percutaneous coronary intervention; STS = Society of Thoracic Surgeons; SYNTAX = Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

[a] Class of recommendation - [b] Level of evidence

[c] Level of evidence refers to prediction of outcomes.

Table 5 Logistic EuroSCOREs[a] in major randomized trials comparing percutaneous coronary intervention (PCI) with coronary artery bypass grafting (CABG)

Trial	EuroSCORE PCI	EuroSCORE CABG
SYNTAX	3.8 ± 2.6	3.8 ± 2.7
BEST	2.9 ± 2.0	3.0 ± 2.1
FREEDOM	2.7 ± 2.4	2.8 ± 2.5
PRECOMBAT	2.7 ± 1.8	2.8 ± 1.9
EXCEL	not reported	not reported
NOBLE	2 [2-4]	2 [2-4]

Numbers are presented as mean ± standard deviation or median [interquartile range].

[a] Compared with the contemporary EuroSCORE II, the logistic EuroSCORE has similar discrimination, but poorer calibration and, thus, overestimates surgical mortality by roughly two-fold.

Table 6 Guide to calculate the SYNTAX score[a]

Steps	Variable assessed	Description
Step 1	Dominance	The weight of individual coronary segments varies according to coronary artery dominance (right or left). Co-dominance does not exist as an option in the SYNTAX score.
Step 2	Coronary segment	The diseased coronary segment directly affects the score as each coronary segment is assigned a weight depending on its location, ranging from 0.5 (i.e. posterolateral branch) to 6 (i.e. left main in case of left dominance). Step 3	Diameter stenosis	The score of each diseased coronary segment is multiplied by x2 in case of a stenosis 50–99% and by x5 in case of total occlusion. In case of total occlusion, additional points will be added as follows: – Age >3 months or unknown: +1 – Blunt stump: +1 – Bridging: +1 – First segment visible distally: +1 per non visible segment – Side branch at the occlusion: +1 if <1.5 mm diameter; + 1 if both <1.5 mm and ≥1.5 mm diameter; +0 if ≥1.5 mm diameter (i.e. bifurcation lesion)
Step 4	Trifurcation lesion	The presence of a trifurcation lesion adds additional points based on the number of diseased segments: – 1 segment: +3 – 2 segments: +4 – 3 segments: +5 – 4 segments: +6

	Bifurcation lesion	The presence of a bifurcation lesion adds additional points based on the type of bifurcation according to the Medina classification:[126] – Medina 1,0,0–0,1,0–1,1,0 +1 – Medina 1,1,1–0,0,1–1,0,1–0,1,1 +2 Moreover, the presence of a bifurcation angle <70° adds 1 additional point
	Aorto-ostial lesion	The presence of aorto-ostial lesion segments adds 1 additional point
	Severe tortuosity	The presence of severe tortuosity proximal of the diseased segment adds 2 additional points
	Lesion length	Lesion length >20 mm adds 1 additional point
	Calcification	The presence of heavy calcification adds 2 additional points
	Thrombus	The presence of thrombus adds 1 additional point
	Diffuse disease/small vessels	The presence of diffusely diseased and narrowed segments distal to the lesion (i.e. when at least 75% of the length of the segment distal to the lesion has a vessel diameter <2 mm) adds 1 point per segment number

X score calculation http://www.syntaxscore.com

Recommendations for selection of the type of myocardial revascularization (CABG or PCI) in patients with stable CAD, with suitable coronary anatomy for both procedures and low predicted surgical mortality, are provided in the table below.

Recommendation for the type of revascularization in patients with stable coronary artery disease with suitable coronary anatomy for both procedures and low predicted surgical mortality[d]

Recommendations according to extent of CAD	CABG		PCI	
	Class[a]	Level[b]	Class[a]	Level[b]
One-vessel CAD				
Without proximal LAD stenosis.	IIb	C	I	C
With proximal LAD stenosis.	I	A	I	A
Two-vessel CAD				
Without proximal LAD stenosis.	IIb	C	I	C
With proximal LAD stenosis.	I	B	I	C
Left main CAD				
Left main disease with low SYNTAX score (0–22).	I	A	I	A
Left main disease with intermediate SYNTAX score (23–32).	I	A	IIa	A
Left main disease with high SYNTAX score (≥33).[c]	I	A	III	B
Three-vessel CAD without diabetes mellitus				
Three-vessel disease with low SYNTAX score (0–22).	I	A	I	A
Three-vessel disease with intermediate or high SYNTAX score (>22).[c]	I	A	III	A
Three-vessel CAD with diabetes mellitus				
Three-vessel disease with low SYNTAX score (0–22).	I	A	IIb	A
Three-vessel disease with intermediate or high SYNTAX score (>22).[c]	I	A	III	A

CABG = coronary artery bypass grafting; CAD = coronary artery disease; LAD = left anterior descending coronary artery; PCI = percutaneous coronary intervention; SYNTAX = Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

SYNTAX score calculation http://www.syntaxscore.com

[a] Class of recommendation - [b] Level of evidence.

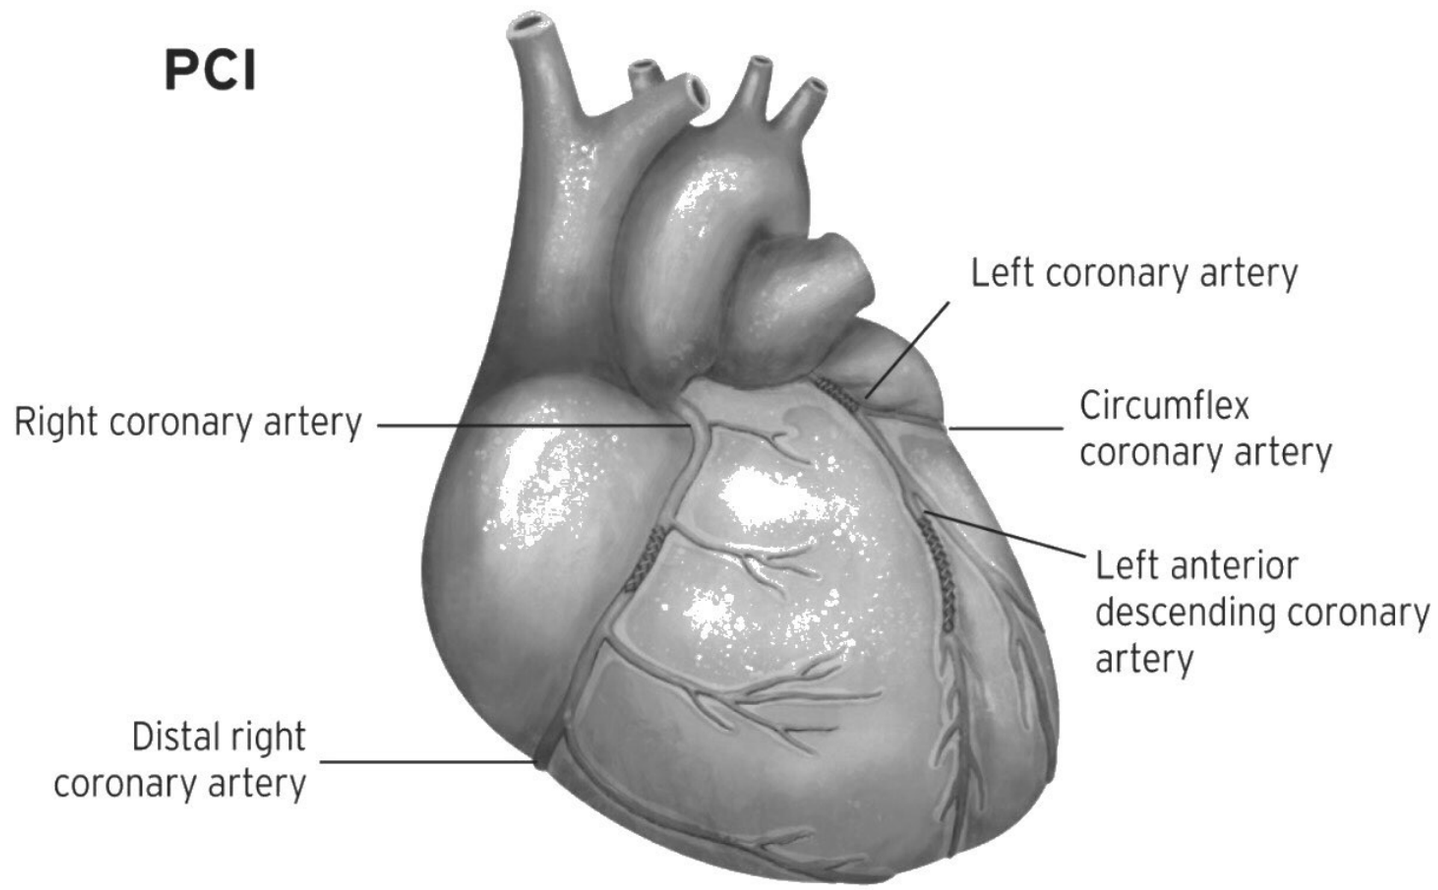
[c] PCI should be considered, if the Heart Team is concerned about the surgical risk or if the patient refuses CABG after adequate counselling by the Heart Team.

[d] For example, absence of previous cardiac surgery, severe morbidities, frailty, immobility, precluding CABG (also see Table 5).

Individualized treatments concepts with respect for the preferences of the patient informed about early and late outcomes call for the Heart Team to be consulted.

Figure 3 summarizes aspects to be considered by the Heart Team.

Figure 3 Aspects to be considered by the Heart Team for the decision making between percutaneous coronary intervention and coronary artery bypass grafting among patients with stable multivessel and/or left main coronary artery disease



FAVOURS PCI

Clinical characteristics

Presence of severe co-morbidity (not adequately reflected by scores)

Advanced age/frailty/reduced life expectancy

Restricted mobility and conditions that affect the rehabilitation process

Anatomical and technical aspects

MVD with SYNTAX score 0–22

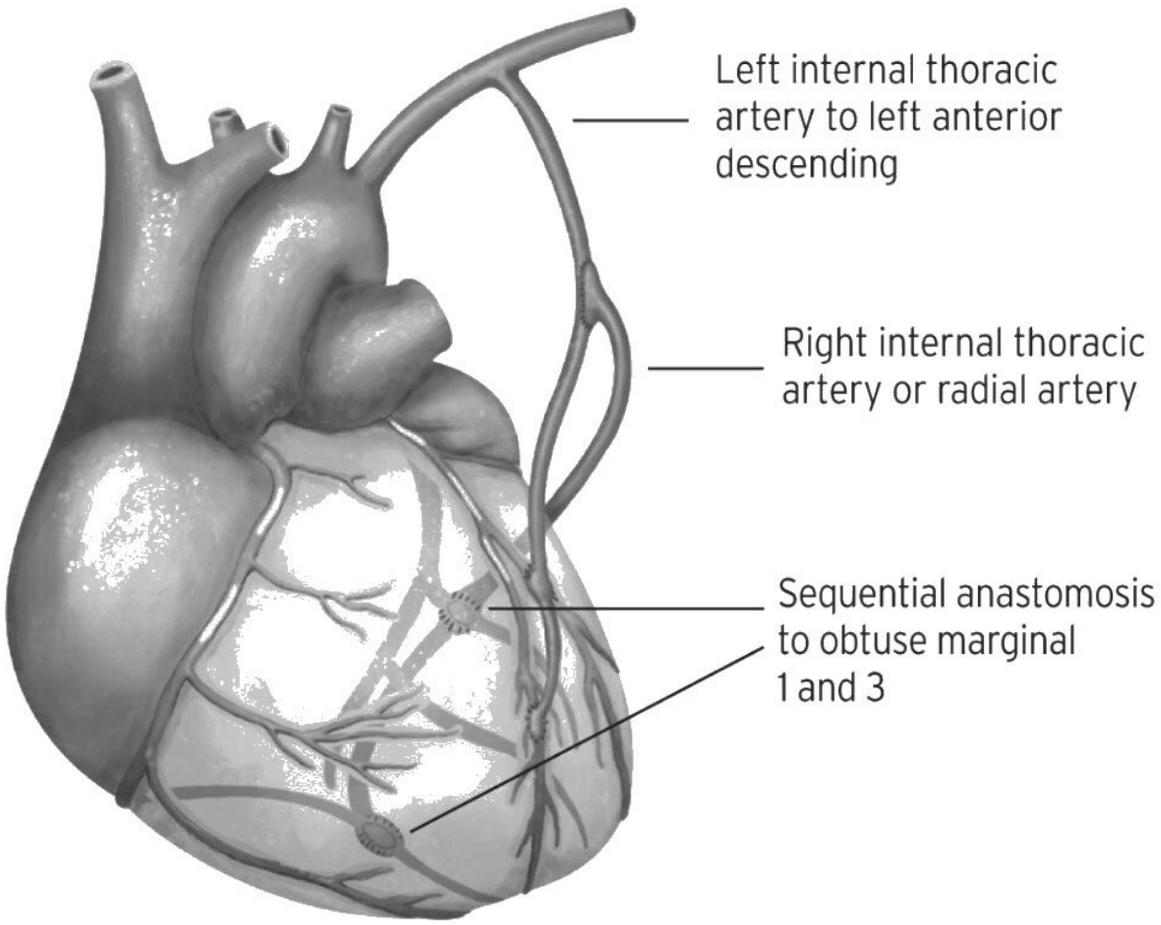
Anatomy likely resulting in incomplete revascularization with CABG due to poor quality or missing conduits

Severe chest deformation or scoliosis

Sequelae of chest radiation

Porcelain aorta[a]

CABG



FAVOURS CABG

Clinical characteristics

- Diabetes.
- Reduced LV function (EF ≤35%).
- Contraindication to DAPT.
- Recurrent diffuse in-stent restenosis.

Anatomical and technical aspects

- MVD with SYNTAX score ≥23
- Anatomy likely resulting in incomplete revascularization with PCI
- Severely calcified coronary artery lesions limiting lesion expansion

Need for concomitant interventions

- Ascending aortic pathology with indication for surgery
- Concomitant cardiac surgery

CABG = coronary artery bypass grafting; Cx = circumflex; DAPT = dual antiplatelet therapy; EF = ejection fraction; LAD = left anterior descending coronary artery; LIMA = left internal mammary artery; LV= left ventricular; MVD = multivessel coronary artery disease; PCI = percutaneous coronary intervention; PDA = posterior descending artery; RA = radial artery; RIMA = right internal mammary artery; SYNTAX = Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

[a]Consider no-touch off-pump CABG in case of porcelain aorta.

Recommendations for timing of invasive evaluation and myocardial revascularization in patients with NSTE-ACS are provided in the table below and in Figure 4.

Recommendations for invasive evaluation and revascularization in non-ST-elevation acute coronary syndrome

Recommendations	Class[a]	Level[b]
Urgent coronary angiography (<2 hours) is recommended in patients at very high ischaemic risk (Figure 4).	I	C
An early invasive strategy (<24 hours) is recommended in patients with at least one high-risk criterion (Figure 4).	I	A
An invasive strategy (<72 hours after first presentation) is indicated in patients with at least one intermediate-risk criterion (Figure 4) or recurrent symptoms.	I	A
It is recommended to base the revascularization strategy (ad hoc culprit-lesion PCI/multivessel PCI/CABG) on the clinical status and comorbidities as well as the disease severity, [i.e. the distribution and angiographic lesion characteristics (e.g. SYNTAX score)], according to the principles for SCAD.[c]	I	B
In cardiogenic shock, routine revascularization of non-IRA lesions is not recommended during primary PCI.	III	B

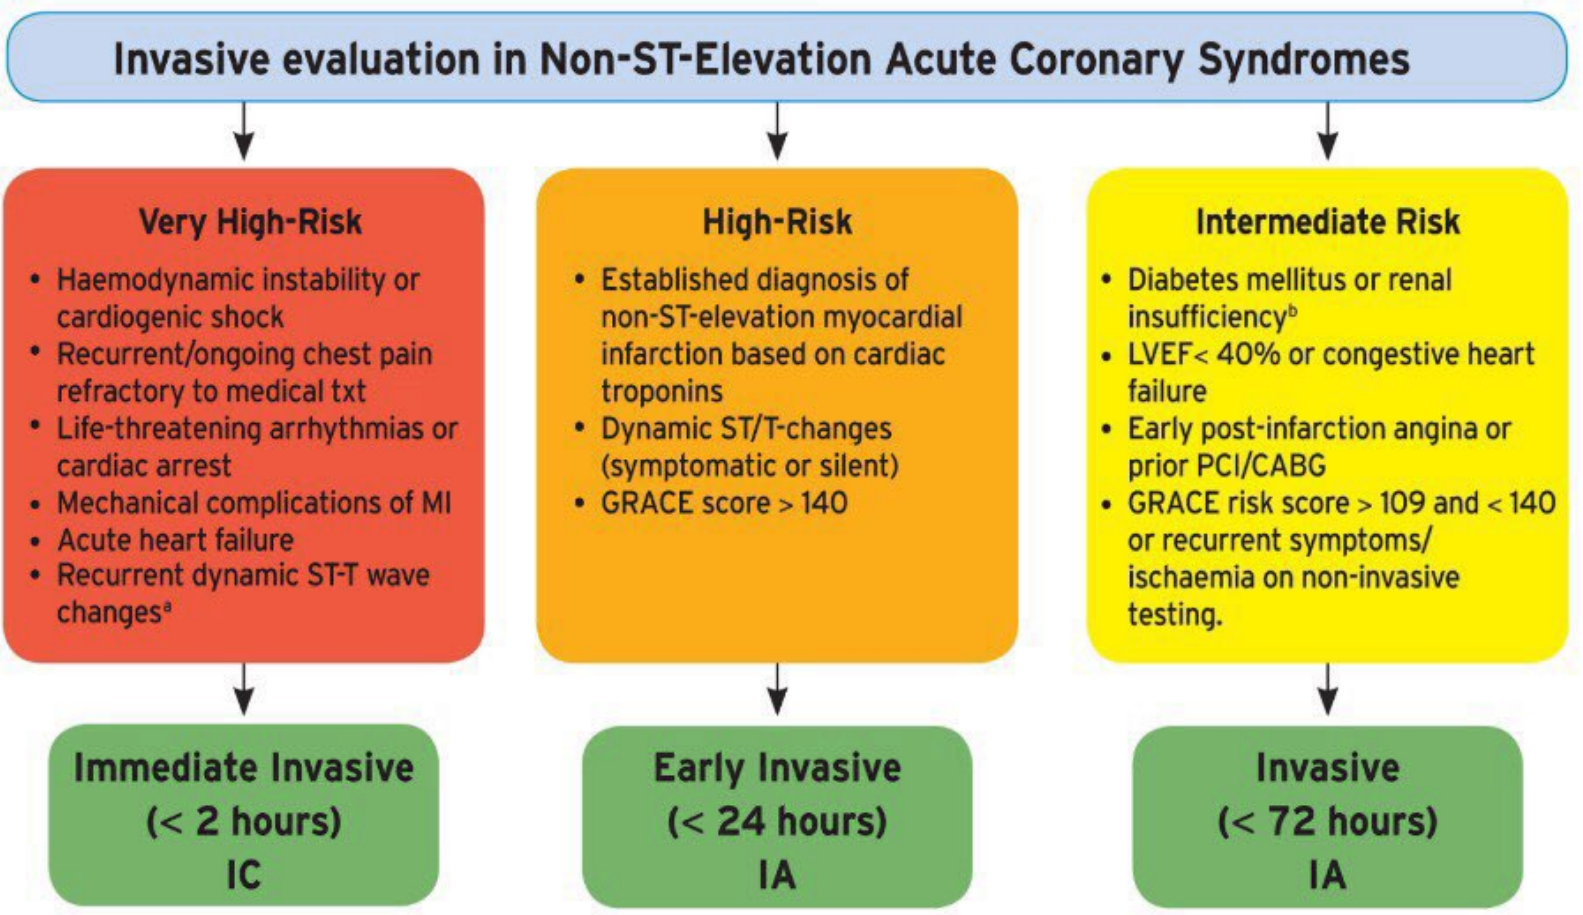
CABG = coronary artery bypass grafting; IRA = infarct-related artery; NSTE-ACS = non-ST-elevation acute coronary syndrome; PCI = percutaneous coronary intervention; SCAD = stable coronary artery disease; SYNTAX = Synergy Between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery.

[a] Class of recommendation.

[b] Level of evidence.

[c] May apply to stabilized NSTE-ACS patients.

Figure 4 Selection of non-ST-elevation acute coronary syndrome (NSTE-ACS) treatment strategy and timing according to initial risk stratification.

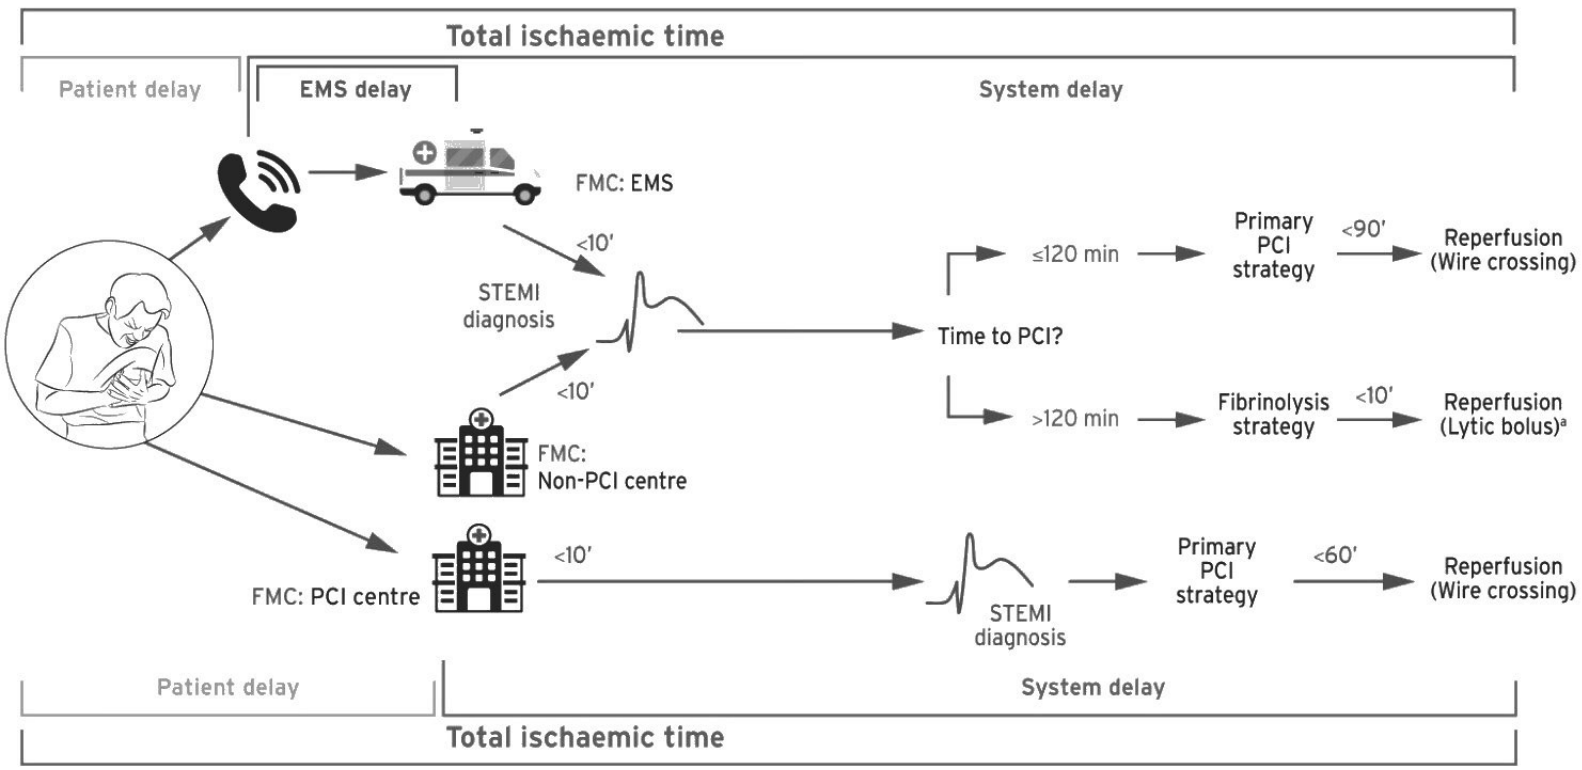


CABG = coronary artery bypass grafting; GRACE = Global Registry of Acute Coronary Events; LVEF = left ventricular ejection fraction; MI =myocardial infarction; PCI = percutaneous coronary intervention.

[a] Particularly intermittent ST-elevation; [b] Estimated glomerular filtration rate <60mL/min/1.73m^2

Delays in the timely implementation of reperfusion therapy are key issues in the management of STEMI as the greatest benefit gained from reperfusion therapy occurs within the first 2–3 hours of symptom onset. Optimal treatment of STEMI should be based on the implementation of regional networks between hospitals with various levels of technology, connected by an efficient ambulance service. The goal of these networks is to provide optimal care while minimizing delays–as summarized in Figure 5–in order to improve clinical outcomes.

Figure 5 Modes of patient's medical contact, components of ischaemia time and flowchart for reperfusion strategy selection



The recommended mode of patient presentation is by alerting the EMS (call national emergency number: 112 or similar number according to region). When STEMI diagnosis is made in the out-of-hospital setting (via EMS) or in a non-PCI centre, the choice of reperfusion strategy is based on the estimated time from STEMI diagnosis to PCI-mediated reperfusion (wire crossing). System delay for patients alerting the EMS starts at the time of phone alert, although FMC occurs when the EMS arrives at the scene.

EMS = emergency medical service; FMC = first medical contact; PCI = percutaneous coronary intervention; STEMI = ST-segment elevation myocardial infarction.

'denotes minutes.

[a] Patients receiving fibrinolysis should be transferred to a PCI centre immediately after administration of the lytic bolus.

Recommendations for myocardial reperfusion with primary PCI in the setting of STEMI are provided in the table below.

Primary percutaneous coronary intervention for myocardial reperfusion in ST-elevation myocardial infarction: indications and logistics

Recommendations	Class[a]	Level[b]
Indication		
Reperfusion therapy is indicated in all patients with time from symptom onset <12 hours' duration and persistent ST-segment elevation.	I	A
In the absence of ST-segment elevation, a primary PCI strategy is indicated in patients with suspected ongoing ischaemic symptoms suggestive of MI and at least one of the following criteria present: • haemodynamic instability or cardiogenic shock • recurrent or ongoing chest pain refractory to medical treatment • life-threatening arrhythmias or cardiac arrest • mechanical complications of MI • acute heart failure • recurrent dynamic ST-segment or T-wave changes, particularly with intermittent ST-segment elevation.	I	C
A primary PCI strategy is recommended over fibrinolysis within the indicated timeframes.	I	A
In patients with time from symptom onset >12 hours, a primary PCI strategy is indicated in the presence of ongoing symptoms or signs suggestive of ischaemia, haemodynamic instability, or life- threatening arrhythmias.	I	C
A routine primary PCI strategy should be considered in patients presenting late (12–48 hours) after symptom onset.	IIa	B
Logistics		
It is recommended that the prehospital management of STEMI patients be based on regional networks designed to deliver reperfusion therapy effectively in a timely fashion, and to offer primary PCI to as many patients as possible.	I	B
It is recommended that all EMS, emergency departments, coronary care units, and catheterization laboratories have a written updated STEMI management protocol, preferably shared within geographic networks.	I	C
It is recommended that primary PCI-capable centres deliver a 24-hour/7-day service and ensure that primary PCI is performed as fast as possible.	I	B
It is recommended that patients transferred to a PCI-capable centre for primary PCI bypass the emergency department and CCU/ICCU and are transferred directly to the catheterization laboratory.	I	B

CCU = coronary care unit; EMS = emergency medical services; ICCU = intensive coronary care unit; MI = myocardial infarction; PCI = percutaneous coronary intervention; STEMI = ST-segment elevation myocardial infarction.

[a] Class of recommendation - [b] Level of evidence.

Recommendations regarding procedural aspects of primary PCI are listed in the table below.

Primary percutaneous coronary intervention for myocardial reperfusion in ST-elevation myocardial infarction: procedural aspects (strategy and technique)

Recommendations	Class[a]	Level[b]
Strategy		
Routine revascularization of non-IRA lesions should be considered in patients with multivessel disease before hospital discharge.	IIa	A
CABG should be considered in patients with ongoing ischaemia and large areas of jeopardized myocardium if PCI of the IRA cannot be performed.	IIa	C
In cardiogenic shock, routine revascularization of non-IRA lesions is not recommended during primary PCI.	III	B
Technique		
Routine use of thrombus aspiration is not recommended.	III	A

CABG = coronary artery bypass grafting; IRA = infarct-related artery; PCI = percutaneous coronary intervention; STEMI = ST-segment elevation myocardial infarction.

[a] Class of recommendation

[b] Level of evidence.

Recommendations for myocardial revascularization in patients with chronic heart failure and systolic LV dysfunction are listed in the table below.

Recommendations on revascularizations in patients with chronic heart failure and systolic left ventricular dysfunction (ejection fraction ≤35%)

Recommendations	Class[a]	Level[b]
In patients with severe LV systolic dysfunction and coronary artery disease suitable for intervention, myocardial revascularization is recommended.	I	B
CABG is recommended as the first revascularization strategy choice in patients with multivessel disease and acceptable surgical risk.	I	B
In patients with one or two-vessel disease, PCI should be considered as an alternative to CABG when complete revascularization can be achieved.	IIa	C
In patients with three-vessel disease, PCI should be considered based on the evaluation by the Heart Team of the patient's coronary anatomy, the expected completeness of revascularization, diabetes status, and comorbidities.	IIa	C
LV aneurysmectomy during CABG should be considered in patients with NYHA class III/IV, large LV aneurysm, large thrombus formation, or if the aneurysm is the origin of arrhythmias.	IIa	C
Surgical ventricular restoration during CABG may be considered in selected patients treated in centres with expertise.	IIb	B

CABG = coronary artery bypass grafting; LV = left ventricular; NYHA = New York Heart Association; PCI = percutaneous coronary intervention.

[a] Class of recommendation.

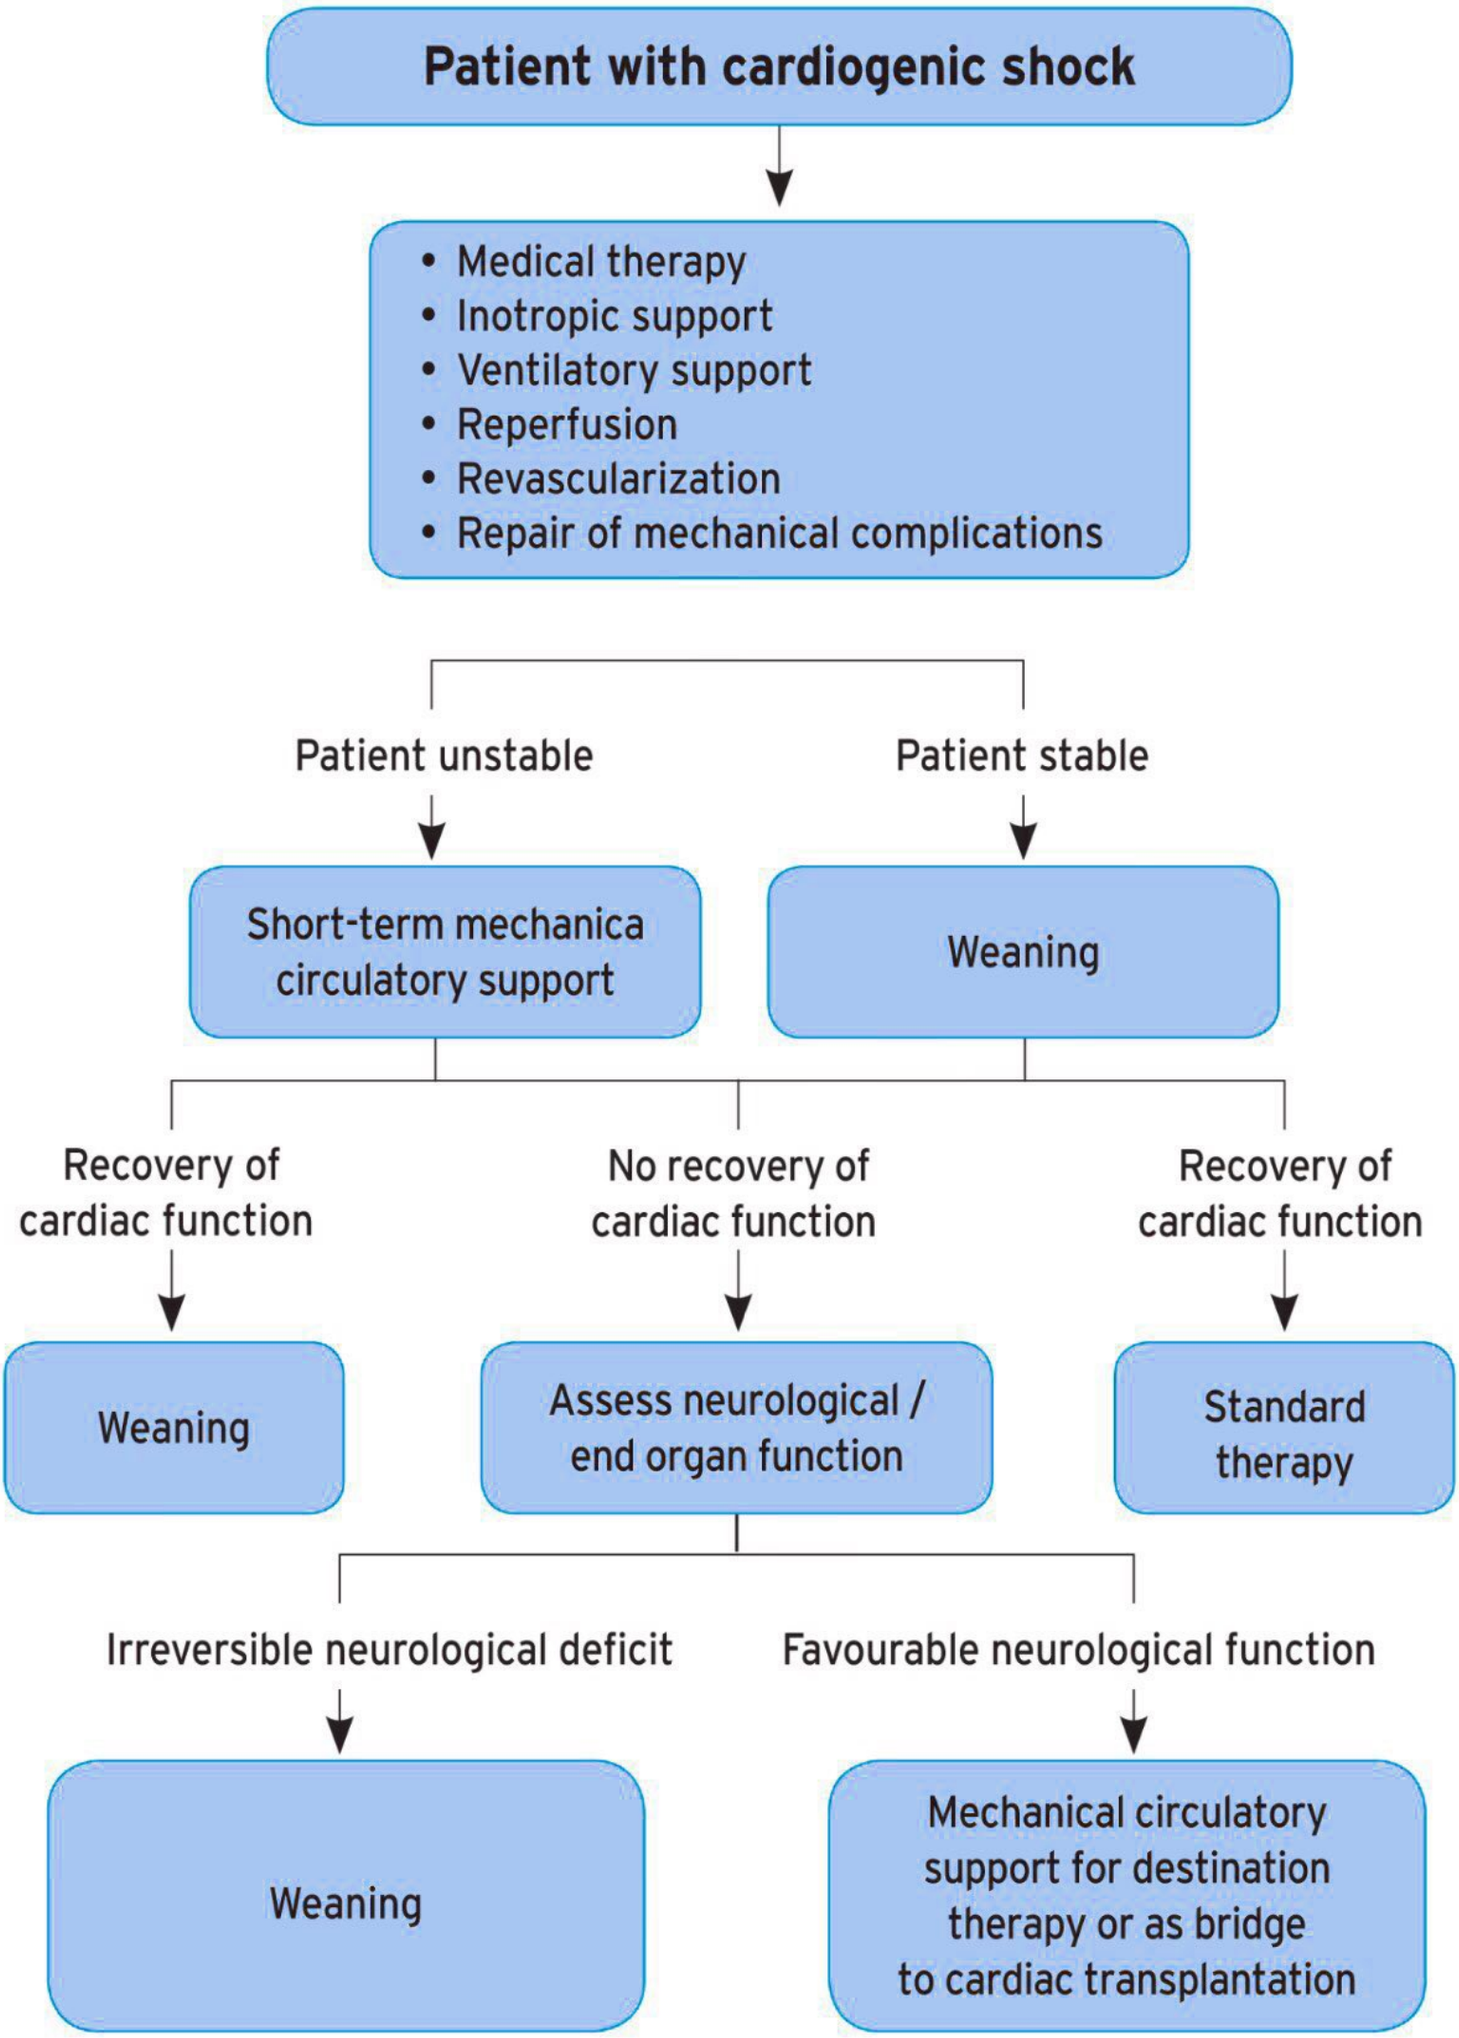
[b] Level of evidence.

Myocardial revascularization is the cornerstone of treatment in patients with cardiogenic shock complicating ACS. Therefore, emergency coronary angiography is indicated in this setting. The general triage and treatment of patients with cardiogenic shock is displayed in Figure 6.

Figure 6 Algorithm for management of patients with cardiogenic shock

raphy is indicated in this setting. The general triage and treatment of patients with cardiogenic shock is displayed in Figure 6.

Figure 6 Algorithm for management of patients with cardiogenic shock



For interactivity see here

Recommendations for the management of patients with cardiogenic shock		
Recommendations	**Class[a]**	**Level[b]**
Emergency coronary angiography is indicated in patients with acute heart failure or cardiogenic shock complicating ACS.	I	B
Emergency PCI of the culprit lesion is indicated for patients with cardiogenic shock due to STEMI or NSTE-ACS, independent of time delay of symptom onset, if coronary anatomy is amenable to PCI.	I	B
Emergency CABG is recommended for patients with cardiogenic shock if the coronary anatomy is not amenable to PCI.	I	B
In cases of haemodynamic instability, emergency surgical or catheter-based repair of mechanical complications of ACS is indicated, as decided by the Heart Team.	I	C
In selected patients with ACS and cardiogenic shock, short-term mechanical circulatory support may be considered, depending on patient age, comorbidities, neurological function, and the prospects for long-term survival and predicted quality of life.	IIb	C
Routine use of IABPs in patients with cardiogenic shock due to ACS is not recommended.	III	B

ACS = acute coronary syndrome; CABG = coronary artery bypass grafting; IABP = intra-aortic balloon pump; NSTE-ACS = non-ST-elevation acute coronary syndrome; PCI = percutaneous coronary intervention; STEMI = ST-elevation myocardial infarction.

[a] Class of recommendation - [b] Level of evidence.

In general the indications for revascularization in diabetic patients with SCAD and ACS are similar to those in patients without diabetes (see Chapter 5). In the selection of the optimal myocardial revascularization strategy for patients with multivessel CAD, diabetes mellitus is an important criterion favouring CABG. Specific recommendations for myocardial revascularization in patients with diabetes are provided in the Table on page 15 (see Chapter 5).

Recommendation for patients on metformin

Recommendation	Class[a]	Level[b]
It is recommended to check renal function if patients have taken metformin immediately before angiography and withhold metformin if renal function deteriorates.	I	C

[a] Class of recommendation - [b] Level of evidence.

Recommendations for prevention of contrast-induced nephropathy in patients undergoing coronary angiography and myocardial revascularization are provided in the table below.

Recommendations for the prevention of contrast-induced nephropathy

Recommendations	Dose	Class[a]	Level[b]
Patients undergoing coronary angiography or MSCT			
It is recommended that all patients are assessed for the risk of contrast-induced nephropathy.		I	C
Adequate hydration is recommended.		I	C
Patients with moderate or severe CKD (National Kidney Foundation stages 3b and 4)			
Use of low-osmolar or iso-osmolar contrast media is recommended.		I	A
It is recommended that the volume of contrast media be minimized.	Total contrast volume/GFR <3.7.[c]	I	B
In statin-naïve patients, pretreatment with high-dose statins should be considered.	Rosuvastatin 40/20 mg or atorvastatin 80 mg.	IIa	A
Pre- and post-hydration with isotonic saline should be considered if the expected contrast volume is >100 mL.	1 mL/kg/h 12 hours before and continued for 24 hours after the procedure (0.5 mL/kg/h if LVEF ≤35% or NYHA >2).	IIa	C
As an alternative to the pre- and post- hydration regimen, tailored hydration regimens[d] may be considered.		IIb	B
Patients with severe CKD (National Kidney Foundation stage 4)			
Prophylactic haemofiltration 6 hours before complex PCI may be considered.	Fluid replacement rate 1000 mL/h without negative loss and saline hydration continued for 24 hours after the procedure.	IIb	B
Haemodialysis is not recommended as a preventive measure.		III	B

CKD = chronic kidney disease; GFR = glomerular filtration rate; LVEF = left ventricular ejection fraction; MSCT = multi-slice computed tomography; NYHA = New York Heart Association; PCI = percutaneous coronary angiography. [a] Class of recommendation - [b] Level of evidence. [c] Example: 370 mL of contrast medium in a patient with a GFR of 100 mL/min will yield a ratio of 3.7. [d] Options are: infusion of normal saline adjusted to central venous pressure; furosemide with matched infusion of normal saline (for details see web addenda).

The table below provides a list of recommendations for combined valvular interventions and myocardial revascularization according to primary diagnosis and type of valvular disease.

Recommendations for combined valvular and coronary interventions		
Recommendations	**Class[a]**	**Level[b]**
Primary valve intervention and coronary revascularization		
CABG is recommended in patients with a primary indication for aortic/mitral valve surgery and coronary artery diameter stenosis >70%.	I	C
CABG should be considered in patients with a primary indication for aortic/mitral valve surgery and coronary artery diameter stenosis of 50–70%.	IIa	C
PCI should be considered in patients with a primary indication to undergo TAVI and coronary artery diameter stenosis >70% in proximal segments.	IIa	C
PCI should be considered in patients with a primary indication to undergo transcatheter mitral valve interventions and coronary artery diameter stenosis >70% in proximal segments.	IIa	C
Primary myocardial revascularization and valve intervention		
SAVR is indicated in patients with severe AS undergoing CABG, or surgery of the ascending aorta or another valve.	I	C
Mitral valve surgery is indicated in patients with severe[c] secondary MR undergoing CABG and LVEF >30%.	I	C
Mitral valve surgery should be considered in symptomatic patients with severe[c] secondary MR, LVEF <30%, but with evidence of myocardial viability and an option for surgical revascularization.	IIa	C

AS = aortic stenosis; CABG = coronary artery bypass grafting; LVEF = left ventricular ejection fraction; MR = mitral regurgitation; PCI = percutaneous coronary intervention; SAVR = surgical aortic valve replacement; TAVI = transcatheter aortic valve implantation. [a] Class of recommendation - [b] Level of evidence. [c] Severe secondary MR was defined as an effective regurgitant orifice area (EROA) >0.40 cm^2.

Recommendations for carotid artery revascularization in patients scheduled for CABG are provided in the table below.

Recommendations on the management of carotid stenosis in patients undergoing coronary artery bypass grafting

Recommendations	Class[a]	Level[b]
In patients scheduled for CABG it is recommended that the indication (and if so the method and timing) for carotid revascularization be individualized after discussion within a multidisciplinary team, including a neurologist.	I	C
In patients scheduled for CABG, with recent (<6 months) history of TIA/stroke:		
– Carotid revascularization should be considered in patients with 50–99% carotid stenosis.	IIa	B
– Carotid revascularization with CEA should be considered as first choice in patients with 50–99% carotid stenosis.	IIa	B
– Carotid revascularization is not recommended in patients with carotid stenosis <50%.	III	C
In neurologically asymptomatic patients scheduled for CABG:		
– Carotid revascularization may be considered in patients with bilateral 70–99% carotid stenosis or 70–99% carotid stenosis and contralateral occlusion.	IIb	C
– Carotid revascularization may be considered in patients with a 70–99% carotid stenosis, in the presence of one or more characteristics that may be associated with an increased risk of ipsilateral stroke[c], in order to reduce stroke risk beyond the perioperative period.	IIb	C
– Routine prophylactic carotid revascularization in patients with a 70–99% carotid stenosis is not recommended.	III	C

CABG = coronary artery bypass grafting; CEA= carotid endarterectomy; TIA = transient ischaemic attack.

[a] Class of recommendation - [b] Level of evidence.

[c] Contralateral TIA/stroke, ipsilateral silent infarction on cerebral imaging, intraplaque haemorrhage or lipid- rich necrotic core on magnetic resonance angiography, or any of the following ultrasound imaging findings: stenosis progression (>20%), spontaneous embolization on transcranial Doppler, impaired cerebral vascular reserve, large plaques, echolucent plaques, increased juxta-luminal hypoechogenic area.

Recommendations for pre-operative strategies to reduce the incidence of stroke in patients undergoing CABG are provided in the table below.

Pre-operative strategies to reduce the incidence of stroke in patients undergoing coronary artery bypass grafting

Recommendations	Class[a]	Level[b]
In patients undergoing CABG, carotid DUS is recommended in patients with recent (<6 months) history of stroke/TIA.	I	B
In patients with no recent (<6 months) history of TIA/stroke, carotid DUS may be considered before CABG in the following cases: age ≥70 years, multivessel coronary artery disease, concomitant LEAD, or carotid bruit.	IIb	B
Screening for carotid stenosis is not indicated in patients requiring urgent CABG with no recent stroke/TIA.	III	C

CABG = coronary artery bypass grafting; DUS = duplex ultrasound; LEAD = lower extremity artery disease; TIA = transient ischaemic attack. [a] Class of recommendation - [b] Level of evidence.

Repeat revascularization procedures

Recommendations on repeat revascularization strategies after CABG and PCI are provided in the tables below.

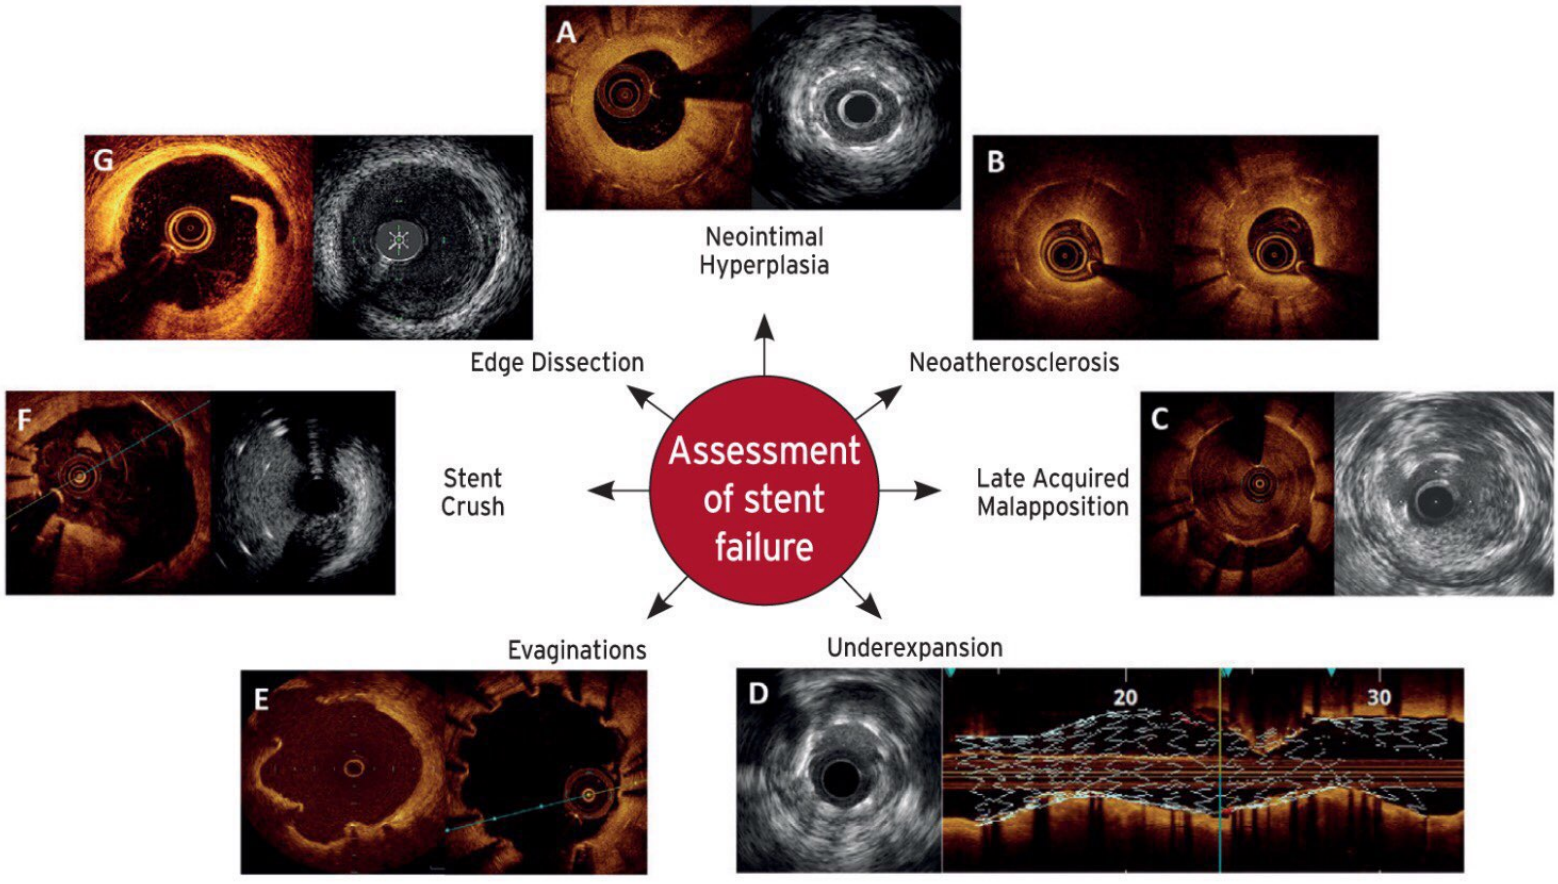
Recommendations on repeat revascularization		
Recommendations	**Class[a]**	**Level[b]**
Early post-operative ischaemia and graft failure		
Coronary angiography post-CABG is recommended for patients with: • symptoms of ischaemia and/or abnormal biomarkers suggestive of peri-operative MI • ischaemic ECG changes indicating large area of risk • new significant wall motion abnormalities • haemodynamic instability.	I	C
It is recommended that either emergency reoperation or PCI is decided upon by ad hoc consultation in the Heart Team, based on the feasibility of revascularization, area at risk, comorbidities, and clinical status.	I	C
Disease progression and late graft failure		
Repeat revascularization is indicated in patients with a large area of ischaemia or severe symptoms despite medical therapy.	I	B
If considered safe, PCI should be considered as first choice over CABG.	IIa	C
Procedural aspects of the revascularization modalities		
CABG		
IMA is the conduit of choice for redo CABG in patients in whom the IMA was not used previously.	I	B
Redo CABG should be considered for patients without a patent IMA graft to the LAD.	IIa	B
PCI		
Distal protection devices should be considered for PCI of SVG lesions.	IIa	B
PCI of the bypassed native artery should be considered over PCI of the bypass graft.	IIa	C
Restenosis		
DES are recommended for the treatment of in-stent restenosis of BMS or DES.	I	A
Drug-coated balloons are recommended for the treatment of in-stent restenosis of BMS or DES.	I	A
In patients with recurrent episodes of diffuse in-stent restenosis, CABG should be considered by the Heart Team over a new PCI attempt.	IIa	C
IVUS and/or OCT should be considered to detect stent-related mechanical problems leading to restenosis.	IIa	C

BMS = bare-metal stent; CABG = coronary artery bypass grafting; DES = drug-eluting stent; ECG = electrocardiogram; IMA = internal mammary artery; IVUS = intravascular ultrasound; LAD = left anterior descending artery; MI = myocardial infarction; OCT = optical coherence tomography; PCI = percutaneous coronary intervention; SVG = saphenous vein graft.

[a] Class of recommendation - [b] Level of evidence.

Figure 7 summarizes the contribution of intracoronary imaging to the management of stent failure.

Figure 7 Intracoronary imaging for the assessment of stent failure



Examples of intravascular imaging findings (IVUS or OCT) in patients with stent failure. Panel A displays OCT (left) and IVUS (right) examples of in-stent restenosis due to excessive neointimal hyperplasia. Panel B displays two OCT examples of in-stent restenosis due to neoatherosclerosis. Panel C displays OCT (left) and IVUS (right) examples of late acquired malapposition. Panel D displays IVUS (left) and longitudinal OCT reconstruction (right) images of stent underexpansion. Panel E displays two OCT examples of in-stent evaginations, a typical finding of delayed arterial healing. Panel F displays OCT (left and IVUS (right) examples of stent crush. Panel G displays an OCT (left) and IVUS (right) case of coronary dissection at the stent edge. IVUS = intravascular ultrasound; OCT = optical coherence tomography.

Intracoronary images for this figure were kindly provided by Drs Nicolas Amabile, Fernando Alfonso, and Gennaro Sardella.

Recommendations for the prevention of ventricular arrhythmias by myocardial revascularization are provided in the table below.

Recommendations for the prevention of ventricular arrhythmias by revascularization

Recommendations	Class[a]	Level[b]
A primary PCI strategy is recommended in patients with resuscitated cardiac arrest and an ECG consistent with STEMI.	I	B
Urgent angiography (and PCI if indicated) should be considered in patients with resuscitated cardiac arrest without diagnostic ST-segment elevation but with a high suspicion of ongoing myocardial ischaemia.	IIa	C
In patients with electrical storm, urgent coronary angiography and revascularization (as required) should be considered.	IIa	C

ECG = electrocardiogram; STEMI = ST-elevation myocardial infarction; PCI = percutaneous coronary intervention.
[a] Class of recommendation - [b] Level of evidence.

Recommendations for prevention and treatment of atrial fibrillation in the setting of myocardial revascularization

Recommendations	Class[a]	Level[b]
Peri-operative oral β-blocker therapy is recommended for the prevention of post-operative AF after CABG surgery.	I	B
Restoration of sinus rhythm by electrical cardioversion or antiarrhythmic drugs is recommended in post-operative AF with haemodynamic instability.	I	C
Peri-operative amiodarone should be considered as prophylactic therapy to prevent AF after CABG surgery.	IIa	A
Long-term anticoagulation should be considered in patients with AF after CABG or PCI, at risk for stroke, considering the individual stroke and bleeding risk.	IIa	B
Rate control and anticoagulation should be considered as the initial management of asymptomatic post-operative AF.	IIa	B
Antiarrhythmic drugs should be considered for symptomatic post- operative AF after CABG or PCI in an attempt to restore sinus rhythm.	IIa	C
Surgical occlusion or exclusion of the LAA may be considered for stroke prevention in patients with AF undergoing CABG surgery.	IIb	B

AF = atrial fibrillation; CABG = coronary artery bypass grafting; LAA = left atrial appendage; PCI = percutaneous coronary intervention. [a] Class of recommendation - [b] Level of evidence.

Procedural aspects of CABG

Recommendations on procedural aspects of CABG are listed in the table below and in Figure 8.

Recommendations on procedural aspects of coronary artery bypass grafting		
Recommendations	**Class[a]**	**Level[b]**
General considerations		
Complete myocardial revascularization is recommended.[c]	I	B
Minimization of aortic manipulation is recommended.	I	B
CT scans of the ascending aorta should be considered in patients over 70 years of age and/or with signs of extensive generalized atherosclerosis.	IIa	C
Routine intraoperative graft flow measurement should be considered.	IIa	B
Prior to aortic manipulation, epiaortic ultrasound should be considered to identify atheromatous plaques and select the optimal surgical strategy.	IIa	C
Conduit selection		
Arterial grafting with IMA to the LAD system is recommended.	I	B
An additional arterial graft should be considered in appropriate patients.	IIa	B
The use of the radial artery is recommended over the saphenous vein in patients with high grade coronary artery stenosis.[d]	I	B
BIMA grafting should be considered in patients who do not have a high risk of sternal wound infection.[e]	IIa	B
Vessel harvesting		
Skeletonized IMA dissection is recommended in patients with a high risk of sternal wound infection[d].	I	B
Endoscopic vein harvesting, if performed by experienced surgeons, should be considered to reduce the incidence of wound complications.	IIa	A
No-touch vein harvesting should be considered, when an open technique is used.	IIa	B
Minimally invasive techniques		
Off-pump CABG and preferably no-touch techniques on the ascending aorta, by experienced operators, are recommended in patients with significant atherosclerotic aortic disease.	I	B
Off-pump CABG should be considered for subgroups of high-risk patients by experienced off-pump teams.	IIa	B
Where expertise exists, minimally invasive CABG through limited thoracic access should be considered in patients with isolated LAD lesions or in the context of hybrid revascularization.	IIa	B
Hybrid procedures, defined as consecutive or combined surgical and percutaneous revascularization, may be considered in specific patient subsets at experienced centres.	IIb	B

BIMA = bilateral internal mammary artery; CABG = coronary artery bypass grafting; CT = computed tomography; IMA = internal mammary artery; LAD = left anterior descending coronary artery. [a] Class of recommendation - [b] Level of evidence.

[c] Definitions of complete revascularization are provided in Section 5.3.1.3. of the Full Text.

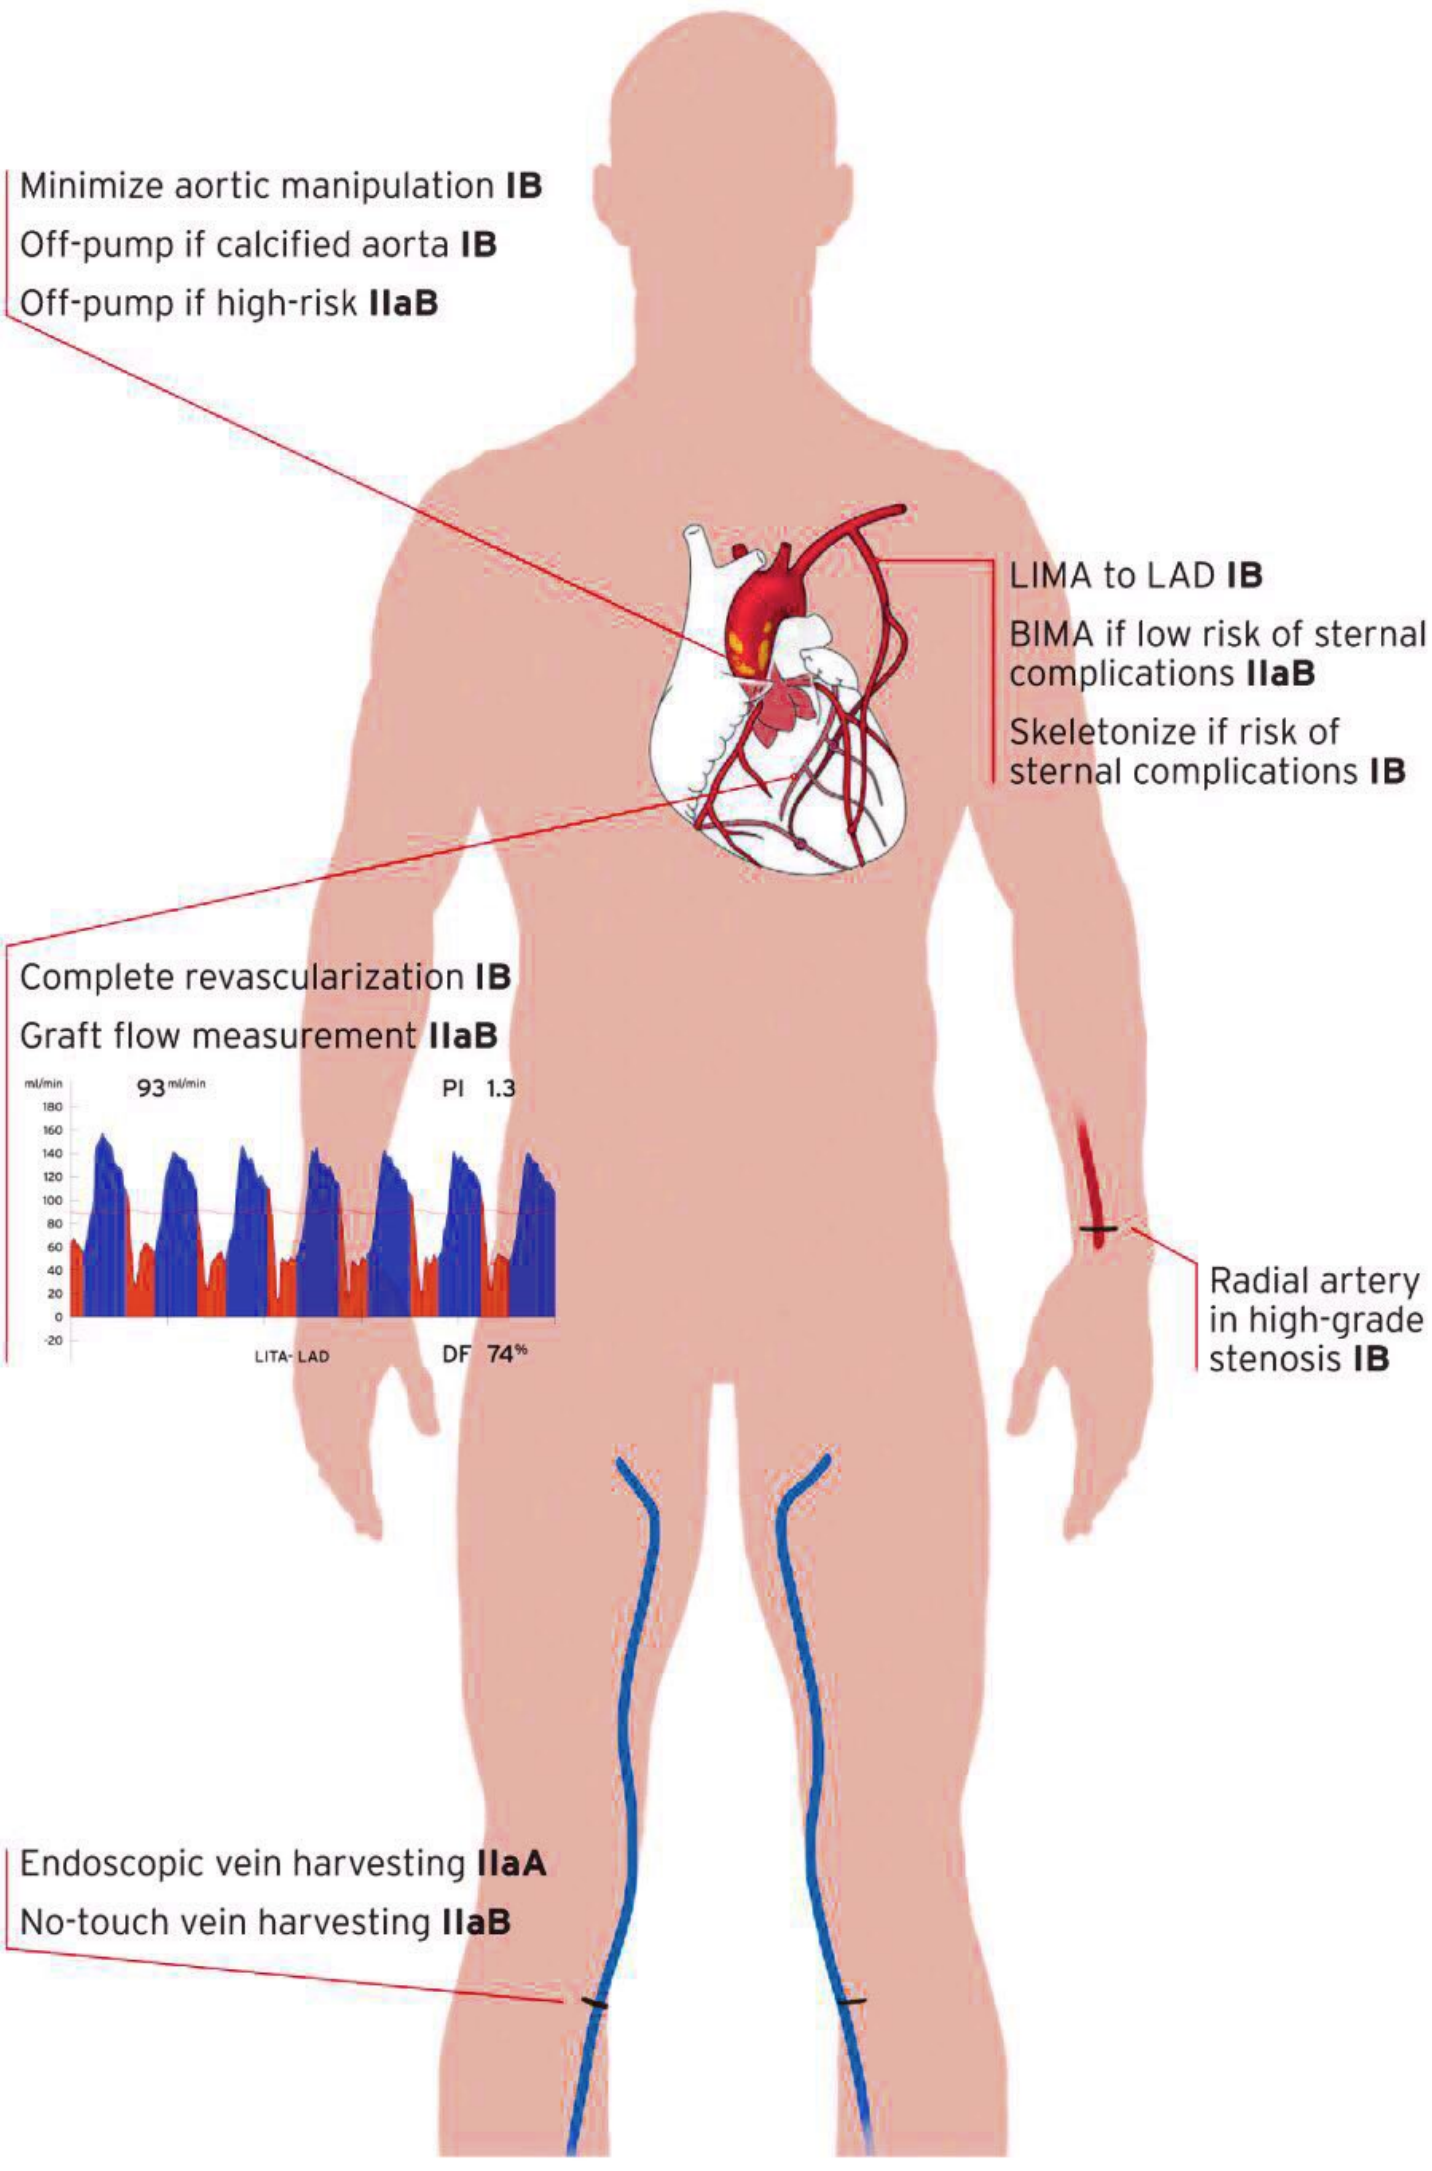
BIMA = bilateral internal mammary artery; CABG = coronary artery bypass grafting; CT = computed tomography; IMA = internal mammary artery; LAD = left anterior descending coronary artery. [a] Class of recommendation - [b] Level of evidence.

[c] Definitions of complete revascularization are provided in Section 5.3.1.3. of the Full Text.

[d] Specially in patients with poor vein grafts. The radial artery should not be used if previously catheterized, if the Allen test is positive or if calcific degeneration is present.

[e] Patients with diabetes mellitus, chronic pulmonary obstructive disease, previous mediastinal radiation, and obesity, particularly when multiples of these are present.

Figure 8 Technical aspects of CABG



BIMA = bilateral internal mammary artery; CABG = coronary artery bypass grafting; IMA = internal mammary artery; LAD = left anterior descending coronary artery.

Recommendations on the choice of stent type and access site are provided in the table below.

Recommendations on choice of stent and access site		
Recommendations	**Class[a]**	**Level[b]**
DES are recommended over BMS for any PCI irrespective of: • clinical presentation • lesion type • planned non-cardiac surgery • anticipated duration of DAPT • concomitant anticoagulant therapy.	I	A
Radial access is recommended as the standard approach, unless there are overriding procedural considerations.	I	A
BRS are currently not recommended for clinical use outside of clinical studies.	III	C

BMS = bare-metal stents; BRS = bioresorbable scaffolds; DAPT = dual antiplatelet therapy; DES = drug- eluting stents; PCI = percutaneous coronary intervention.
[a] Class of recommendation.
[b] Level of evidence.

Recommendations on the use and clinical value of FFR and iwFR are found in Chapters 3 and 5. The table below provides recommendations on intracoronary imaging for procedural optimization.

Recommendations on intravascular imaging for procedural optimization		
Recommendations	**Class[a]**	**Level[b]**
IVUS or OCT should be considered in selected patients to optimize stent implantation.	IIa	B
IVUS should be considered to optimize treatment of unprotected left main lesions.	IIa	B

IVUS = intravascular ultrasound; OCT = optical coherence tomography.
[a] Class of recommendation.
[b] Level of evidence.

Recommendations for the treatment by PCI of specific lesion subsets are provided in the table below.

Recommendations on specific lesion subsets		
Recommendations	**Class[a]**	**Level[b]**
Stent implantation in the main vessel only, followed by provisional balloon angioplasty with or without stenting of the side branch, is recommended for PCI of bifurcation lesions.	I	A
Percutaneous revascularization of CTOs should be considered in patients with angina resistant to medical therapy or with a large area of documented ischaemia in the territory of the occluded vessel.	IIa	B
In true bifurcation lesions of the left main, the double-kissing crush technique may be preferred over provisional T-stenting.	IIb	B

Antithrombotic drugs for myocardial revascularization and their pharmacological targets are illustrated in Figure 9. Dosages are found in Table 7 below.

Table 7: Doses of antiplatelet and anticoagulant drugs used during and after myocardial revascularization

Antiplatelet drugs	
Aspirin	Loading dose of 150–300 mg orally or 75–150 mg i.v. if oral ingestion is not possible, followed by a maintenance dose of 75–100 mg/day.
Clopidogrel	Loading dose of 600 mg orally, followed by a maintenance dose of 75 mg/day.
Prasugrel	Loading dose of 60 mg orally, followed by a maintenance dose of 10 mg/day. In patients with body weight <60 kg, a maintenance dose of 5 mg is recommended. In patients >75 years, prasugrel is generally not recommended, but a dose of 5 mg should be used if treatment is deemed necessary.
Ticagrelor	Loading dose of 180 mg orally, followed by a maintenance dose of 90 mg *b.i.d.*
Abciximab	Bolus of 0.25 mg/kg i.v. and 0.125 µg/kg/min infusion (maximum 10 µg/min) for 12 hours.
Eptifibatide	Double bolus of 180 µg/kg i.v. (given at a 10-min interval) followed by an infusion of 2.0 µg/kg/min for up to 18 hours.
Tirofiban	Bolus of 25 µg/kg over 3 min i.v., followed by an infusion of 0.15 µg/kg/min for up to 18 hours.
Cangrelor	Bolus of 30 µg/kg i.v. followed by 4 µg/kg/min infusion for at least 2 hours or duration of procedure, whichever is longer.
Anticoagulant drugs for PCI	
Unfractionated heparin	70–100 U/kg i.v. bolus when no GP IIb/IIIa inhibitor is planned. 50–70 U/kg i.v. bolus with GP IIb/IIIa inhibitors.
Enoxaparin	0.5 mg/kg i.v. bolus.
Bivalirudin	0.75 mg/kg i.v. bolus followed by i.v infusion of 1.75 mg/kg/h for up to 4 hours after the procedure as clinically warranted.
Oral anticoagulant drugs (concomitant treatment after PCI)	
Vitamin K antagonists (e.g. warfarin, phenprocoumon)	Dosing is based on INR value and the respective clinical indication.
Apixaban	Maintenance doses of 5 and 2.5[a] mg *b.i.d.*
Dabigatran	Maintenance doses of 150 and 110 mg *b.i.d.*
Edoxaban	Maintenance dose of 60 and 30[a] mg/day
Rivaroxaban	Maintenance doses of 20 and 15[a] mg/day and 2.5 mg *b.i.d.* (vascular dose).

b.i.d. = twice daily; GP = glycoprotein; INR = international normalized ratio; i.v. = intravenous; PCI = percutaneous coronary intervention.

[a] Specific criteria for reduced dose apply (see Recommendation Table here).

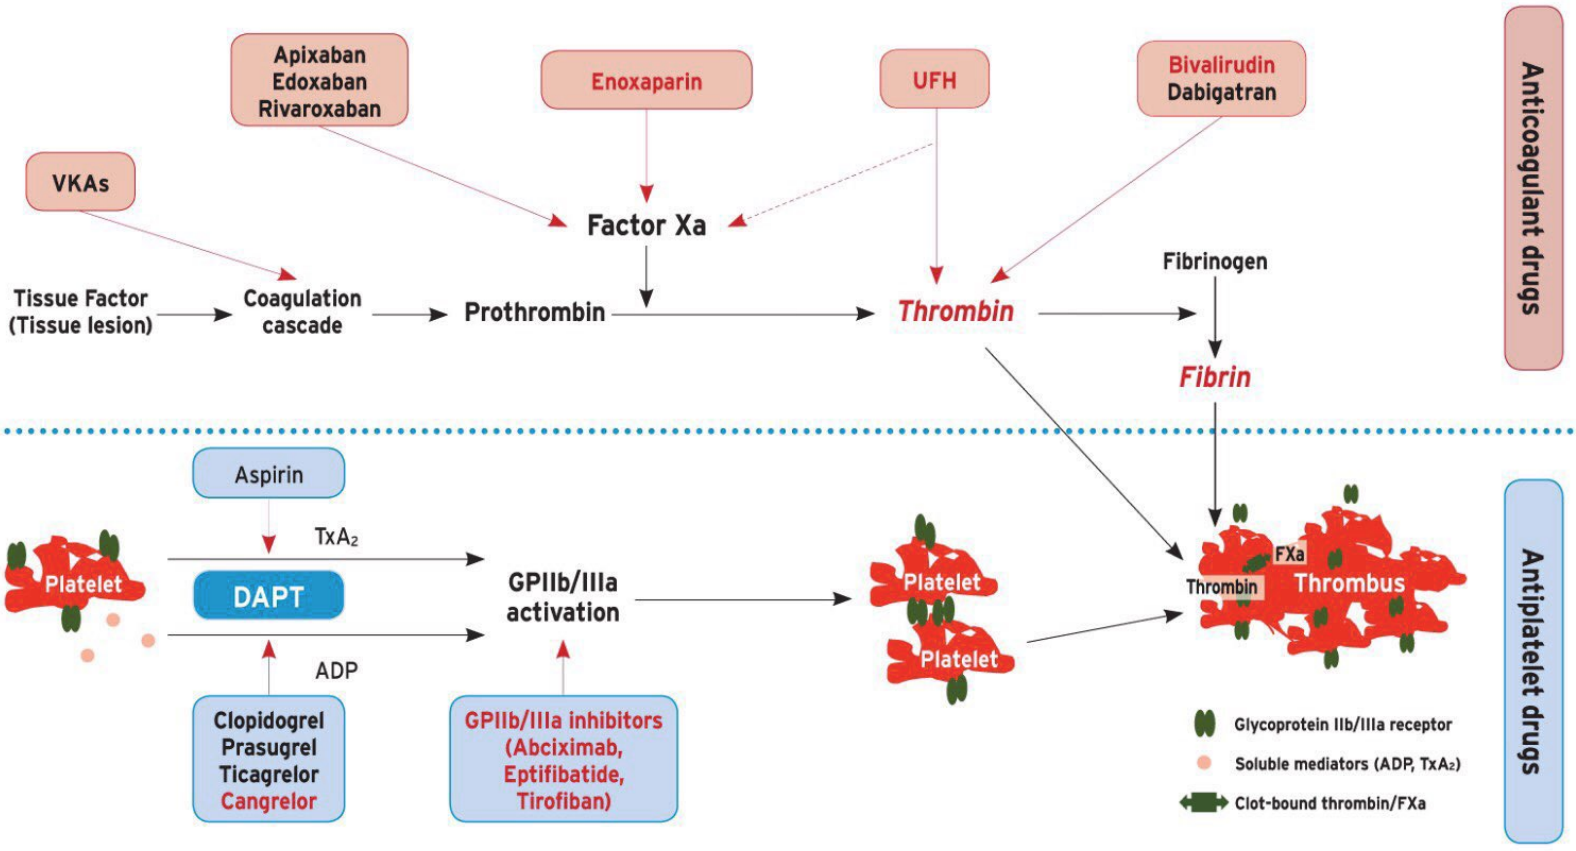
Figure 9 Antithrombotic treatment for myocardial revascularization and its pharmacological targets

Apixaban	Maintenance doses of 5 and 2.5[a] mg *b.i.d.*
Dabigatran	Maintenance doses of 150 and 110 mg *b.i.d.*
Edoxaban	Maintenance dose of 60 and 30[a] mg/day
Rivaroxaban	Maintenance doses of 20 and 15[a] mg/day and 2.5 mg *b.i.d.* (vascular dose).

b.i.d. = twice daily; GP = glycoprotein; INR = international normalized ratio; i.v. = intravenous; PCI = percutaneous coronary intervention.

[a] Specific criteria for reduced dose apply (see Recommendation Table here).

Figure 9 Antithrombotic treatment for myocardial revascularization and its pharmacological targets



The figure illustrates anticoagulant and antiplatelet drugs being used during and after myocardial revascularization (percutaneous coronary intervention or coronary artery bypass grafting). Drugs with oral administration are shown in black letters and drugs with preferred parenteral administration in red.

ADP = adenosine diphosphate; DAPT = dual antiplatelet therapy; FXa = factor Xa; GP = glycoprotein; TxA_2 = thromboxane A_2; UFH = unfractionated heparin; VKAs = vitamin K antagonists.

Recommendations for antithrombotic treatment in patients with stable CAD undergoing PCI are listed in the table below.

Recommendations for antithrombotic treatment in stable coronary artery disease patients undergoing percutaneous coronary intervention

Recommendations	Class[a]	Level[b]
Pre-treatment and antiplatelet therapy		
Treatment with 600 mg clopidogrel is recommended in elective PCI patients once the coronary anatomy is known and a decision is made to proceed with PCI.	I	A
Pre-treatment with clopidogrel may be considered if the probability of PCI is high.	IIb	C
In patients on a maintenance dose of 75 mg clopidogrel, a new loading dose of 600 mg may be considered once the indication for PCI is confirmed.	IIb	C
Peri-interventional treatment		
Aspirin is indicated before elective stenting.	I	A
An oral loading dose of aspirin (150–300 mg p.o. or 75–250 mg i.v.) is recommended if the patient is not pretreated.	I	C
Clopidogrel (600 mg loading dose, 75 mg daily maintenance dose) is recommended for elective stenting.	I	A
Glycoprotein IIb/IIIa antagonists should be considered only for bail-out.	IIa	C
Prasugrel or ticagrelor may be considered in specific high-risk situations of elective stenting (e.g. history of stent thrombosis, left main stenting).	IIb	C
Unfractionated heparin is indicated as the standard anticoagulant (70–100 U/kg).	I	B
Bivalirudin (0.75 mg/kg bolus, followed by 1.75 mg/kg/h for up to 4 hours after the procedure) is indicated in the case of heparin- induced thrombocytopenia.	I	C
Enoxaparin (i.v. 0.5 mg/kg) should be considered as an alternative agent.	IIa	B
Cangrelor may be considered in $P2Y_{12}$-inhibitor naïve patients undergoing PCI.	IIb	A

Enoxaparin (i.v. 0.5 mg/kg) should be considered as an alternative agent.	IIa	B
Cangrelor may be considered in $P2Y_{12}$-inhibitor naïve patients undergoing PCI.	IIb	A
Post-interventional and maintenance treatment		
Life-long single antiplatelet therapy, usually aspirin, is recommended.	I	A
Instruction of patients about the importance of complying with antiplatelet therapy is recommended.	I	C
In patients with SCAD treated with coronary stent implantation, DAPT consisting of clopidogrel in addition to aspirin is generally recommended for 6 months, irrespective of the stent type[c].	I	A
In patients with SCAD treated with BRS, DAPT should be considered for at least 12 months and up to the presumed full absorption of the BRS, based on an individual assessment of bleeding and ischaemic risk.	IIa	C
In patients with SCAD treated with DCB, DAPT should be considered for 6 months.	IIa	B
In patients with SCAD considered at high bleeding risk (e.g. PRECISE- DAPT ≥25), DAPT should be considered for 3 months[d].	IIa	A
In patients with SCAD who have tolerated DAPT without a bleeding complication and who are at low bleeding risk but high thrombotic risk, continuation of DAPT with clopidogrel for >6 months and up to 30 months may be considered.	IIb	A
In patients with SCAD in whom 3-month DAPT poses safety concerns, DAPT may be considered for 1 month.	IIb	C

BRS = bioresorbable scaffold; CAD = coronary artery disease; DAPT = dual antiplatelet therapy; DCB = drug-coated balloon; DES = drug-eluting stent; i.v. = intravenous; MI = myocardial infarction; PCI = percutaneous coronary intervention; p.o. = orally; PRECISE-DAPT = PREdicting bleeding

Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; SCAD = stable coronary artery disease.

[a] Class of recommendation.

[b] Level of evidence.

[c] These recommendations refer to stents which are supported by large-scale randomized trials with clinical endpoint evaluation leading to unconditional CE mark.

[d] The evidence supporting this recommendation comes from two studies where the zotarolimus-eluting Endeavour stent was investigated in conjunction with a 3-month DAPT regimen.

Recommendations for pre- and peri-interventional antithrombotic treatment in patients with non-ST-elevation acute coronary syndromes undergoing PCI are listed in the table below.

Recommendations for antithrombotic treatment in patients with non-ST-elevation acute coronary syndromes undergoing percutaneous coronary intervention

Recommendations	Class[a]	Level[b]
Pre-treatment and antiplatelet therapy		
Aspirin is recommended for all patients without contraindications at an initial oral loading dose of 150–300 mg (or 75–250 mg i.v.), and at a maintenance dose of 75–100 mg daily long-term.	I	A
A $P2Y_{12}$-inhibitor is recommended in addition to aspirin, maintained over 12 months unless there are contraindications such as excessive risk of bleeding. Options are:	I	A
• Prasugrel in $P2Y_{12}$-inhibitor naïve patients who proceed to PCI (60 mg loading dose, 10 mg daily dose).	I	B
• Ticagrelor irrespective of the preceding $P2Y_{12}$-inhibitor regimen (180 mg loading dose, 90 mg *b.i.d.*).	I	B
• Clopidogrel (600 mg loading dose, 75 mg daily dose) only when prasugrel or ticagrelor are not available or are contraindicated.	I	B
GP IIb/IIIa antagonists should be considered for bail-out if there is evidence of no-reflow or a thrombotic complication.	IIa	C
For pre-treatment in patients with NSTE-ACS undergoing invasive management, ticagrelor administration (180 mg loading dose, 90 mg *b.i.d.*), or clopidogrel (600 mg loading dose, 75 mg daily dose) if ticagrelor is not an option, should be considered as soon as the diagnosis is established.	IIa	C
Cangrelor may be considered in $P2Y_{12}$-inhibitor naïve patients undergoing PCI.	IIb	A
GP IIb/IIIa antagonist may be considered in $P2Y_{12}$-inhibitor naïve patients undergoing PCI.	IIb	C
Pre-treatment with GP IIb/IIIa antagonists in patients in whom coronary anatomy is not known is not recommended.	III	A
Administration of prasugrel in patients in whom coronary anatomy is not known is not recommended.	III	B

is not recommended.		
Administration of prasugrel in patients in whom coronary anatomy is not known is not recommended.	III	B
Peri-interventional therapy		
Anticoagulation is recommended for all patients in addition to antiplatelet therapy.	I	A
It is recommended that anticoagulation is selected according to both ischaemic and bleeding risks, and according to the efficacy–safety profile of the chosen agent.	I	C
UFH is recommended.	I	C
In patients on fondaparinux, a single bolus UFH (85 IU/kg, or 60 IU in the case of concomitant use of GP IIb/IIIa receptor inhibitors) is indicated.	I	B
Enoxaparin should be considered in patients pre-treated with subcutaneous enoxaparin.	IIa	B
Discontinuation of parenteral anticoagulation should be considered immediately after an invasive procedure.	IIa	C
Bivalirudin (0.75 mg/kg bolus, followed by 1.75 mg/kg/h for up to 4 hours after the procedure) may be considered as an alternative to UFH.	IIb	A
Crossover of UFH and LMWH is not recommended.	III	B

b.i.d. = twice daily; GP = glycoprotein; LMWH = low-molecular-weight heparin; NSTE-ACS = non-ST- segment elevation acute coronary syndromes; PCI = percutaneous coronary intervention; UFH = unfractionated heparin.

[a] Class of recommendation.

[b] Level of evidence.

Recommendations for post-interventional and maintenance antithrombotic treatment in patients with non-ST-elevation acute coronary syndromes or ST-elevation myocardial infarction undergoing PCI are listed in the table below.

Recommendations for post-interventional and maintenance treatment in patients with non-ST-elevation acute coronary syndromes and ST-elevation myocardial infarction undergoing percutaneous coronary intervention

Recommendations	Class[a]	Level[b]
In patients with ACS treated with coronary stent implantation, DAPT with a $P2Y_{12}$-inhibitor on top of aspirin is recommended for 12 months unless there are contraindications such as an excessive risk of bleeding (e.g. PRECISE-DAPT ≥25)	I	A
In patients with ACS and stent implantation who are at high risk of bleeding (e.g. PRECISE-DAPT ≥25), discontinuation of $P2Y_{12}$-inhibitor therapy after 6 months should be considered.	IIa	B
In patients with ACS treated with BRS, DAPT should be considered for at least 12 months and up to the presumed full absorption of the BRS, based on an individual assessment of bleeding and ischaemic risk.	IIa	C
De-escalation of $P2Y_{12}$-inhibitor treatment (e.g. with a switch from prasugrel or ticagrelor to clopidogrel) guided by platelet function testing may be considered as an alternative DAPT strategy, especially for ACS patients deemed unsuitable for 12-month potent platelet inhibition.	IIb	B
In patients with ACS who have tolerated DAPT without a bleeding complication, continuation of DAPT for longer than 12 months may be considered.	IIb	A
In patients with MI and high ischaemic risk[c] who have tolerated DAPT without a bleeding complication, ticagrelor 60 mg *b.i.d.* for longer than 12 months on top of aspirin may be preferred over clopidogrel or prasugrel.	IIb	B
In ACS patients with no prior stroke/TIA and at high ischaemic risk as well as low bleeding risk, receiving aspirin and clopidogrel, low- dose rivaroxaban (2.5 mg *b.i.d.* for approximately 1 year) may be considered after discontinuation of parenteral anticoagulation.	IIb	B

ACS = acute coronary syndrome; *b.i.d.* = twice daily; BRS = bioresorbable scaffold; DAPT = dual antiplatelet therapy; MI = myocardial infarction; PCI = percutaneous coronary intervention; PRECISE- DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; TIA = transient ischaemic attack.

[a] Class of recommendation - [b] Level of evidence - [c] Defined as at least 50 years of age, and had one of the following additional high-risk features: age 65 years or older, diabetes mellitus requiring medication, a second prior spontaneous MI, multivessel coronary artery disease, or chronic renal dysfunction, defined as an estimated creatinine clearance <60 mL/min.

Recommendations for pre- and peri-interventional antithrombotic treatment in patients with ST-elevation myocardial infarction undergoing PCI are listed in the table below. For recommendations on post-interventional and maintenance antithrombotic treatment in patients with ST-elevation myocardial infarction undergoing PCI see table here.

Recommendations for antithrombotic treatment in ST-elevation myocardial infarction patients undergoing percutaneous coronary intervention

Recommendations	Class[a]	Level[b]
Pre-treatment and antiplatelet therapy		
Aspirin is recommended for all patients without contraindications at an initial oral loading dose of 150–300 mg (or 75–250 mg i.v.), and at a maintenance dose of 75–100 mg daily long-term regardless of treatment strategy.	I	A
A potent $P2Y_{12}$-inhibitor (prasugrel or ticagrelor), or clopidogrel if these are not available or are contraindicated, is recommended before (or at latest at the time of) PCI and maintained over 12 months, unless there are contraindications such as excessive risk of bleeding.	I	A
GP IIb/IIIa inhibitors should be considered for bail-out if there is evidence of no-reflow or a thrombotic complication.	IIa	C
Cangrelor may be considered in $P2Y_{12}$-inhibitor naïve patients undergoing PCI.	IIb	A
GP IIb/IIIa antagonist may be considered in $P2Y_{12}$-inhibitor naïve patients undergoing PCI.	IIb	C
Peri-interventional therapy		
Anticoagulation is recommended for all patients in addition to antiplatelet therapy during PCI.	I	A
Routine use of UFH is recommended.	I	C
Routine use of enoxaparin should be considered.	IIa	B
Routine use of bivalirudin may be considered.	IIb	A

GP = glycoprotein; i.v. = intravenous; PCI = percutaneous coronary intervention; UFH = unfractionated heparin.

[a] Class of recommendation - [b] Level of evidence.

30 months		

Antiplatelet drugs: A = Aspirin; C = Clopidogrel; T = Ticagrelor; P = Prasugrel

DAPT = dual antiplatelet therapy; DCB = drug-coated balloon; NSTE-ACS = non-ST-elevation acute coronary syndrome; PCI = percutaneous coronary intervention; PRECISE-DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; STEMI = ST-elevation myocardial infarction; UFH = unfractioned heparin.

Colour-coding refers to the ESC classes of recommendations (green = Class I; yellow = Class IIa; orange = Class IIb).

[1]After PCI with DCB 6 months DAPT should be considered (class IIa) - [2]Clopidogrel if patient is not eligible for a treatment with prasugrel or ticagrelor; or in a setting of DAPT de-escalation (Class IIb). [3]Clopidogrel or prasugrel if patient is not eligible for a treatment with ticagrelor. [4]Pretreatment before PCI (or at the latest at the time of PCI); clopidogrel if potent P2Y12 inhibitors are contraindicated or not available. (For scores see Supplementary Table 4.). High bleeding risk is considered as an increased risk of spontaneous bleeding during DAPT (e.g. PRECISE-DAPT score ≥25).

Recommendations and dual antiplatelet therapy in patients undergoing cardiac surgery are shown in the table below.

Dual antiplatelet therapy in patients undergoing cardiac surgery

Recommendations	Class[a]	Level[b]
It is recommended that the Heart Team estimates the individual bleeding and ischaemic risks and guides the timing of CABG as well as the anti-thrombotic management.	I	C
In patients on aspirin who need to undergo non-emergent cardiac surgery, it is recommended to continue aspirin at a low daily regimen throughout the peri-operative period.	I	C
In patients treated with DAPT after coronary stent implantation who subsequently undergo cardiac surgery, it is recommended to resume $P2Y_{12}$-inhibitor therapy post-operatively as soon as it is deemed safe so that DAPT continues until the recommended duration of therapy is completed.	I	C
In patients with ACS (NSTE-ACS or STEMI) treated with DAPT who are undergoing CABG and do not require long-term OAC therapy, resumption of $P2Y_{12}$-inhibitor therapy as soon as deemed safe after surgery and its continuation up to 12 months is recommended.	I	C
In patients on $P2Y_{12}$-inhibitors who need to undergo non-emergent cardiac surgery, postponing surgery for at least 3 days after discontinuation of ticagrelor, at least 5 days after clopidogrel, and at least 7 days after prasugrel should be considered.	IIa	B
In CABG patients with prior MI who are at high risk of severe bleeding (e.g. PRECISE-DAPT ≥25), discontinuation of $P2Y_{12}$-inhibitor therapy after 6 months should be considered.	IIa	C
Platelet function testing may be considered to guide the decision on the timing of cardiac surgery in patients who have recently received $P2Y_{12}$-inhibitors.	IIb	B
In patients perceived to be at high ischaemic risk with prior MI and CABG who have tolerated DAPT without a bleeding complication, treatment with DAPT for longer than 12 months and up to 36 months may be considered.	IIb	C

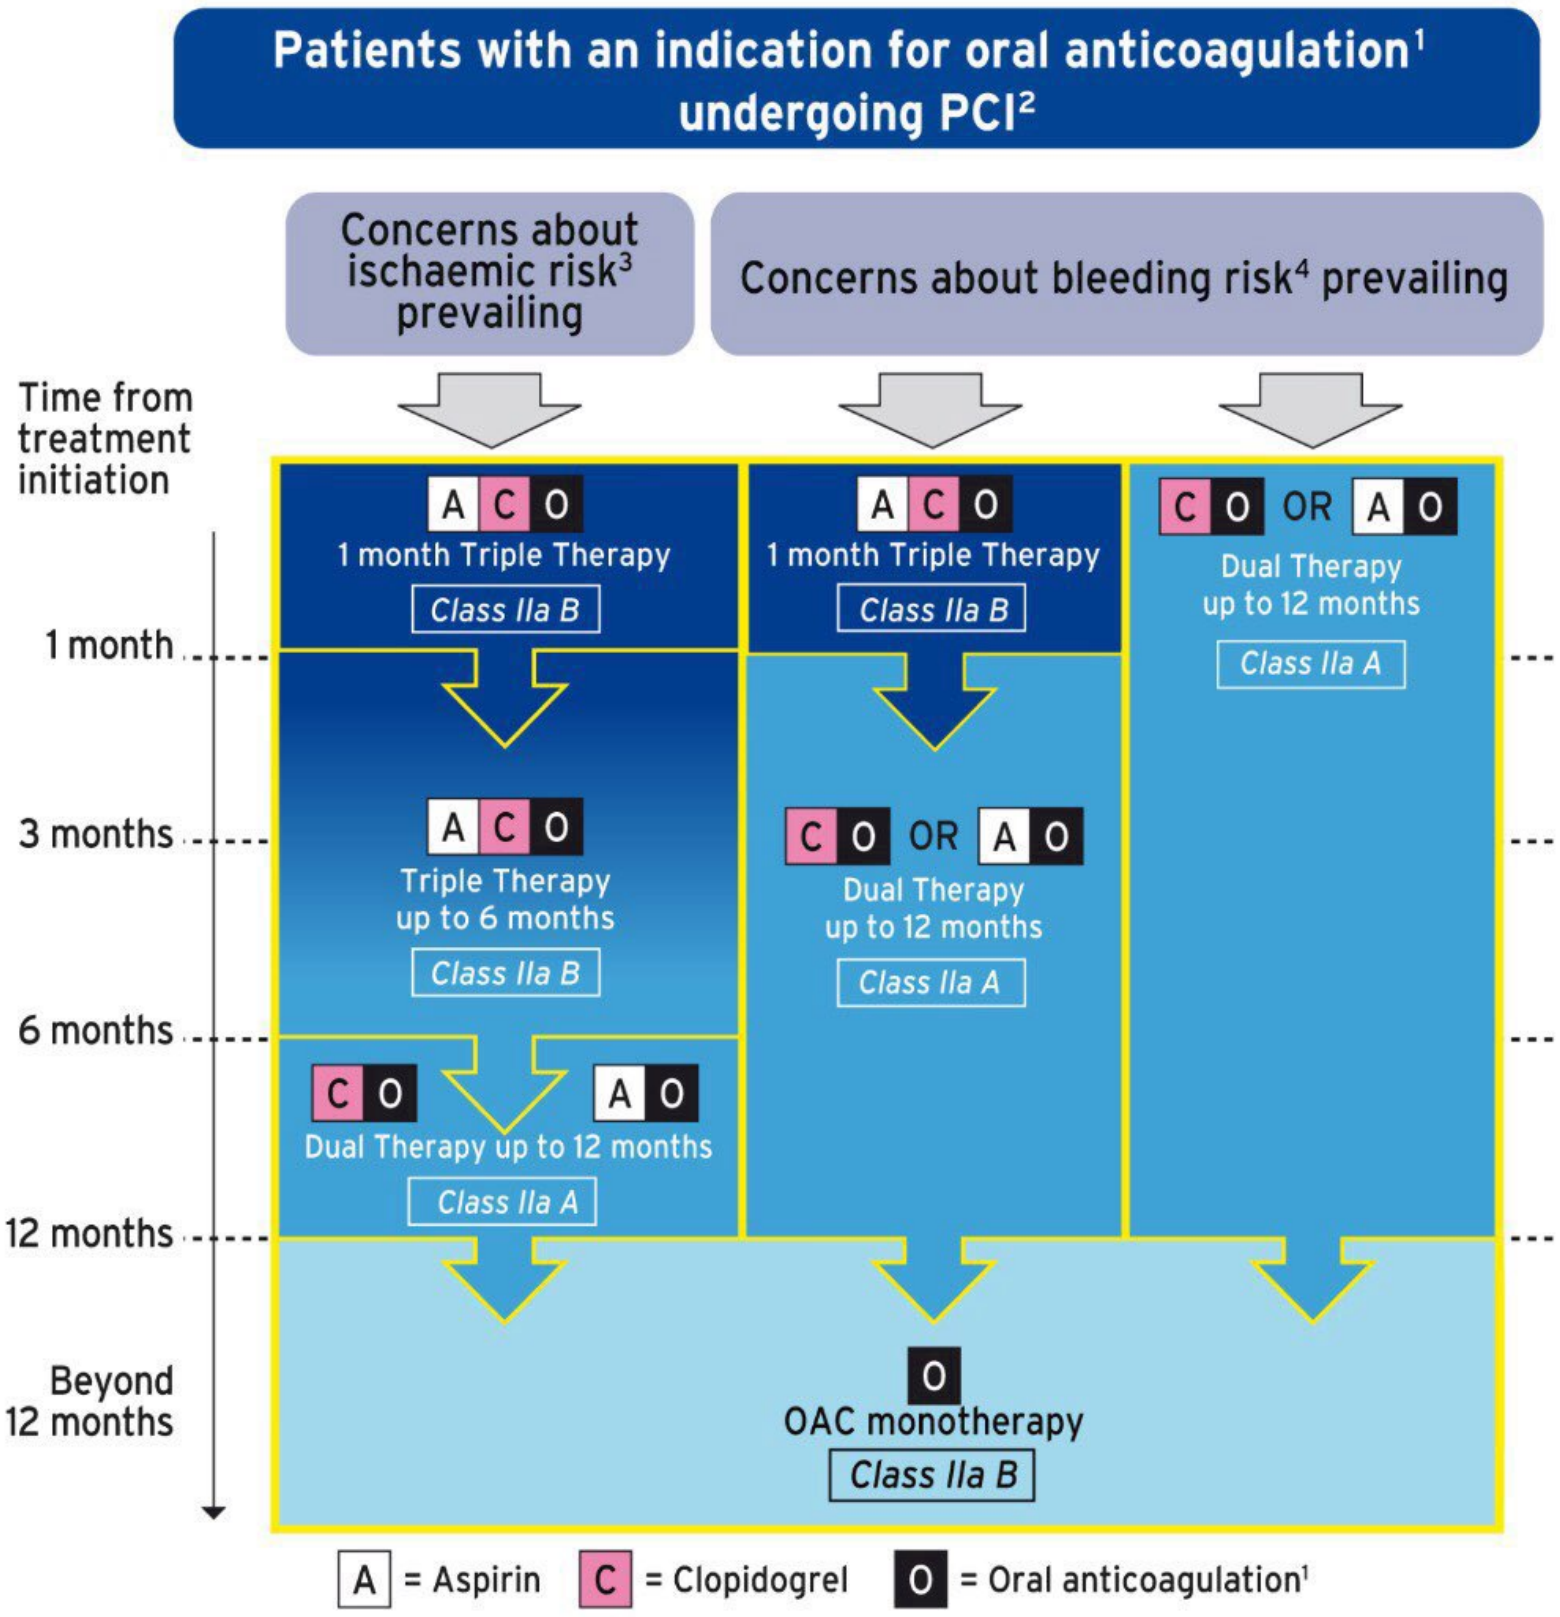
ACS = acute coronary syndrome; CABG = coronary artery bypass grafting; DAPT = dual antiplatelet therapy; NSTE-ACS = non-ST-elevation acute coronary syndrome; OAC = oral anticoagulant; STEMI = ST-elevation myocardial infarction. PRECISE-DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy.

[a] Class of recommendation - [b] Level of evidence.

In patients with an indication for anticoagulation undergoing PCI the choice of concomitant antiplatelet therapy is critical and depends on the assessment of the risk of ischaemic complications relative to the risk of bleeding complications.

Figure 11 shows the suggested algorithm based on the recommendations. In addition, Tables 8 to 10 specify strategies to avoid bleeding as well as high-risk features for ischaemic events and unfavourable patient profiles for a combination of oral anticoagulant and antiplatelet therapy.

Figure 11 Algorithm for dual antiplatelet therapy (DAPT) in patients with an indication for oral anticoagulation undergoing percutaneous coronary intervention (PCI)



Colour-coding refers to the number of concomitant antithrombotic medication(s). Triple therapy denotes treatment with DAPT plus oral anticoagulant (OAC). Dual therapy denotes treatment with a single antiplatelet agent (aspirin or clopidogrel) plus OAC.

ABC = Age, Biomarkers, Clinical history; AF = atrial fibrillation; HAS-BLED = Hypertension, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile INR, Elderly, Drugs/alcohol concomitantly; VKA = vitamin K antagonist. [1] Non-vitamin K antagonist oral anticoagulant (NOAC) preferred over VKA in patients with non-valvular AF. (Class IIaA). [2] Periprocedural administration of aspirin and clopidogrel during PCI is recommended irrespective of the treatment strategy. [3] High ischaemic risk is considered as an acute clinical presentation or anatomical/procedural features which might increase the risk for myocardial infarction. [4] Bleeding risk can be estimated by HAS-BLED or ABC score.

Table 8 Strategies to avoid bleeding complications in oral anticoagulation patients
Assess ischaemic and bleeding risks using validated risk predictors (e.g. CHA_2DS_2-VASc, ABC, HAS-BLED) with a focus on modifiable risk factors.
Keep triple therapy duration as short as possible; dual therapy after PCI (oral anticoagulant and clopidogrel) to be considered instead of triple therapy.
One should consider the use of NOAC instead of VKA when NOACs are not contraindicated.
Consider a target INR in the lower part of the recommended target range and maximize time in therapeutic range (i.e. >65%) when VKA is used.
Clopidogrel is the $P2Y_{12}$-inhibitor of choice.
Use low-dose (≤100 mg daily) aspirin.
Routine use of PPIs.

ABC = Age, Biomarkers, Clinical history; CHA_2DS_2-VASc = Congestive heart failure, Hypertension, Age ≥75 years (doubled), Diabetes mellitus, prior Stroke or transient ischaemic attack or thromboembolism (doubled), Vascular disease, Age 65–74 years, Sex category; HAS-BLED = Hypertension, Abnormal renal/ liver function, Stroke, Bleeding history or predisposition, Labile INR, Elderly, Drugs/alcohol concomitantly; INR = international normalized ratio; NOAC = non-vitamin K antagonist oral anticoagulant; PPIs = proton pump inhibitors; VKA = vitamin K antagonist.

Table 9 High-risk features for ischaemic events
• Prior stent thrombosis on adequate antiplatelet therapy
• Stenting of the last remaining patent coronary artery
• Diffuse multivessel disease especially in diabetic patients
• Chronic kidney disease (i.e. creatinine clearance <60 mL/min)
• At least three stents implanted
• At least three lesions treated
• Bifurcation with two stents implanted
• Total stented length >60 mm
• Treatment of a chronic total occlusion
• History of STEMI

STEMI = ST-elevation myocardial infarction.

Table 10 Unfavourable patient profile for a combination of oral anticoagulant and antiplatelet therapy
• Short life expectancy
• Ongoing malignancy
• Poor expected adherence
• Poor mental status
• End stage renal failure
• Advanced age
• Prior major bleeding/prior haemorrhagic stroke
• Chronic alcohol abuse
• Anaemia
• Clinically significant bleeding on dual antithrombotic therapy

Dual antiplatelet therapy duration in patients with indication for oral anticoagulation		
Recommendations	**Class[a]**	**Level[b]**
It is recommended that peri-procedural aspirin and clopidogrel are administered to patients undergoing coronary stent implantation.	I	C
In patients treated with coronary stent implantation, triple therapy with aspirin, clopidogrel and an OAC should be considered for 1 month, irrespective of the type of stent used.	IIa	B
Triple therapy with aspirin, clopidogrel and an OAC for longer than 1 month and up to 6 months should be considered in patients with high ischaemic risk due to ACS or other anatomical/procedural characteristics, which outweigh the bleeding risk.	IIa	B
Dual therapy with clopidogrel 75 mg/day and an OAC should be considered as an alternative to 1-month triple antithrombotic therapy in patients in whom the bleeding risk outweighs the ischaemic risk.	IIa	A
In patients with non-valvular AF requiring anticoagulation and antiplatelet treatment, a NOAC should be preferred over VKAs.	IIa	A
Discontinuation of antiplatelet treatment in patients treated with OAC should be considered at 12 months.	IIa	B
In patients with an indication for a VKA in combination with aspirin and/or clopidogrel, the dose intensity of the VKA should be carefully regulated with a target INR in the lower part of the recommended target range and time in the therapeutic range >65%.	IIa	B
When a NOAC is used in combination with aspirin and/or clopidogrel, the lowest approved dose effective for stroke prevention tested in AF trials should be considered[c].	IIa	C
When rivaroxaban is used in combination with aspirin and/ or clopidogrel, rivaroxaban 15 mg *q.d.* may be used instead of rivaroxaban 20 mg *q.d.*	IIb	B
When dabigatran is used in combination with aspirin or clopidogrel, a dose of 150 mg b.i.d may be preferred over a dose of 110 mg b.i.d.	IIb	B
The use of ticagrelor or prasugrel is not recommended as part of triple antithrombotic therapy with aspirin and OAC.	III	C

ACS = acute coronary syndrome; AF = atrial fibrillation; *b.i.d.* = twice daily; INR = international normalized ratio; OAC = oral anticoagulant; NOAC = non-vitamin K oral anticoagulant; *q.d.* = once daily; VKA = vitamin K antagonist.

[a] Class of recommendation.

[b] Level of evidence.

[c] Apixaban 5 mg *b.i.d.* or apixaban 2.5 mg *b.i.d.* if at least two of the following: age ≥80 years, body weight ≤60 kg or serum creatinine level ≥1.5 mg/dL (133 µmol/L); dabigatran 110 mg or 150 mg *b.i.d.*; edoxaban 60 mg *q.d.* or edoxaban 30 mg *q.d.* if any of the following: creatinine clearance of 30–50 mL/min, body weight ≤60 kg, concomitant use of verapamil, quinidine, or dronedarone; rivaroxaban 20 mg *q.d.* or rivaroxaban 15 mg *q.d.* if creatinine clearance 30–49 mL/min.

Operator experience impacts outcomes, in particular in critical, complex situations. Increased experience of an entire hospital team consisting of supporting members in the operating room or catheterization laboratory and those responsible for the post-operative care are associated with favourable outcomes.

The tables below provide recommendations for training, proficiency, and operator/ institutional competence in CABG and PCI.

Recommendations for operator/institutional volume in myocardial revascularization

Recommendations	Class[a]	Level[b]
CABG		
It should be considered that CABG be performed at institutions with an annual institutional volume of at least 200 CABG cases.	IIa	C
PCI		
It should be considered that PCI for ACS be performed by trained operators with an annual volume of at least 75 procedures at institutions performing at least 400 PCIs per year with an established 24-hour/7-day service for the treatment of patients with ACS.	IIa	C
It should be considered that PCI for SCAD be performed by trained operators with an annual volume of at least 75 procedures at institutions performing at least 200 PCIs per year.	IIa	C
It should be considered that institutions with annual volumes of fewer than 400 PCIs collaborate in networks with higher-volume institutions (>400 PCIs per year), with shared written protocols and exchange of operators and support staff.	IIa	C
It should be considered that PCI for LM be performed by trained operators with annual volumes of at least 25 LM PCI cases per year.	IIa	C
It should be considered that non-emergency high-risk PCI procedures - such as for LM disease, single remaining patent coronary artery, and complex chronic total occlusions - are only performed by adequately experienced operators at centres that have access to circulatory support and intensive care treatment.	IIa	C

ACS = acute coronary syndromes; CABG = coronary artery bypass grafting; LM = left main; PCI = percutaneous coronary intervention; SCAD = stable coronary artery disease.

[a] Class of recommendation.

[b] Level of evidence.

Recommendations for training in myocardial revascularization		
Recommendations	**Class[a]**	**Level[b]**
Training in CABG		
It is recommended that trainees in cardiac surgery and interventional cardiology follow a competency-driven residency programme with regular evaluation of progression.	I	C
It should be considered that trainees in cardiac surgery perform at least 200 CABG procedures under supervision before being independent.	IIa	C
Training in PCI		
It should be considered that trainees in interventional cardiology perform at least 200 PCI procedures as first operator, with one-third of PCI procedures in emergency or ACS patients under supervision, before being independent.	IIa	C
It should be considered that trainees in interventional cardiology complete formal training according to a 1–2 year curriculum at institutions with at least 800 PCIs per year and an established 24-hour/7-day service for the treatment of patients with ACS.	IIa	C

ACS = acute coronary syndrome; CABG = coronary artery bypass grafting; PCI = percutaneous coronary intervention.

[a] Class of recommendation.

[b] Level of evidence.

Recommendations for outcome registration, monitoring, and benchmarking		
Recommendations	**Class[a]**	**Level[b]**
It is recommended that specific quality performance measures for CABG are adopted at a national level to allow outcome monitoring and benchmarking.	I	C
It is recommended that national societies establish national databases on CABG practice and outcomes.	I	C
It is recommended that CABG outcome data are reported by hospitals to national databases.	I	C

CABG = coronary artery bypass grafting.

[a] Class of recommendation.

[b] Level of evidence.

Secondary prevention and cardiac rehabilitation are an integral part of the management after revascularization because such measures reduce future morbidity and mortality in a cost-effective way and can further improve symptoms. Specific recommendations for long-term medical therapy, secondary preventions and cardiac rehabilitation programmes are provided in separate dedicated guideline documents. Recurrence of symptoms or ischaemia due to disease progression or restenosis after myocardial revascularization deserves attention.

Recommendations on strategies for follow-up and management of patients after myocardial revascularization are provided in the table below.

Strategies for follow-up and management in patients after myocardial revascularization

Recommendations	Class[a]	Level[b]
After CABG or PCI for AMI participation in a cardiac rehabilitation programme is recommended to improve patient outcomes.	I	A
It is recommended that secondary prevention measures, including medical therapy and lifestyle changes, are started and reinforced after myocardial revascularization.	I	A
It is recommended that patients are re-evaluated after myocardial revascularization (e.g. at 3 months and thereafter, at least on an annual basis) in order to reassess symptoms and adherence with secondary prevention measures, and reinforce medical therapy and lifestyle changes when appropriate.	I	C
Symptomatic patients		
Coronary angiography is recommended in patients with intermediate- to high-risk findings[c] at stress testing.	I	C
An imaging stress test should be considered in patients with prior revascularization over stress ECG.	IIa	B
Asymptomatic patients		
Surveillance by non-invasive imaging-based stress testing may be considered in high-risk patient subsets 6 months after revascularization.	IIb	C
After high-risk PCI (e.g. unprotected LM stenosis), late (3–12 months) surveillance angiography may be considered, irrespective of symptoms.	IIb	C
Routine non-invasive imaging-based stress testing may be considered 1 year after PCI and >5 years after CABG.	IIb	C

AMI = acute myocardial infarction; CABG = coronary artery bypass grafting; LM = left main; PCI = percutaneous coronary intervention.

[a] Class of recommendation.

[b] Level of evidence.

[c] Intermediate- and high-risk findings at stress imaging are ischaemia at low workload with exercise stress testing, early onset ischaemia with pharmacological stress testing, inducible wall motion abnormality or reversible perfusion defect in ≥10% of LV myocardium.

2017 ESC Pocket Guidelines

Committee for Practice Guidelines

DAPT

Focused Update on Dual Antiplatelet Therapy in Coronary Artery Disease

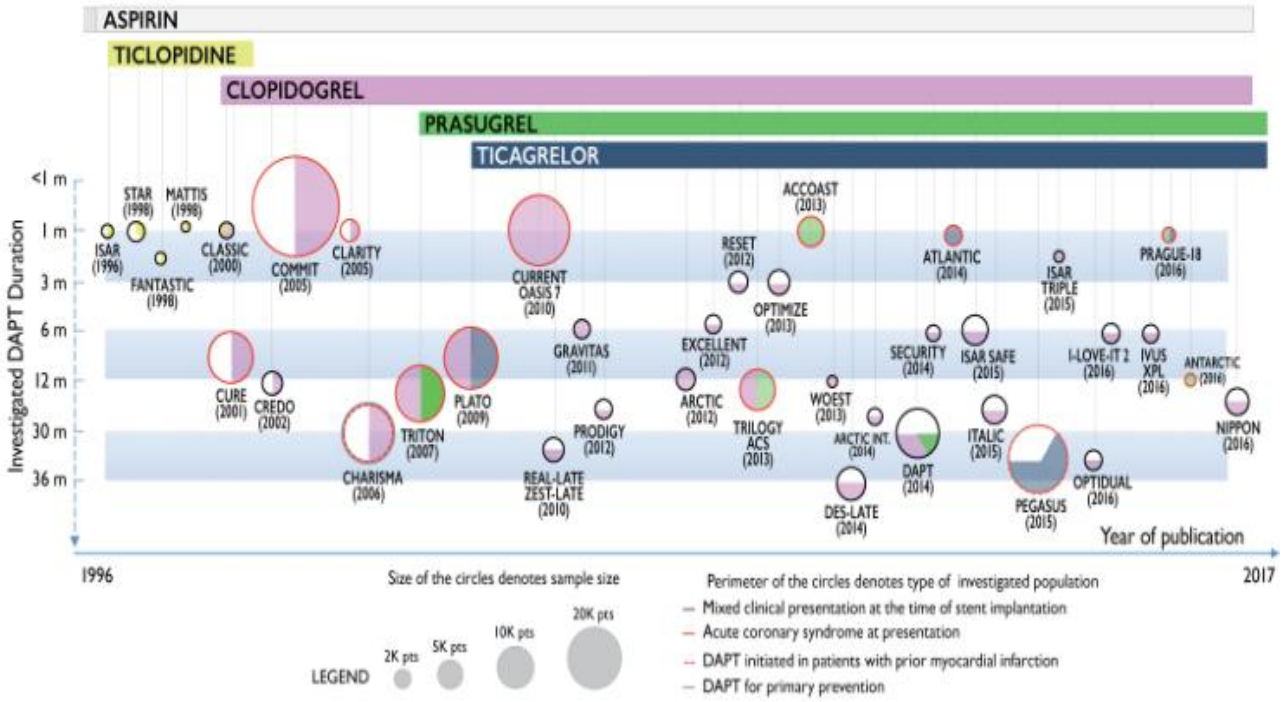
ESC
European Society of Cardiology

www.escardio.org/guidelines

Based on population estimates from 2015, in the region of 1 400 000 and 2 200 000 patients per year may have an indication for DAPT after coronary intervention or myocardial infarction (MI), respectively in Europe.

In 2017, it is the 21st anniversary of the publication of the first randomized clinical trial establishing the superiority of DAPT over anticoagulant therapy among patients undergoing percutaneous coronary intervention (PCI) (Figure 1). Based on over 35 randomized clinical trials, including more than 225 000 patients, DAPT is among the most intensively investigated treatment options in the field of cardiovascular medicine (Figure 1).

Figure 1 History of dual antiplatelet therapy (DAPT) in patients with coronary artery disease



The size of the circles denotes sample size. The colours of perimeters identify the type of included patient populations within each study. The colours within each circle identify the antiplatelet agent(s) investigated. Head-to-head studies comparing similar durations of two different antiplatelet strategies are shown with a vertical line, whereas those investigating different treatment durations are shown with a horizontal line.

Studies investigating different treatment strategies or regimens and not treatment durations or type (e.g. pre-treatment in ACCOAST, tailored therapy in GRAVITAS, double dose of clopidogrel in CURRENT OASIS 7, etc.) are represented with a single colour indicating the $P2Y_{12}$ inhibitor, which was tested on top of aspirin.

Risk scores

Given the trade-off between ischaemic vs. bleeding risks for any given DAPT duration, the use of scores might prove useful to tailor DAPT duration in order to maximize ischaemic protection and minimize bleeding risks in the individual patient. The use of risk scores, which were specifically designed to guide and inform decision-making on DAPT duration, should be prioritized over other available risk scores (Table 3).

The table below provides an overview for the risk scores, which have been validated for dual antiplatelet therapy duration decision-making

Table 3 Risk scores validated for dual antiplatelet therapy duration decision making

PRECISE-DAPT score	
Time of use	At the time of coronary stenting
DAPT duration strategies assessed	Short DAPT (3–6 months) vs. Standard/long DAPT (12–24 months)
Score calculation[a]	Score range	0 to 100 points
Decision making cut-off suggested	Score ≥25 → Short DAPT Score <25 → Standard/long DAPT
Calculator	www.precisedaptscore.com

DAPT score		
Time of use	After 12 months of uneventful DAPT	
DAPT duration strategies assessed	Standard DAPT (12 months) vs. Long DAPT (30 months)	
Score calculation[a]	Age	
	≥75	–2 pt
	65 to <75	–1 pt
	<65	0 pt
	Cigarette smoking	+1 pt
	Diabetes mellitus	+1 pt
	MI at presentation	+1 pt
	Prior PCI or prior MI	+1 pt
	Paclitaxel-eluting stent	+1 pt
	Stent diameter <3 mm	+1 pt
	CHF or LVEF <30%	+2 pt
	Vein graft stent	+2 pt
Score range	–2 to 10 points	
Decision making cut-off suggested	Score ≥2 → Long DAPT Score <2 → Standard DAPT	
Calculator	www.daptstudy.org	

PCI = percutaneous coronary intervention; PRECISE-DAPT = PREdicting bleeding Complications
In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; WBC = white blood cell count.
[a]For the PRECISE-DAPT score use the score nomogram: mark patient's value for each of the five clinical variables of the score and draw a vertical line to the 'Point' axis to determine the number of points obtained for each clinical variable.Than summate the points obtained for each clinical variable to the total score.

Recommendations

Use of risk scores

The table below provides a recommendation on the use of risk scores as guidance for the duration of dual antiplatelet therapy.

Recommendations for the use of risk scores as guidance for the duration of dual antiplatelet therapy

Recommendation	Class[a]	Level[b]
The use of risk scores designed to evaluate the benefits and risks of different DAPT durations[c] may be considered.	IIb	A

DAPT = dual antiplatelet therapy.
[a]Class of recommendation.
[b]Level of evidence.
[c]The DAPT and PRECISE-DAPT scores are those currently fulfilling these requirements.

P2Y12 inhibitor selection and timing

Recommendations on $P2Y_{12}$ inhibitor selection and timing

Recommendations	Class[a]	Level[b]
In patients with ACS, ticagrelor (180 mg loading dose, 90 mg twice daily) on top of aspirin[c] is recommended, regardless of initial treatment strategy, including patients pre-treated with clopidogrel (which should be discontinued when ticagrelor is commenced) unless there are contra-indications[c].	I	B
In patients with ACS undergoing PCI, prasugrel (60 mg loading dose, 10 mg daily dose) on top of aspirin is recommended for $P2Y_{12}$ inhibitor-naïve patients with NSTE-ACS or initially conservatively managed STEMI if indication for PCI is established, or in STEMI patients undergoing immediate coronary catheterization unless there is a high-risk of life-threatening bleeding or other contra-indications[c]	I	B
Pre-treatment with a $P2Y_{12}$ inhibitor is generally recommended in patients in whom coronary anatomy is known and the decision to proceed to PCI is made as well as in patients with STEMI.	I	A
In patients with NSTE-ACS undergoing invasive management, ticagrelor administration (180 mg loading dose, 90 mg twice daily), or clopidogrel (600 mg loading dose, 75 mg daily dose) if ticagrelor is not an option, should be considered as soon as the diagnosis is established.	IIa	C
In patients with stable CAD pre-treatment with clopidogrel may be considered if the probability of PCI is high.	IIb	C

Clopidogrel (600 mg loading dose, 75 mg daily dose) on top of aspirin is recommended in stable CAD patients undergoing coronary stent implantation and in ACS patients who cannot receive ticagrelor or prasugrel, including those with prior intracranial bleeding or indication for OAC.	I	A
Clopidogrel (300 mg loading dose in patients aged ≤75, 75 mg daily dose) is recommended on top of aspirin in STEMI patients receiving thrombolysis.	I	A
Ticagrelor or prasugrel on top of aspirin may be considered instead of clopidogrel in stable CAD patients undergoing PCI, taking into account the ischaemic (e.g. high SYNTAX score, prior stent thrombosis, location and number of implanted stents) and bleeding (e.g. according to PRECISE-DAPT) risks.	IIb	C
In NSTE-ACS patients in whom coronary anatomy is not known, it is not recommended to administer prasugrel.	III	B

ACS = acute coronary syndrome; CAD = coronary artery disease; DAPT = dual antiplatelet therapy; NSTE-ACS = non-ST-elevation acute coronary syndrome; OAC = oral anticoagulant; PCI = percutaneous coronary intervention; PRECISE-DAPT = PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; STEMI = ST-elevation myocardial infarction; SYNTAX = Synergy Between Percutaneous Coronary Intervention With Taxus and Cardiac Surgery.

[a]Class of recommendation - [b]Level of evidence - [c]Contra-indications for ticagrelor: previous intracranial haemorrhage or ongoing bleeds. Contra-indications for prasugrel: previous intracranial haemorrhage, previous ischaemic stroke or transient ischaemic attack or ongoing bleeds; prasugrel is not recommended for patients ≥75 years of age or with a bodyweight <60 kg.

Measures to minimize bleeding

Recommendations on measures to minimize bleeding while on dual antiplatelet therapy

Recommendations	Class[a]	Level[b]
Radial over femoral access is recommended for coronary angiography and PCI if performed by an expert radial operator.	I	A
In patients treated with DAPT, a daily aspirin dose of 75–100 mg is recommended.	I	A
A PPI in combination with DAPT is recommended.[c]	I	B
Routine platelet function testing to adjust antiplatelet therapy before or after elective stenting is not recommended.	III	A

DAPT = dual antiplatelet therapy; PCI = percutaneous coronary intervention; PPI proton pump inhibitor.

[a]Class of recommendation - [b]Level of evidence - [c]While the evidence that a PPI does not increase the risk of cardiovascular events was generated with omeprazole, based on drug-drug interaction studies, omeprazole and esomeprazole would appear to have the highest propensity for clinically relevant interactions, while pantoprazole and rabeprazole have the lowest.

Switching oral P2Y12 inhibitors

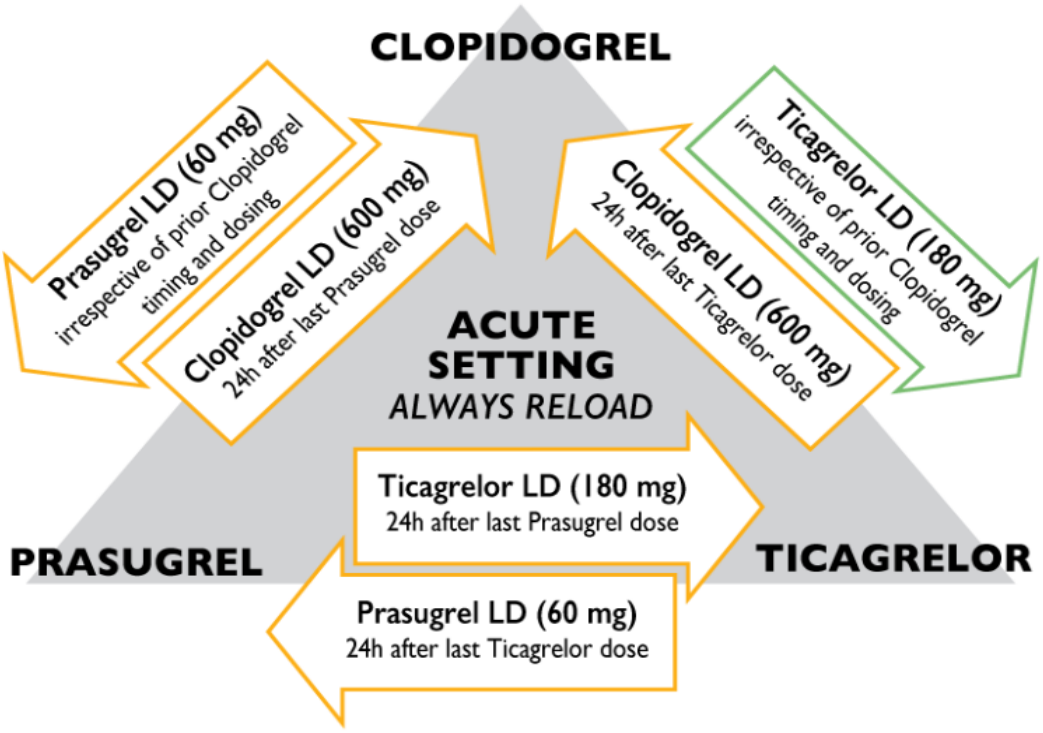
Recommendations for switching between oral $P2Y_{12}$ inhibitors

Recommendations	Class[a]	Level[b]
In patients with ACS who were previously exposed to clopidogrel, switching from clopidogrel to ticagrelor is recommended early after hospital admission at a loading dose of 180 mg irrespective of timing and loading dose of clopidogrel, unless contra-indications to ticagrelor exist.[c]	I	B
Additional switching between oral $P2Y_{12}$ inhibitors may be considered in cases of side effects/drug intolerance according to the proposed algorithms.	IIb	C

ACS = acute coronary syndrome.
[a]Class of recommendation - [b]Level of evidence.
[c]Contra-indications for ticagrelor: previous intracranial haemorrhage or ongoing bleeds.

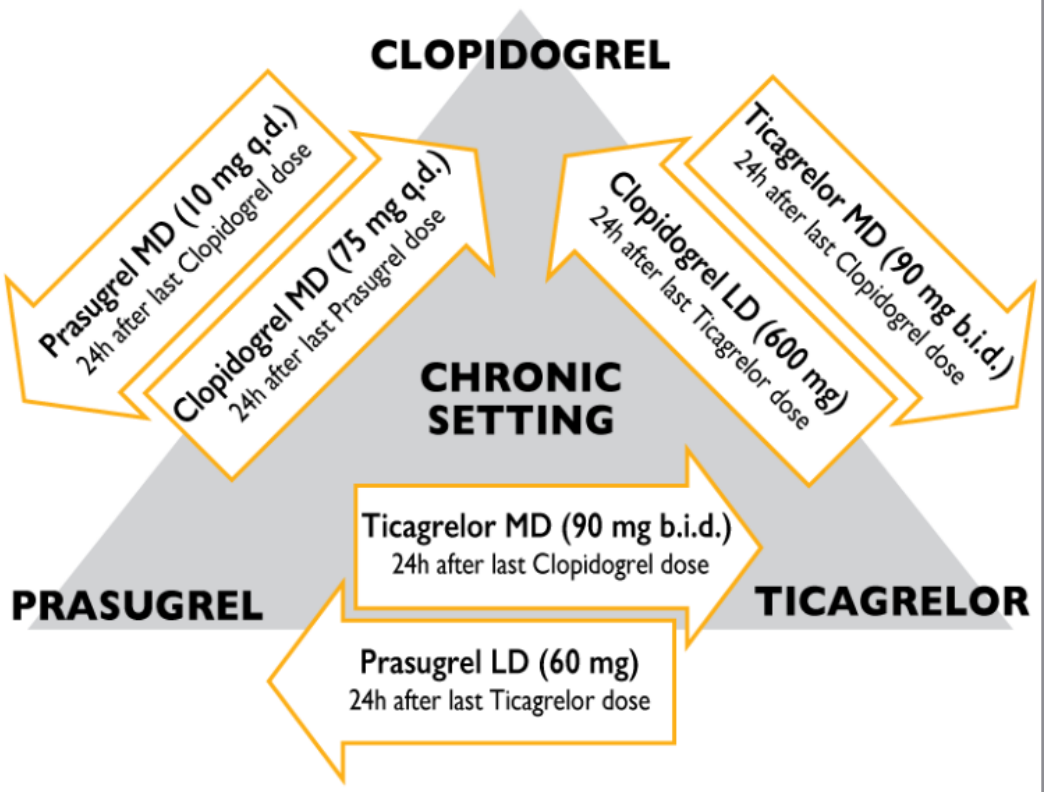
Switching algorithms

Figure 2 Algorithm for switching between oral $P2Y_{12}$ inhibitors in the acute setting



LD = loading dose; MD = maintenance dose
Colour-coding refers to the ESC class of recommendation (green = Class I; orange = Class IIb).
The green arrow from clopidogrel to ticagrelor highlights the only switching algorithm for which outcome data are available in patients with acute coronary syndrome. No outcome data (orange arrows) are available for all other switching algorithms. Acute setting is considered as a switching occurring during hospitalization.

Figure 2bis Algorithm for switching between oral $P2Y_{12}$ inhibitors in the chronic setting



LD = loading dose; MD = maintenance dose
Colour-coding refers to the ESC class of recommendation (orange = Class IIb).
The green arrow from clopidogrel to ticagrelor highlights the only switching algorithm for which outcome data are available in patients with acute coronary syndrome. No outcome data (orange arrows) are available for all other switching algorithms.

An overview of recommendations endorsed by these guidelines regarding DAPT duration after PCI, as well as after CABG or in medically managed ACS patients, is provided in Figure 3 (see below).

Figure 3 Algorithm for dual antiplatelet therapy (DAPT) in patients with coronary artery disease. High bleeding risk is considered as an increased risk of spontaneous bleeding during DAPT (e.g. PRECISE-DAPT score ≥25).

ACS = acute coronary syndrome; BMS = bare-metal stent; BRS = biore-sorbable vascular scaffold; CABG = coronary artery bypass graft ; DCB = drug-coated balloon; DES = drug-eluting stent; PCI = percutaneous coronary intervention; Stable CAD= stable coronary artery disease.
High bleeding risk is considered as an increased risk of spontaneous bleed-ing during DAPT (e.g. PRECISE-DAPT score ≥25).
Colour-coding refers to the ESC Classes of Recommendations (green = Class I; yellow = Class IIa; orange = Class IIb).
Treatments presented within the same line are sorted in alphabetic order, no preferential recommendation unless clearly stated otherwise.
[1]After PCI with DCB 6 mo. DAPT should be considered (Class IIa B).
[2]if patient presents with Stable CAD or, in case of ACS, is not eligible for a treatment with prasugrel or ticagrelor.
[3]if patient is not eligible for a treatment with prasugrel or ticagrelor.
[4]if patient is not eligible for a treatment with ticagrelor.

Recommendations on dual antiplatelet therapy duration and related stent choices in patients with stable coronary artery disease treated with percutaneous coronary intervention

Recommendations	Class[a]	Level[b]
In patients with stable CAD treated with coronary stent implantation, DAPT consisting of clopidogrel in addition to aspirin is generally recommended for 6 months, irrespective of the stent type.[c]	I	A
Irrespective of the intended DAPT duration, DES is the preferred treatment option.[c]	I	A
In patients with stable CAD considered at high bleeding risk (e.g. PRECISE-DAPT ≥25), DAPT for 3 months should be considered.[d]	IIa	B
In patients with stable CAD treated with drug-coated balloon, DAPT for 6 months should be considered.	IIa	B
In patients with stable CAD treated with bioresorbable vascular scaffolds, DAPT for at least 12 months should be considered.	IIa	C
In patients with stable CAD who have tolerated DAPT without a bleeding complication and who are at low bleeding but high thrombotic risk, continuation of DAPT with clopidogrel for >6 months and up to ≤30 months may be considered.	IIb	A
In patients with stable CAD in whom 3-month DAPT poses safety concerns, DAPT for 1 month[e] may be considered.	IIb	C

CAD = coronary artery disease; DAPT = dual antiplatelet therapy; DES = drug-eluting stent; PRECISE-DAPT= PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy.

[a]Class of recommendation.

[b]Level of evidence.

[c]These recommendations refer to stents which are supported by large-scale randomized trials with clinical endpoint evaluation leading to unconditional CE-mark as detailed in Byrne *et al.* (see Full Text at www.escardio.org/guidelines).

[d]The evidence supporting this recommendation comes from two studies where zotarolimus-eluting Endeavour sprint stent has been investigated in conjunction with a 3-month DAPT regimen.

[e]1-month DAPT following implantation of zotarolimus-eluting Endeavour sprint stent or drug coated stent reduced risks of re-intervention, myocardial infarction and inconsistently of stent thrombosis compared to bare-metal stent under similar DAPT duration. It is unclear if this evidence applies to other contemporary DES.

Recommendations on dual antiplatelet therapy duration in patients with acute coronary syndrome treated with percutaneous coronary intervention

Recommendations	Class[a]	Level[b]
In patients with ACS treated with coronary stent implantation, DAPT with a $P2Y_{12}$ inhibitor on top of aspirin is recommended for 12 months unless there are contra-indications such as excessive risk of bleeding (e.g. PRECISE-DAPT ≥ 25).	I	A
In patients with ACS and stent implantation who are at high-risk of bleeding (e.g. PRECISE-DAPT ≥ 25), discontinuation of $P2Y_{12}$ inhibitor therapy after 6 months should be considered.	IIa	B
In patients with ACS treated with bioresorbable vascular scaffolds, DAPT for at least 12 months should be considered.	IIa	C
In patients with ACS who have tolerated DAPT without a bleeding complication, continuation of DAPT for longer than 12 months may be considered.	IIb	A
In patients with MI and high ischaemic risk[c] who have tolerated DAPT without a bleeding complication, ticagrelor 60 mg b.i.d. for longer than 12 months on top of aspirin may be preferred over clopidogrel or prasugrel.	IIb	B

ACS = acute coronary syndrome; b.i.d. = bis in die; DAPT = dual antiplatelet therapy. PRECISE-DAPT= PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy.

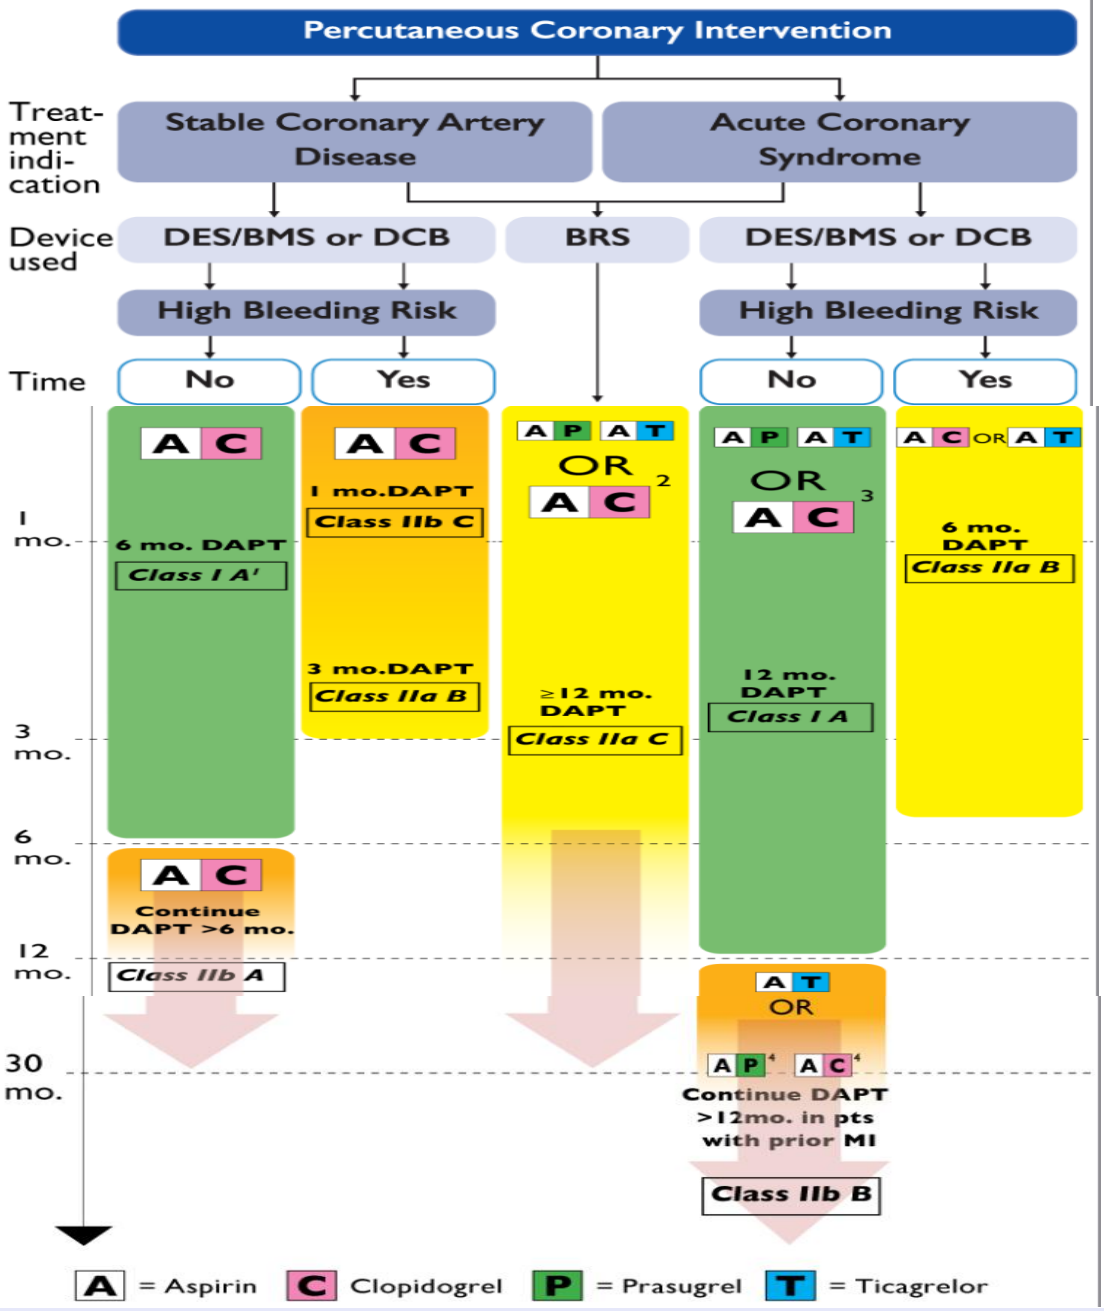
[a]Class of recommendation.

[b]Level of evidence.

[c]Defined as at least ≥50 years of age, and one or more of the following additional high-risk features: age of 65 years or older, diabetes mellitus requiring medication, a second prior spontaneous myocardial infarction, multivessel coronary artery disease, or chronic renal dysfunction, defined as an estimated creatinine clearance <60 mL per minute.

These recommendations refer to stents that are supported by large-scale randomized trials with clinical endpoint evaluation leading to unconditional CE mark, as detailed in Byrne et al. (see Full Text at www.escardio.org/guidelines)

Figure 4 Algorithm for dual antiplatelet therapy (DAPT) in patients treated with percutaneous coronary intervention.



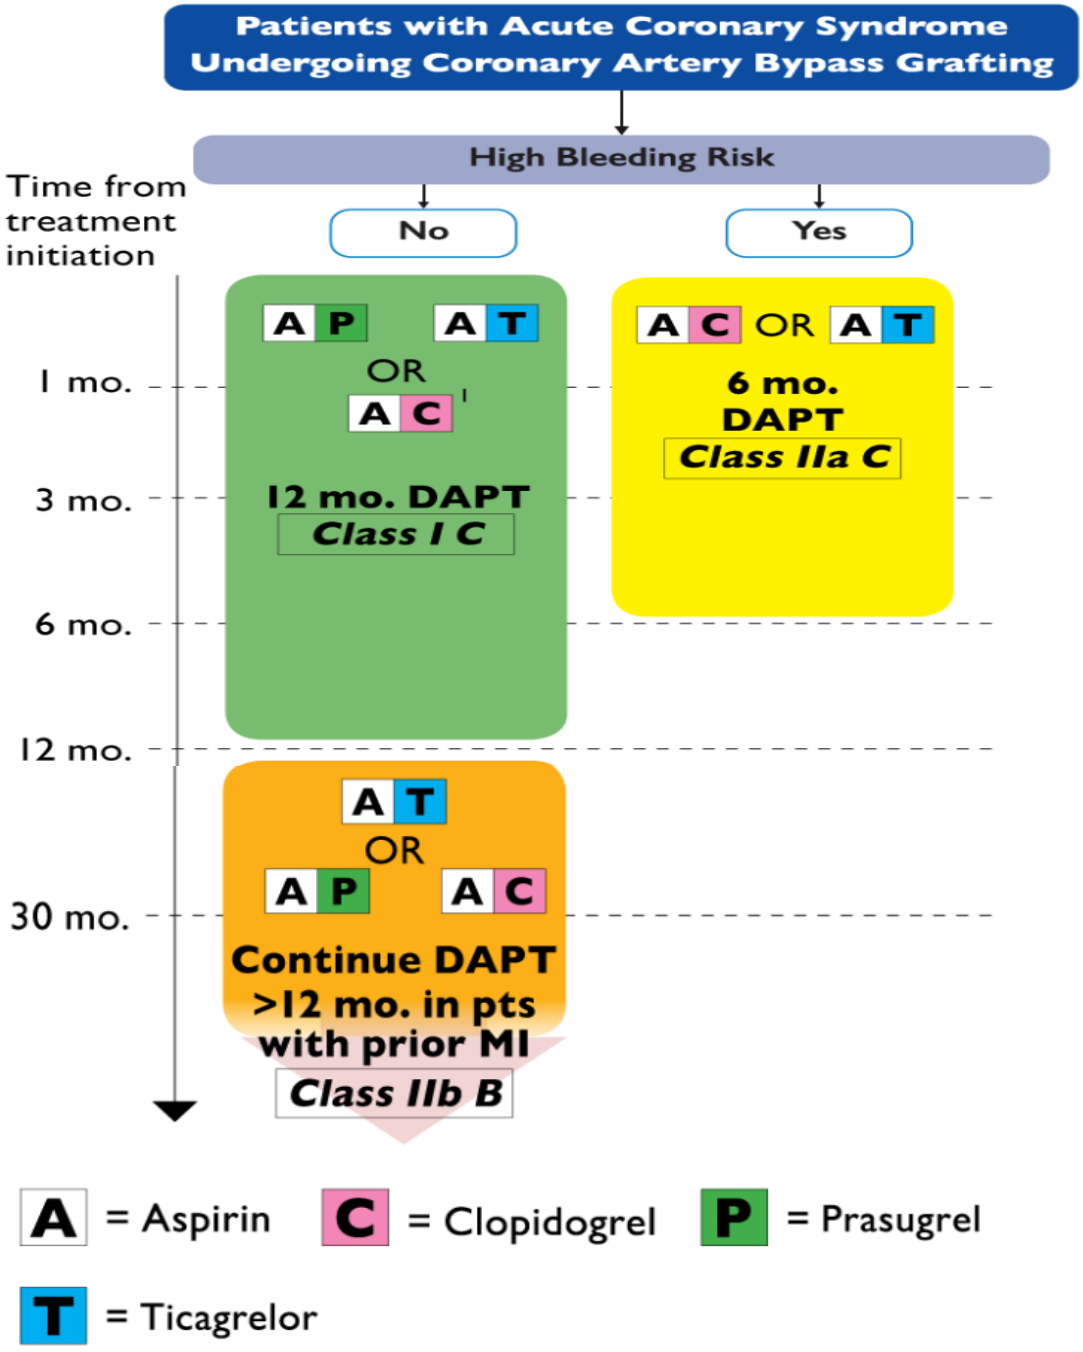
ACS = acute coronary syndrome; BMS = bare-metal stent; BRS = bioresorbable vascular scaffold; CABG = coronary artery bypass graft surgery; DCB = percutaneous coronary intervention; Stable CAD = stable coronary artery disease. High bleeding risk is considered as an increased risk of spontaneous bleeding during DAPT (e.g. PRECISE-DAPT score ≥ 25).
Colour-coding refers to the ESC Classes of Recommendations (green = Class I; yellow = Class IIa; orange = Class IIb).
Treatments presented within the same line are sorted in alphabetic order, no preferential recommendation unless clearly stated otherwise.
[1]After PCI with DCB 6 mo. DAPT should be considered (Class IIa B).
[2]if patient presents with SCAD or, in case of ACS, is not eligible for a treatment with prasugrel or ticagrelor.
[3]if patient is not eligible for a treatment with prasugrel or ticagrelor.
[4]if patient is not eligible for a treatment with ticagrelor.

Recommendations on dual antiplatelet therapy in patients treated with cardiac surgery with stable or unstable coronary artery disease

Recommendations	Class[a]	Level[b]
It is recommended that the Heart Team estimates the individual bleeding and ischaemic risks and guide the timing of CABG as well as the antithrombotic management.	I	C
In patients on aspirin who need to undergo non-emergent cardiac surgery, it is recommended to continue aspirin at a low daily regimen throughout the peri-operative period.	I	C
In patients treated with DAPT after coronary stent implantation who subsequently undergo cardiac surgery, it is recommended to resume $P2Y_{12}$ inhibitor therapy postoperatively as soon as deemed safe so that DAPT continues until the recommended duration of therapy is completed.	I	C
In patients with ACS (NSTE-ACS or STEMI) treated with DAPT and undergoing CABG and not requiring long-term OAC therapy, resumption of $P2Y_{12}$ inhibitor therapy as soon as deemed safe after surgery and continuation up to 12 months is recommended.	I	C
In patients on P2Y12 inhibitors who need to undergo non-emergent cardiac surgery, postponing surgery for at least 3 days after discontinuation of ticagrelor, at least 5 days after clopidogrel, and at least 7 days after prasugrel should be considered.	IIa	B
In CABG patients with prior MI who are at high-risk of severe bleeding (e.g. PRECISE-DAPT ≥25), discontinuation of $P2Y_{12}$ inhibitor therapy after 6 months should be considered.	IIa	C
Platelet function testing may be considered to guide decisions on timing of cardiac surgery in patients who have recently received $P2Y_{12}$ inhibitors.	IIb	B
In patients perceived at high ischaemic risk with prior MI and CABG who have tolerated DAPT without a bleeding complication, treatment with DAPT for longer than 12 and up to 36 months may be considered.	IIb	C

ACS = acute coronary syndrome; CABG = coronary artery bypass graft; DAPT = non-ST-elevation acute coronary syndrome; OAC = oral anticoagulant; PRECISE-DAPT= PREdicting bleeding Complications in patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy; STEMI = ST-elevation myocardial infarction.

Figure 5 Algorithm for dual antiplatelet therapy (DAPT) in patients with acute coronary syndrome undergoing coronary artery bypass grafting



Treatments presented within the same line are sorted in alphabetic order, no preferential recommendation unless clearly stated otherwise.

High bleeding risk is considered as an increased risk of spontaneous bleeding during DAPT (e.g. PRECISE-DAPT score ≥25).

Colour-coding refers to the ESC Classes of Recommendations (green = Class I; yellow = Class IIa;
orange = Class IIb).

[1]if patient is not eligible for a treatment with prasugrel or ticagrelor.

Recommendations on dual antiplatelet therapy duration in patients with acute coronary syndrome undergoing medical therapy management

Recommendations	Class[a]	Level[b]
In patients with ACS who are managed with medical therapy alone and treated with DAPT, it is recommended to continue $P2Y_{12}$ inhibitor therapy (either ticagrelor or clopidogrel) for 12 months.	I	A
Ticagrelor is recommended over clopidogrel, unless the bleeding risk outweighs the potential ischaemic benefit.	I	B
In patients with medically managed ACS who are at high-risk of bleeding (e.g. PRECISE-DAPT ≥ 25), DAPT for at least 1 month should be considered.	IIa	C
In patients with prior MI at high ischaemic risk[c] who are managed with medical therapy alone and have tolerated DAPT without a bleeding complication, treatment with DAPT in the form of ticagrelor 60 mg b.i.d. on top of aspirin for longer than 12 months and up to 36 months may be considered.	IIb	B
In patients with prior MI not treated with coronary stent implantation who have tolerated DAPT without a bleeding complication and who are not eligible for treatment with ticagrelor, continuation of clopidogrel on top of aspirin for longer than 12 months may be considered.	IIb	C
Prasugrel is not recommended in medically managed ACS patients.	III	B

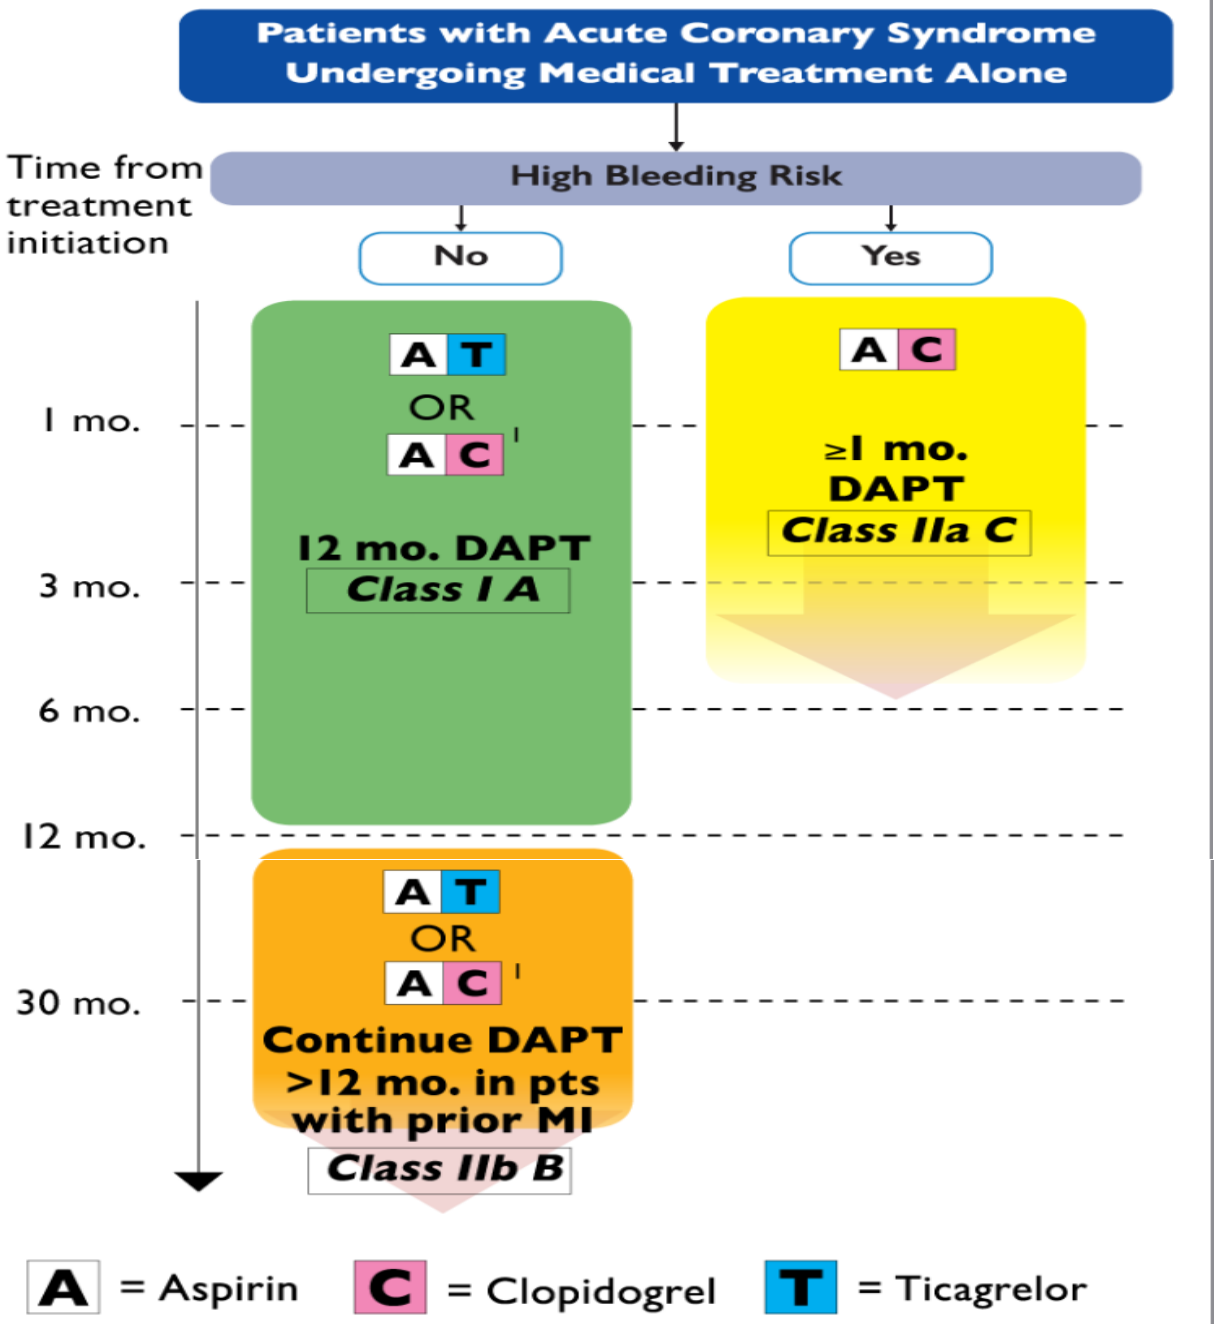
ACS = acute coronary syndrome; DAPT = dual antiplatelet therapy; MI = myocardial infarction. PRECISE- DAPT= PREdicting bleeding Complications In patients undergoing Stent implantation and subsEquent Dual Anti Platelet Therapy.

[a]Class of recommendation.

[b]Level of evidence.

[c]Defined as ≥50 years of age, and one or more of the following additional high-risk features: age of 65 years or older, diabetes mellitus requiring medication, a second prior spontaneous myocardial infarction, multivessel coronary artery disease, or chronic renal dysfunction, defined as an estimated creatinine clearance <60 mL per minute.

Figure 6 Algorithm for dual antiplatelet therapy (DAPT) in patients with acute coronary syndrome undergoing medical management



Treatments presented within the same line are sorted in alphabetic order, no preferential recommendation unless clearly stated otherwise.

High bleeding risk is considered as an increased risk of spontaneous bleeding during DAPT (e.g. PRECISE-DAPT score ≥ 25).

Colour-coding refers to the ESC Classes of Recommendations (green = Class I; yellow = Class IIa; orange = Class IIb).

[1]if patient is not eligible for a treatment with ticagrelor

Strategies to avoid bleeding complications in patients treated with oral anticoagulant are summarised in the table below.

Table 4 Strategies to avoid bleeding complications in patients treated with oral anticoagulant

• Assess ischaemic and bleeding risks using validated risk predictors (e.g. CHA_2DS_2-VASc, ABC, HAS-BLED) with a focus on modifiable risk factors.
• Keep triple therapy duration as short as possible; dual therapy after PCI (oral anticoagulant and clopidogrel) to be considered instead of triple therapy.
• Consider the use of NOACs instead of VKA when NOACs are not contra-indicated.
• Consider a target INR in the lower part of the recommended target range and maximize time in therapeutic range (i.e. >65–70%) when VKA is used.
• Consider the lower NOAC regimen tested in approval studies and apply other NOAC regimens based on drug-specific criteria for drug accumulation.[a]
• Clopidogrel is the $P2Y_{12}$ inhibitor of choice.
• Use low-dose (≤100 mg daily) aspirin.
• Routine use of PPIs.

ABC = Age, Biomarkers, Clinical history; CHA_2DS_2-VASc = Congestive heart failure, Hypertension,Age ≥ 75 years (doubled), Diabetes mellitus, prior Stroke or transient ischaemic attack or thromboembolism (doubled),Vascular disease, Age 65–74 years, Sex category; HAS-BLED = Hypertension, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile INR = non-vitamin-K oral anticoagulant; INR = international normalized ratio; PCI = percutaneous coronary intervention; PPIs = proton pump inhibitors;VKA = vitamin K antagonist.

[a]Apixaban 5 mg b.i.d. or apixaban 2.5 mg b.i.d. if at least two of the following: age ≥80 years, body weight ≤60 kg or serum creatinine level ≥1.5 mg/dL (133 µmol/L); dabigatran 110 mg b.i.d.; edoxaban 60 mg q.d. or edoxaban 30 mg q.d. if any of the following: creatinine clearance (CrCl) of 30–50 mL/min, body weight ≤60 kg, concomitant use of verapamil or quinidine or dronedarone; rivaroxaban 20 mg q.d. or rivaroxaban 15 mg q.d. if CrCl 30–49 mL/min.

DAPT and concomitant OAC

Stent-related high ischemic risk features

Table 5 High-risk features of stent-driven recurrent ischaemic events
• Prior stent thrombosis on adequate antiplatelet therapy
• Stenting of the last remaining patent coronary artery
• Diffuse multivessel disease especially in diabetic patients
• Chronic kidney disease (i.e. creatinine clearance <60 mL/min)
• At least three stents implanted
• At least three lesions treated
• Bifurcation with two stents implanted
• Total stent length >60 mm
• Treatment of a chronic total occlusion

DAPT and concomitant OAC

Unfavourable pt. profile for OAC & APT

Table 6 Unfavourable patient profile for a combination of oral anticoagulant and antiplatelet therapy
• Short life expectancy
• Ongoing malignancy
• Poor expected adherence
• Poor mental status
• End stage renal failure
• Advanced age
• Prior major bleeding/prior haemorrhagic stroke
• Chronic alcohol abuse
• Anaemia
• Clinically significant bleeding on dual antithrombotic therapy

Recommendations on dual antiplatelet therapy duration in patients with indication for oral anticoagulation

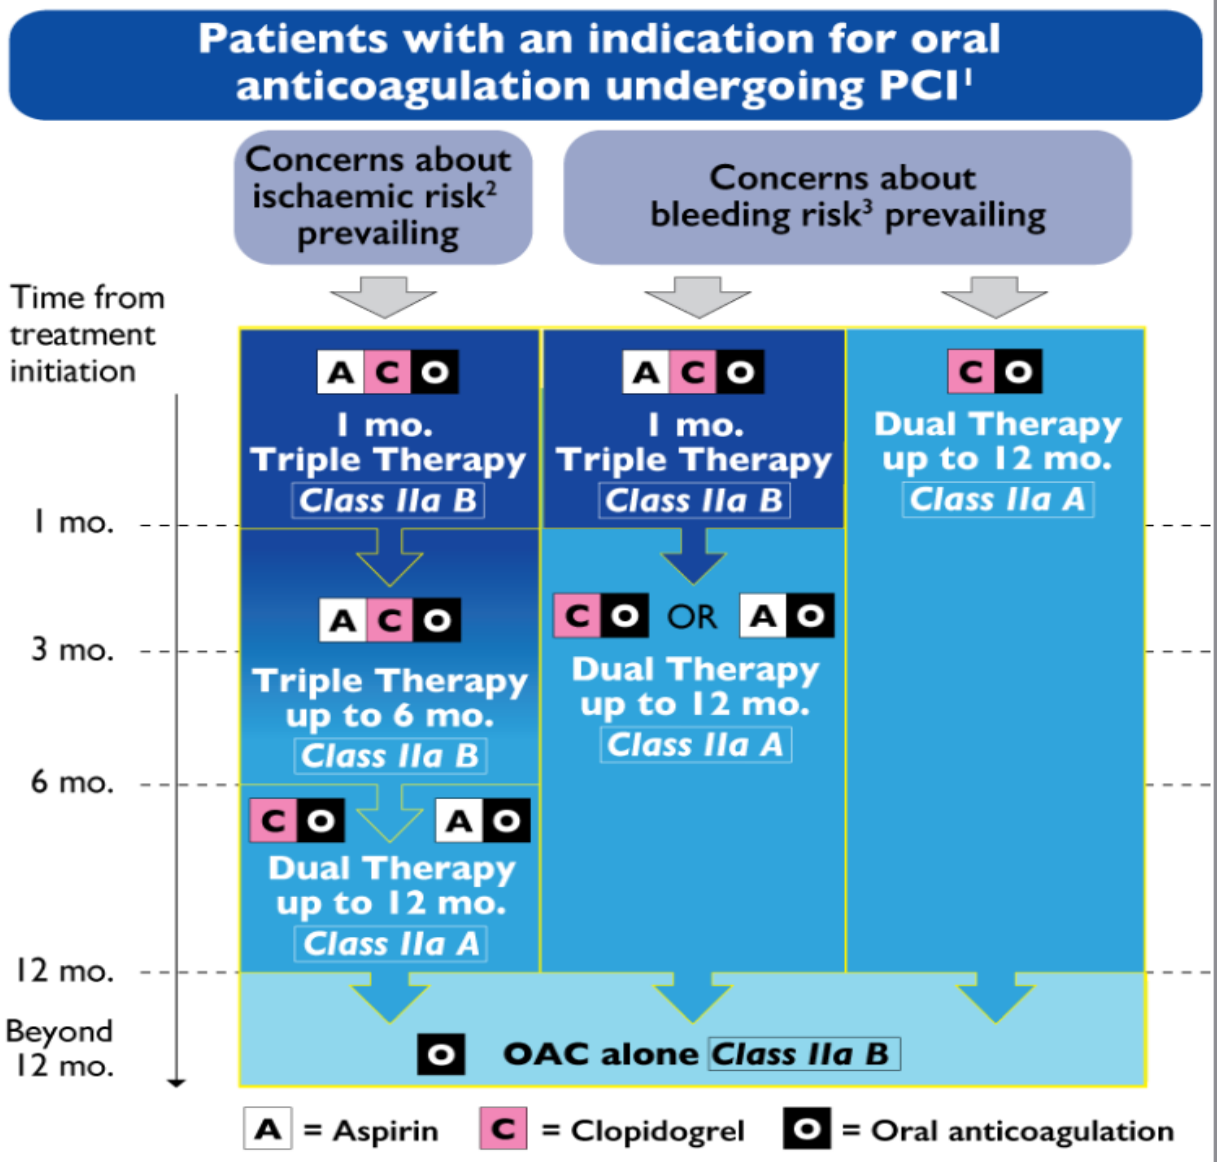
Recommendations	Class[a]	Level[b]
It is recommended to administer periprocedurally aspirin and clopidogrel in patients undergoing coronary stent implantation.	I	C
In patients treated with coronary stent implantation, triple therapy with aspirin, clopidogrel and OAC should be considered for 1 month, irrespective of the type of stent used.	IIa	B
Triple therapy with aspirin, clopidogrel and OAC for longer than 1 month and up to 6 months should be considered in patients with high ischaemic risk due to ACS or other anatomical/procedural characteristics, which outweigh the bleeding risk.	IIa	B
Dual therapy with clopidogrel 75 mg/day and OAC should be considered as an alternative to 1-month triple antithrombotic therapy in patients in whom the bleeding risk outweighs the ischaemic risk.	IIa	A
Discontinuation of antiplatelet treatment in patients treated with OAC should be considered at 12 months.	IIa	B
In patients with an indication for VKA in combination with aspirin and/or clopidogrel, the dose intensity of VKA should be carefully regulated with a target INR in the lower part of the recommended target range and a time in the therapeutic range >65–70%.	IIa	B
When a NOAC is used in combination with aspirin and/or clopidogrel, the lowest approved dose effective for stroke prevention tested in AFib trials should be considered.[c]	IIa	C
When rivaroxaban is used in combination with aspirin and/ or clopidogrel, rivaroxaban 15 mg q.d. may be used instead of rivaroxaban 20 mg q.d.	IIb	B
The use of ticagrelor or prasugrel is not recommended as part of triple antithrombotic therapy with aspirin and OAC.	III	C

ACS = acute coronary syndrome; INR = international normalized ratio; OAC = oral anticoagulant; NOAC = non-vitamin K oral anticoagulant; *q.d.* = *quaque die*; VKA = vitamin K antagonist.

[a]Class of recommendation - [b]Level of evidence.

[c]Apixaban 5 mg *b.i.d.* or apixaban 2.5 mg b.i.d. if at least two of the following: age ≥80 years, body weight ≤60 kg or serum creatinine level ≥1.5 mg/dL (133 µmol/L); dabigatran 110 mg *b.i.d.*; edoxaban 60 mg q.d. or edoxaban 30 mg *q.d.* if any of the following: creatinine clearance (CrCl) of 30–50 mL/min, body weight ≤60 kg, concomitant use of verapamil or quinidine or dronedarone; rivaroxaban 20 mg *q.d.* or rivaroxaban 15 mg *q.d.* if CrCl 30–49 mL/min.

Figure 7 Algorithm for dual antiplatelet therapy (DAPT) in patients with an indication for oral anticoagulation undergoing percutaneous coronary intervention (PCI)



Colour-coding refers to the number of concomitant antithrombotic medication(s). Triple therapy denotes treatment with DAPT plus oral anticoagulant (OAC). Dual therapy denotes treatment with a single antiplatelet agent (aspirin or clopidogrel) plus OAC.

ABC = age, biomarkers, clinical history; ACS = acute coronary syndrome; mo. = month(s); PCI = percutaneous coronary intervention

[1]Periprocedural administration of aspirin and clopidogrel during PCI is recommended irrespective of the treatment strategy.

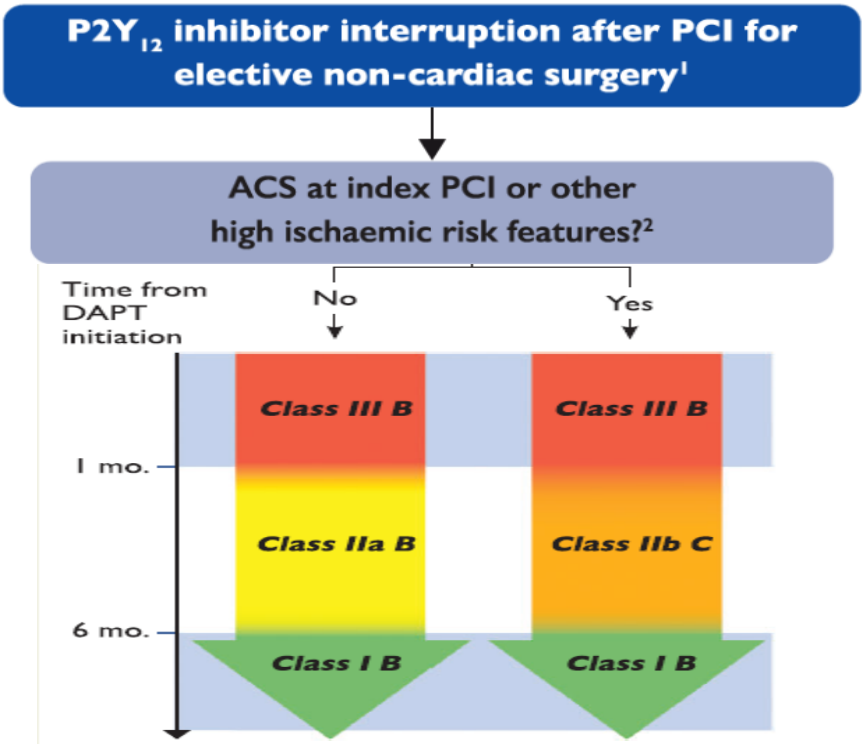
[2]High ischaemic risk is considered as an acute clinical presentation or anatomical/procedural features which might increase the risk for myocardial infarction. 3: Bleeding risk can be estimated by HAS-BLED or ABC score.

The table below summarizes the recommendations on dual antiplatelet therapy in patients undergoing elective non-cardiac surgery.

Recommendations on dual antiplatelet therapy in patients undergoing elective non-cardiac surgery

Recommendations	Class[a]	Level[b]
It is recommended to continue aspirin perioperatively if the bleeding risk allows, and to resume the recommended antiplatelet therapy as soon as possible post-operatively.	I	B
After coronary stent implantation, elective surgery requiring discontinuation of the $P2Y_{12}$ inhibitor should be considered after 1 month, irrespective of the stent type, if aspirin can be maintained throughout the peri-operative period.	IIa	B
Discontinuation of $P2Y_{12}$ inhibitors should be considered at least 3 days before surgery for ticagrelor, at least 5 days for clopidogrel and at least 7 days for prasugrel.	IIa	B
A multidisciplinary expert team should be considered for pre-operative evaluation of patients with an indication for DAPT before elective surgery.	IIa	C
In patients with recent MI or other high ischaemic risk features[c] requiring DAPT, elective surgery may be postponed for up 6 to months.	IIb	C
If both oral antiplatelet agents have to be discontinued perioperatively, a bridging strategy with intravenous antiplatelet agents may be considered, especially if surgery has to be performed within 1 month after stent implantation.	IIb	C
It is not recommended to discontinue DAPT within the first month of treatment in patients undergoing elective non-cardiac surgery.	III	B

Figure 8 Timing for elective non-cardiac surgery in patients treated with dual antiplatelet therapy (DAPT) after percutaneous coronary intervention (PCI)



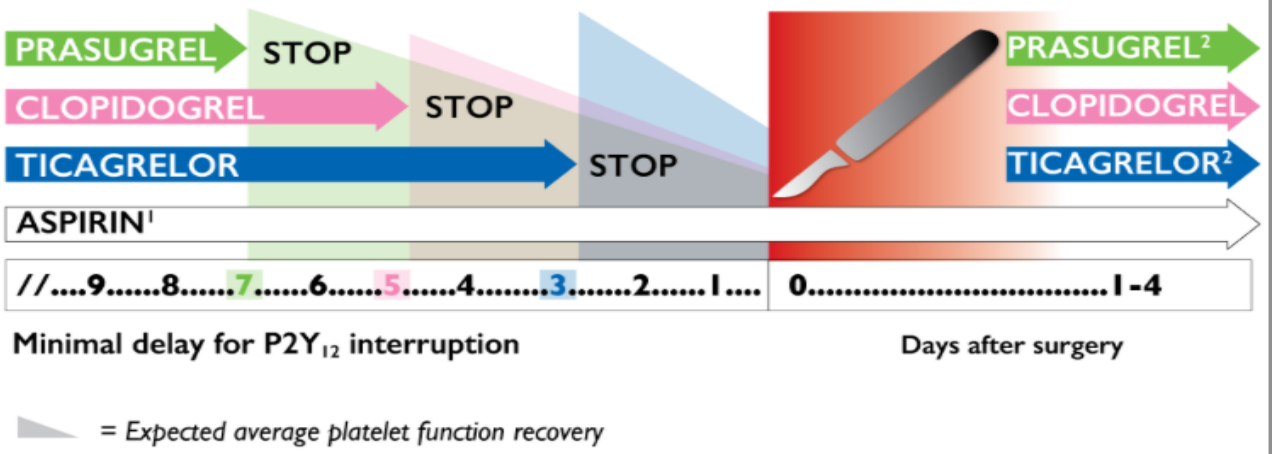
Colour-coding refers to the ESC Classes of Recommendations (green = Class I; yellow = Class IIa; orange = Class IIb).

ACS = acute coronary syndromes.

[1]Availability of H24 cath-lab service in place is suggested in case of major surgery within 6 months after PCI.

[2]High ischaemic risk features are presented in Table 5.

Figure 9 Minimal discontinuation and re-implementation time frames of dual antiplatelet therapy (DAPT) for patients undergoing elective surgery



[1]Decision to stop aspirin throughout surgery should be made on a single case basis taking into account the surgical bleeding risk.

[2]In patients not requiring

OAC = oral anticoagulant.

Gender and special populations

Recommendations related to gender considerations and those for special populations are shown in the table below.

Recommendations on gender considerations and those for special populations

Recommendations	Class[a]	Level[b]
Similar type and duration of DAPT are recommended in male and female patients.	I	A
It is recommended to reassess the type, dose and duration of DAPT in patients with actionable bleeding complication while on treatment.	I	C
Similar type and duration of DAPT should be considered in patients with and without diabetes mellitus.	IIa	B
Prolonged (i.e. >12 months[c]) DAPT duration should be considered in patients with prior stent thrombosis, especially in the absence of correctable causes (e.g. lack of adherence or correctable mechanical stent-related issues).	IIa	C
Prolonged (i.e. >12 months) DAPT duration may be considered in CAD patients with LEAD.	IIb	B
Prolonged (i.e. >6 months) DAPT duration may be considered in patients who underwent complex PCI.[d]	IIb	B

CAD = coronary artery disease; DAPT = dual antiplatelet therapy; LEAD = lower-extremities artery disease; PCI = percutaneous coronary intervention.

[a]Class of recommendation.

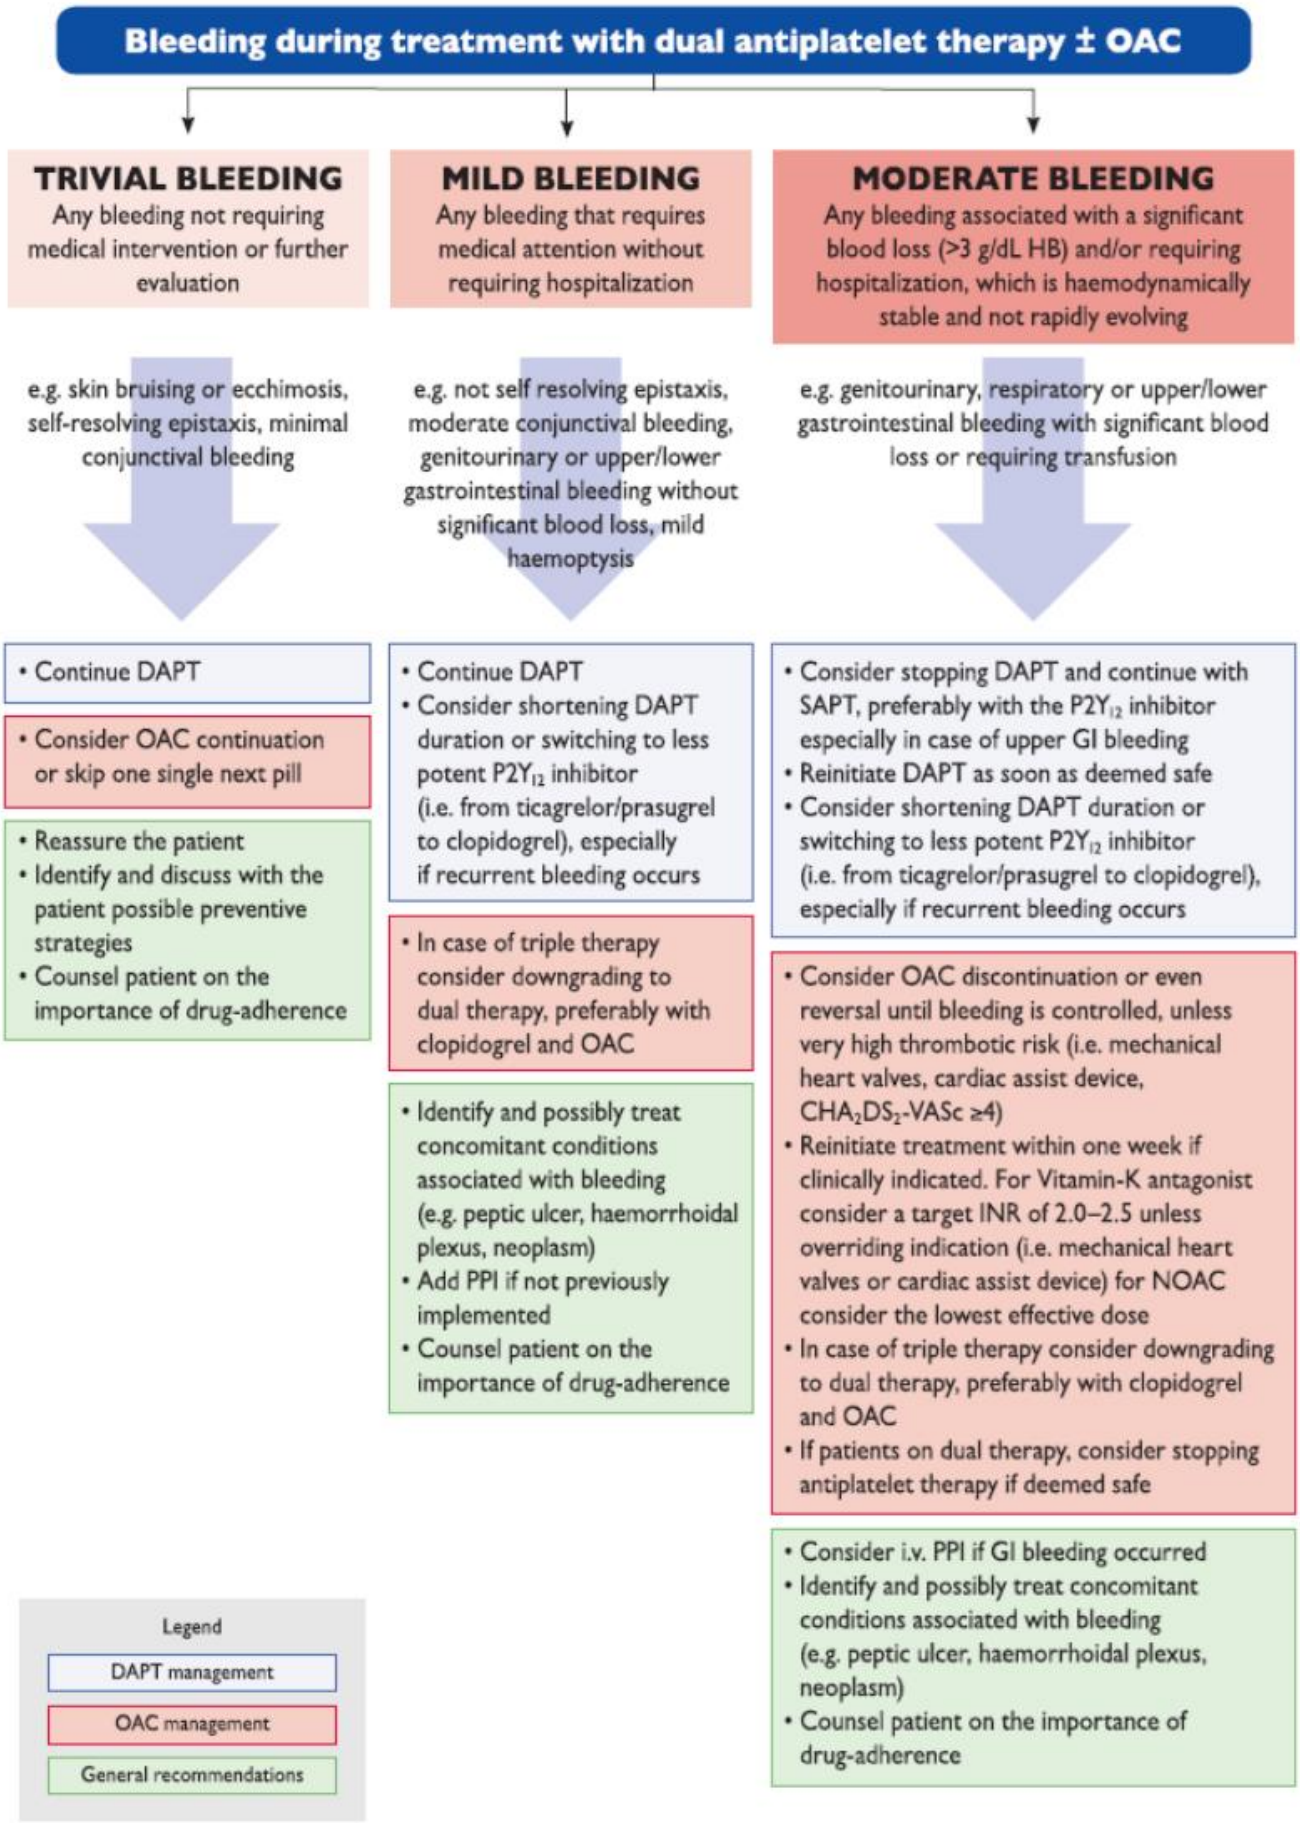
[b]Level of evidence.

[c]And possibly as long as tolerated.

[d]Complex PCI defined as the composite of ≥ three stents implanted, ≥ three lesions treated, bifurcation with two stents implanted, total stent length >60 mm and chronic total occlusion as target lesion.

Practical recom. for management

Practical recommendations for the management of bleeding in patients treated with dual antiplatelet therapy with or without concomitant oral anticoagulation are showed in the figure 10.



Bleeding during treatment with dual antiplatelet therapy ± OAC
TRIVIAL BLEEDING
Any bleeding not requiring medical intervention or further evaluation
MILD BLEEDING
Any bleeding that requires medical attention without requiring hospitalization
MODERATE BLEEDING
Any bleeding associated with a significant blood loss (>3 g/dL HB) and/or requiring hospitalization, which is haemodynamically stable and not rapidly evolving
e.g. skin bruising or ecchimosis, self-resolving epistaxis, minimal conjunctival bleeding
e.g. not self resolving epistaxis, moderate conjunctival bleeding, genitourinary or upper/lower gastrointestinal bleeding without significant blood loss, mild haemoptysis
e.g. genitourinary, respiratory or upper/lower gastrointestinal bleeding with significant blood loss or requiring transfusion
• Continue DAPT
• Consider OAC continuation or skip one single next pill
• Reassure the patient
• Identify and discuss with the patient possible preventive strategies
• Counsel patient on the importance of drug-adherence
• Continue DAPT
• Consider shortening DAPT duration or switching to less potent P2Y12 inhibitor (i.e. from ticagrelor/prasugrel to clopidogrel), especially if recurrent bleeding occurs
• In case of triple therapy consider downgrading to dual therapy, preferably with clopidogrel and OAC
• Identify and possibly treat concomitant conditions associated with bleeding (e.g. peptic ulcer, haemorrhoidal plexus, neoplasm)
• Add PPI if not previously implemented
• Counsel patient on the importance of drug-adherence
• Consider stopping DAPT and continue with SAPT, preferably with the P2Y12 inhibitor especially in case of upper GI bleeding
• Reinitiate DAPT as soon as deemed safe
• Consider shortening DAPT duration or switching to less potent P2Y12 inhibitor (i.e. from ticagrelor/prasugrel to clopidogrel), especially if recurrent bleeding occurs
• Consider OAC discontinuation or even reversal until bleeding is controlled, unless very high thrombotic risk (i.e. mechanical heart valves, cardiac assist device, CHA2DS2-VASc ≥4)
• Reinitiate treatment within one week if clinically indicated. For Vitamin-K antagonist consider a target INR of 2.0–2.5 unless overriding indication (i.e. mechanical heart valves or cardiac assist device) for NOAC consider the lowest effective dose
• In case of triple therapy consider downgrading to dual therapy, preferably with clopidogrel and OAC
• If patients on dual therapy, consider stopping antiplatelet therapy if deemed safe
• Consider i.v. PPI if GI bleeding occurred
• Identify and possibly treat concomitant conditions associated with bleeding (e.g. peptic ulcer, haemorrhoidal plexus, neoplasm)
• Counsel patient on the importance of drug-adherence
Legend

OAC management
General recommendations
©ESC 2017

Bleeding during treatment with dual antiplatelet therapy ± OAC

SEVERE BLEEDING

Any bleeding requiring hospitalisation, associated with a severe blood loss (>5 g/dL HB) which is haemodynamically stable and not rapidly evolving

e.g. severe genitourinary, respiratory or upper/lower gastrointestinal bleeding

- Consider stopping DAPT and continue with SAPT, preferably with the $P2Y_{12}$ inhibitor especially in case of upper GI bleeding
- If bleeding persists despite treatment or treatment is not possible, consider stopping all antithrombotic medications
- Once bleeding has ceased, re-evaluate the need for DAPT or SAPT, preferably with the $P2Y_{12}$ inhibitor especially in case of upper GI bleeding
- If DAPT is re-started, consider shortening DAPT duration or switching to less potent $P2Y_{12}$ inhibitor (i.e. from ticagrelor/prasugrel to clopidogrel), especially if recurrent bleeding occurs

- Consider stopping and reversing OAC until bleeding is controlled unless prohibitive thrombotic risk (i.e. mechanical heart valve in mitral position, cardiac assist device)
- Reinitiate treatment within one week if clinically indicated. For vitamin-K antagonists consider a target INR of 2.0–2.5 unless overriding indication (i.e. mechanical heart valves or cardiac assist device) for NOAC consider the lowest effective dose
- If patient on triple therapy consider downgrading to dual therapy with clopidogrel and OAC. If patients on dual therapy, consider stopping antiplatelet therapy if deemed safe

- Consider i.v. PPI if GI bleeding occurred
- RBC transfusion if HB <7-8 g/dL
- Consider platelet transfusion
- Urgent surgical or endoscopic treatment of bleeding source if deemed possible

LIFE-THREATENING BLEEDING

Any severe active bleeding putting patient's life immediately at risk

e.g. massive overt genitourinary, respiratory or upper/lower gastrointestinal bleeding, active intracranial, spinal or intraocular haemorrhage, or any bleeding causing haemodynamic instability

- Immediately discontinue all antithrombotic medications
- Once bleeding has ceased, re-evaluate the need for DAPT or SAPT, preferably with the $P2Y_{12}$ inhibitor especially in case of upper GI bleeding

- Stop and reverse OAC

- Fluid replacement if hypotension
- Consider RBC transfusion irrespective of HB values
- Platelet transfusion
- Consider i.v. PPI if GI bleeding occurred
- Urgent surgical or endoscopic treatment of bleeding source if deemed possible

1. WHAT IS NEW IN THE UNIVERSAL DEFINITION OF MYOCARDIAL INFARCTION?

What's new in the universal definition of myocardial infarction?
New concepts
• Differentiation of myocardial infarction from myocardial injury.
• Highlighting peri-procedural myocardial injury after cardiac and non-cardiac procedures as discrete from myocardial infarction.
• Consideration of electrical remodelling (cardiac memory) in assessing repolarization abnormalities with tachyarrhythmia, pacing, and rate-related conduction disturbances.
• Use of cardiovascular magnetic resonance to define aetiology of myocardial injury.
• Use of computed tomographic coronary angiography in suspected myocardial infarction.
Updated concepts
• Type 1 myocardial infarction: Emphasis on the causal relationship of plaque disruption with coronary athero-thrombosis; *new Figure 3*.
• Type 2 myocardial infarction: Settings with oxygen demand and supply imbalance unrelated to acute coronary athero-thrombosis; *new Figures 4 and 5*.
• Type 2 myocardial infarction: Relevance of presence or absence of coronary artery disease to prognosis and therapy.
• Differentiation of myocardial injury from type 2 myocardial infarction; *new Figure 6*.
• Type 3 myocardial infarction: Clarify why type 3 myocardial infarction is a useful category to differentiate from sudden cardiac death.
• Types 4–5 myocardial infarction: Emphasis on distinction between procedure-related myocardial injury and procedure-related myocardial infarction.
• Cardiac troponin: Analytical issues for cardiac troponins; *new Figure 7*.
• Emphasis on the benefits of high-sensitivity cardiac troponin assays.
• Considerations relevant to the use of rapid rule-out and rule-in protocols for myocardial injury and myocardial infarction.
• Issues related to specific diagnostic change ('delta') criteria for the use of cardiac troponins to detect or exclude acute myocardial injury.
• Consideration of new non-rate-related right bundle branch block with specific repolarization patterns.
• ST-segment elevation in lead aVR with specific repolarization patterns, as a STEMI equivalent.
• ECG detection of myocardial ischaemia in patients with an implantable cardiac defibrillator or a pacemaker.
• Enhanced role of imaging including cardiac magnetic resonance imaging for the diagnosis of myocardial infarction; *new Figure 8*.
New sections
• Takotsubo syndrome.
• MINOCA.
• Chronic kidney disease.
• Atrial fibrillation.
• Regulatory perspective on myocardial infarction.
• Silent or unrecognized myocardial infarction.

ECG = electrocardiogram; MINOCA = myocardial infarction with non-obstructive coronary arteries; STEMI = ST-elevation myocardial infarction.

2. UNIVERSAL DEFINITIONS OF MYOCARDIAL INJURY AND MYOCARDIAL INFARCTION: SUMMARY

Universal definitions of myocardial injury and myocardial infarction

Criteria for myocardial injury

The term myocardial injury should be used when there is evidence of elevated cardiac troponin values (cTn) with at least one value above the 99th percentile upper reference limit (URL). The myocardial injury is considered acute if there is a rise and/or fall of cTn values.

Criteria for acute myocardial infarction (types 1, 2 and 3 MI)

The term acute myocardial infarction should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischaemia and with detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL and at least one of the following:

- Symptoms of myocardial ischaemia;
- New ischaemic ECG changes;
- Development of pathological Q waves;
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology;
- Identification of a coronary thrombus by angiography or autopsy (not for types 2 or 3 MIs).

Post-mortem demonstration of acute athero-thrombosis in the artery supplying the infarcted myocardium meets criteria for *type 1 MI*. Evidence of an imbalance between myocardial oxygen supply and demand unrelated to acute athero-thrombosis meets criteria for *type 2 MI*. Cardiac death in patients with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes before cTn values become available or abnormal meets criteria for *type 3 MI*.

Criteria for coronary procedure-related myocardial infarction (types 4 and 5 MI)

Percutaneous coronary intervention (PCI) related MI is termed *type 4a MI*.

Coronary artery bypass grafting (CABG) related MI is termed *type 5 MI*.

Coronary procedure-related MI ≤ 48 hours after the index procedure is arbitrarily defined by an elevation of cTn values > 5 times for *type 4a MI* and > 10 times for *type 5 MI* of the 99th percentile URL in patients with normal baseline values. Patients with elevated pre-procedural cTn values, in whom the pre-procedural cTn level are stable (≤ 20% variation) or falling, must meet the criteria for a > 5 or > 10 fold increase and manifest a change from the baseline value of > 20%. In addition with at least one of the following:

- New ischaemic ECG changes (this criterion is related to *type 4a MI* only);
- Development of new pathological Q waves;
- Imaging evidence of loss of viable myocardium that is presumed to be new and in a pattern consistent with an ischaemic aetiology;
- Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or graft, side-branch occlusion-thrombus, disruption of collateral flow or distal embolization.

Isolated development of new pathological Q waves meets the *type 4a MI* or *type 5 MI* criteria with either revascularization procedure if cTn values are elevated and rising but less than the pre-specified thresholds for PCI and CABG.

Other types of 4 MI include *type 4b MI* stent thrombosis and *type 4c MI* restenosis that both meet *type 1 MI* criteria.

Post-mortem demonstration of a procedure-related thrombus meets the *type 4a MI* criteria or *type 4b MI* criteria if associated with a stent.

Criteria for prior or silent/unrecognized myocardial infarction

Any one of the following criteria meets the diagnosis for prior or silent/unrecognized MI:

- Abnormal Q waves with or without symptoms in the absence of non-ischaemic causes.
- Imaging evidence of loss of viable myocardium in a pattern consistent with ischaemic aetiology.
- Patho-anatomical findings of a prior MI.

CABG = coronary artery bypass grafting; cTn = cardiac troponin; ECG = electrocardiogram; MI = myocardial infarction; PCI = percutaneous coronary intervention; URL = upper reference limit.

3. INTRODUCTION

In the late 19th century, post-mortem examinations demonstrated a possible relationship between thrombotic occlusion of a coronary artery and myocardial infarction (MI).[1] However, it was not until the beginning of the 20th century that the first clinical descriptions appeared describing a connection between the formation of a thrombus in a coronary artery and its associated clinical features.[2,3] Despite these landmark observations, considerable time elapsed before general clinical acceptance of this entity was achieved, in part due to one autopsy study that showed no thrombi in the coronary arteries of 31% of deceased patients with an MI.[4] The clinical entity was referred to as coronary thrombosis, although use of the term 'MI' ultimately prevailed. Over the years, several different definitions of MI have been used, leading to controversy and confusion. Hence, a general and worldwide definition for MI was needed. This occurred for the first time in the 1950–70s, when working groups from the World Health Organization (WHO) established a primarily electrocardiographic (ECG)-based definition of MI intended for epidemiological use.[5] The original description, with minor modifications, is still used in epidemiological surveys (*Figure 1*).[6–8]

With the introduction of more sensitive cardiac biomarkers, the European Society of Cardiology (ESC) and the American College of Cardiology (ACC) collaborated to redefine MI using a biochemical and clinical approach, and reported that myocardial injury detected by abnormal biomarkers in the setting of acute myocardial

Downloaded from http://ahajournals.org by on August 25, 2018

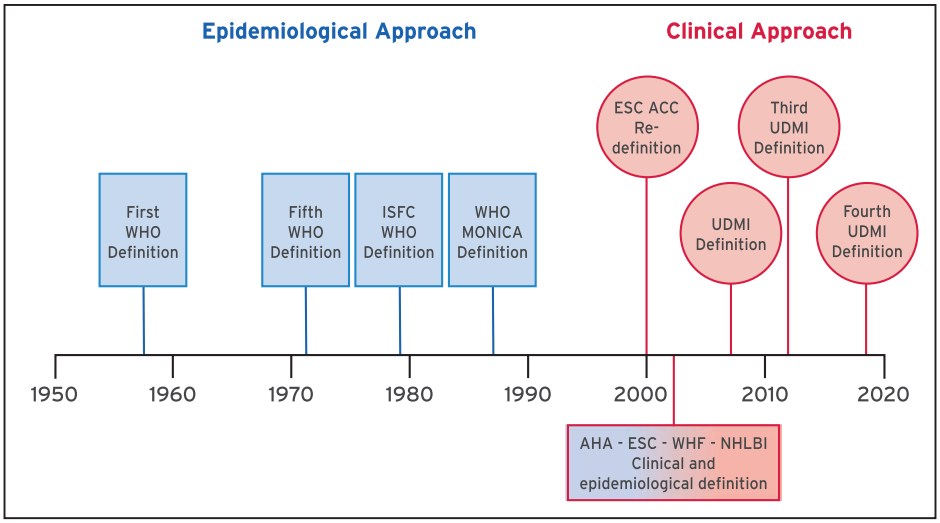

Figure 1. History of documents on the definition of myocardial infarction.
ACC = American College of Cardiology; AHA = American Heart Association; ESC = European Society of Cardiology; ISFC = International Society and Federation of Cardiology; MONICA = MONItoring of trends and determinants in CArdiovascular disease; NHLBI = National Heart, Lung, and Blood Institute; UDMI = Universal Definition of Myocardial Infarction; WHF = World Heart Federation; WHO = World Health Organization.

ischaemia should be labelled as MI.[9] The principle was further refined by the Global MI Task Force, leading to the Universal Definition of Myocardial Infarction Consensus Document in 2007, introducing a novel MI classification system with five subcategories.[10] This document, endorsed by the ESC, the ACC), the American Heart Association (AHA), and the World Heart Federation (WHF), was adopted by the WHO.[11] The development of even more sensitive assays for markers of myocardial injury made further revision of the document necessary, particularly for patients who undergo coronary procedures or cardiac surgery. As a result, the Joint ESC/ACC/AHA/WHF Task Force produced the Third Universal Definition of Myocardial Infarction Consensus Document in 2012.[12]

Studies have shown that myocardial injury, defined by an elevated cardiac troponin (cTn) value, is frequently encountered clinically and is associated with an adverse prognosis.[13,14] Although myocardial injury is a prerequisite for the diagnosis of MI, it is also an entity in itself. To establish a diagnosis of MI, criteria in addition to abnormal biomarkers are required. Non-ischaemic myocardial injury may arise secondary to many cardiac conditions such as myocarditis, or may be associated with non-cardiac conditions such as renal failure.[15] Therefore, for patients with increased cTn values, clinicians must distinguish whether patients have suffered a non-ischaemic myocardial injury or one of the MI subtypes. If there is no evidence to support the presence of myocardial ischaemia, a diagnosis of myocardial injury should be made. This diagnosis can be changed if subsequent evaluation indicates criteria for MI. The current Fourth Universal Definition of Myocardial Infarction Consensus Document reflects these considerations through adhering to the clinical approach of the definition of MI.

Clinical Criteria for MI

The clinical definition of MI denotes the presence of acute myocardial injury detected by abnormal cardiac biomarkers in the setting of evidence of acute myocardial ischaemia.

4. PATHOLOGICAL CHARACTERISTICS OF MYOCARDIAL ISCHAEMIA AND INFARCTION

MI is defined pathologically as myocardial cell death due to prolonged ischaemia. Diminished cellular glycogen, and relaxed myofibrils and sarcolemmal disruption, are the first ultrastructural changes and are seen as early as 10–15 min after the onset of ischaemia.[16] Mitochondrial abnormalities are observed as early as 10 min after coronary occlusion by electron microscopy and are progressive.[17] It can take hours before myocyte necrosis can be identified by post-mortem examination in humans; this is in contrast to animal models, in which biochemical evidence of myocardial cell death due to apoptosis can be detected within 10 min of induced myocardial ischaemia in association with myocyte death.[15] Experimentally, necrosis progresses from the subendocardium to the subepicardium over several hours. The time course may be prolonged by increased collateral flow, reduced determinants of myocardial oxygen consumption, and intermittent occlusion/reperfusion, which can precondition the heart.[18] Timely imple-

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

mentation of reperfusion therapy, when appropriate, reduces ischaemic injury of the myocardium.[19,20]

5. BIOMARKER DETECTION OF MYOCARDIAL INJURY AND INFARCTION

Cardiac troponin I (cTnI) and T (cTnT) are components of the contractile apparatus of myocardial cells and are expressed almost exclusively in the heart.[21,22] Increases in cTnI values have not been reported to occur following injury to non-cardiac tissues. The situation is more complex for cTnT. Biochemical data indicate that injured skeletal muscle expresses proteins that are detected by the cTnT assay, leading to some situations where elevations of cTnT could emanate from skeletal muscle.[23–27] Recent data suggest that the frequency of such elevations in the absence of ischaemic heart disease may be higher than originally thought.[28,29] cTnI and cTnT are the preferred biomarkers for the evaluation of myocardial injury,[12,21,22,30] and high-sensitivity (hs)-cTn assays are recommended for routine clinical use.[22] Other biomarkers, e.g. wwm (CK-MB), are less sensitive and less specific.[31] Myocardial injury is defined as being present when blood levels of cTn are increased above the 99th percentile upper reference limit (URL).[12,21,22,30] The injury may be acute, as evidenced by a newly detected dynamic rising and/or falling pattern of cTn values above the 99th percentile URL, or chronic, in the setting of persistently elevated cTn levels.

Criteria for Myocardial Injury

Detection of an elevated cTn value above the 99th percentile URL is defined as myocardial injury. The injury is considered acute if there is a rise and/or fall of cTn values.

Although elevated cTn values reflect injury to myocardial cells, they do not indicate the underlying pathophysiological mechanisms, and can arise following preload-induced mechanical stretch or physiological stresses in otherwise normal hearts.[32–34] Various causes have been suggested for the release of structural proteins from the myocardium, including normal turnover of myocardial cells, apoptosis, cellular release of cTn degradation products, increased cellular wall permeability, the formation and release of membranous blebs, and myocyte necrosis.[27,35] Yet, it is not clinically possible to distinguish which increases of cTn levels are due to which mechanisms.[36] However, regardless of the mechanism, acute myocardial injury, when associated with a rising and/or falling pattern of cTn values with at least one value above the 99th percentile URL and caused by myocardial ischaemia, is designated as an acute MI.[12,21,22,30] Histological evidence of myocardial injury with myocyte death can be detected in clinical conditions associated with non-ischaemic mechanisms of myocardial injury as well[37,38] (*Figure 2*).

Myocardial ischaemic or non-ischaemic conditions associated with increased cTn values are presented in *Table 1*. The complexity of clinical circumstances may sometimes make it difficult to discriminate specific individual mechanism(s) of myocardial injury. In this situation, the multifactorial contributions resulting in myocardial injury should be described in the patient record.

6. CLINICAL PRESENTATIONS OF MYOCARDIAL INFARCTION

Onset of myocardial ischaemia is the initial step in the development of MI and results from an imbalance between oxygen supply and demand. Myocardial ischaemia in a clinical setting can most often be identified from the patient's history and from the ECG. Possible ischaemic symptoms include various combinations of chest, upper extremity, mandibular, or epigastric discomfort during exertion or at rest, or an ischaemic equivalent such as dyspnoea or fatigue. Often, the discomfort is diffuse; not localized, nor positional, nor affected by movement of the region. However, these symptoms are not specific for myocardial ischaemia and can be observed in other conditions such as gastrointestinal, neurological, pulmonary, or musculoskeletal complaints. MI may occur with atypical symptoms such as palpitations or cardiac arrest, or even without symptoms.[12] Very brief episodes of ischaemia too short to cause necrosis can also cause cTn release and elevations. The involved myocytes can subsequently die due to apoptosis.[42]

If myocardial ischaemia is present clinically or detected by ECG changes together with myocardial injury, manifested by a rising and/or falling pattern of cTn values, a diagnosis of acute MI is appropriate. If myocardial ischaemia is not present clinically, then elevated cTn levels may be indicative of acute myocardial injury if the pattern of values is rising and/or falling, or related to more chronic ongoing injury if the pattern is unchanging.[14] Similar considerations are relevant when evaluating events that are potentially related to procedures that may cause myocardial injury and/or MI. Additional evaluations may lead to a need for the initial diagnosis to be revised.

Patients with suspected acute coronary syndrome (ACS) that are ruled out for MI with normal cardiac biomarker values (≤ 99th percentile URL) may have unstable angina or an alternative diagnosis. These patients should be evaluated and treated accordingly.[11,43]

7. CLINICAL CLASSIFICATION OF MYOCARDIAL INFARCTION

For the sake of immediate treatment strategies such as reperfusion therapy, it is usual practice to designate MI in patients with chest discomfort or other ischaemic symptoms, who develop new ST-segment elevations in two contiguous leads or new bundle branch blocks with ischaemic repolarization patterns as an ST-elevation MI (STEMI) (see section 27). In contrast, patients without ST-segment elevation at presentation are usually designated non-ST-elevation MI (NSTEMI). The categories of patients with STEMI, NSTEMI, or unstable angina are customarily included in the concept of ACS. In addition to these categories, MI may be classified into various types based on pathological, clinical, and prognostic differences, along with different treatment strategies.

7.1. Myocardial Infarction Type 1

MI caused by atherothrombotic coronary artery disease (CAD) and usually precipitated by atherosclerotic plaque disruption (rupture or erosion) is designated as a type 1 MI. The relative burden of atherosclerosis and thrombosis in the culprit lesion varies greatly, and the dynamic thrombotic component may lead to distal coronary embolization resulting in myocyte necrosis.[44,45] Plaque rupture may not only be complicated by intraluminal thrombosis but also by haemorrhage into the plaque through the disrupted surface (*Figure 3*).[44,45]

Criteria for Type 1 MI

Detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL and with at least one of the following:

- Symptoms of acute myocardial ischaemia;
- New ischaemic ECG changes;
- Development of pathological Q waves;
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology;
- Identification of a coronary thrombus by angiography including intracoronary imaging or by autopsy.[a]

cTn = cardiac troponin; ECG = electrocardiogram; URL = upper reference limit.
[a]Post-mortem demonstration of an atherothrombus in the artery supplying the infarcted myocardium, or a macroscopically large circumscribed area of necrosis with or without intramyocardial haemorrhage, meets the type 1 MI criteria regardless of cTn values.

Downloaded from http://ahajournals.org by on August 25, 2018

Table 1. Reasons for the Elevation of Cardiac Troponin Values Because of Myocardial Injury

Myocardial injury related to acute myocardial ischaemia
Atherosclerotic plaque disruption with thrombosis.
Myocardial injury related to acute myocardial ischaemia because of oxygen supply/demand imbalance
Reduced myocardial perfusion, e.g.
• Coronary artery spasm, microvascular dysfunction
• Coronary embolism
• Coronary artery dissection
• Sustained bradyarrhythmia
• Hypotension or shock
• Respiratory failure
• Severe anaemia
Increased myocardial oxygen demand, e.g.
• Sustained tachyarrhythmia
• Severe hypertension with or without left ventricular hypertrophy
Other causes of myocardial injury
Cardiac conditions, e.g.
• Heart failure
• Myocarditis
• Cardiomyopathy (any type)
• Takotsubo syndrome
• Coronary revascularization procedure
• Cardiac procedure other than revascularization
• Catheter ablation
• Defibrillator shocks
• Cardiac contusion
Systemic conditions, e.g.
• Sepsis, infectious disease
• Chronic kidney disease
• Stroke, subarachnoid haemorrhage
• Pulmonary embolism, pulmonary hypertension
• Infiltrative diseases, e.g. amyloidosis, sarcoidosis
• Chemotherapeutic agents
• Critically ill patients
• Strenuous exercise

For a more comprehensive listing, see[39–41].

It is essential to integrate the ECG findings with the aim of classifying type 1 MI into STEMI or NSTEMI in order to establish the appropriate treatment according to current Guidelines.[46,47]

7.2. Myocardial Infarction Type 2

The pathophysiological mechanism leading to ischaemic myocardial injury in the context of a mismatch between oxygen supply and demand has been classified as type 2 MI.[10,12] By definition, acute atherothrombotic plaque disruption is not a feature of type 2 MI. In patients with stable known or presumed CAD, an acute stressor such as an acute gastrointestinal bleed with a precipitous drop in haemoglobin, or a sustained tachyarrhythmia with clinical manifestations of myocardial ischaemia, may result in myocardial injury and a type 2 MI. These effects are due to insufficient blood flow to the ischaemic myocardium to meet the increased myocardial oxygen demand of the stressor. Ischaemic thresholds may vary substantially in individual patients depending on the magnitude of the stressor, the presence of non-cardiac comorbidities, and the extent of underlying CAD and cardiac structural abnormalities.

Studies have shown variable occurrences of type 2 MI depending on criteria used for diagnosis. Some reports rely on specific predetermined oxygen mismatch criteria,[48,49] whereas others apply more liberal criteria. Most studies show a higher frequency of type 2 MI in women. The shortand long-term mortality rates for patients with type 2 MI are generally higher than for type 1 MI patients in most but not all studies due to an increased prevalence of comorbid conditions.[49–57] Coronary atherosclerosis is a common finding in type 2 MI patients selected for coronary angiography. In general, these patients have a worse prognosis than those without CAD.[54–57] Prospective evaluations of the importance of CAD with type 2 MI using consistent definitions and approaches are needed.

It has been shown that the frequency of ST-segment elevation in type 2 MI varies from 3–24%.[53] In some cases, coronary embolism caused by thrombi, calcium or vegetation from the atria or ventricles, or acute aortic dissection may result in a type 2 MI. Spontaneous coronary artery dissection with or without intramural haematoma is another non-atherosclerotic condition that may occur, especially in young women. It is defined as spontaneous dissection of the coronary artery wall with accumulation of blood within the false lumen, which can compress the true lumen to varying degrees (*Figure 4*).[58]

All of the clinical information available should be considered in distinguishing type 1 MI from type 2 MI. The context and mechanisms of type 2 MI should be considered when establishing this diagnosis (*Figure 5*). The myocardial oxygen supply/demand imbalance attributable to acute myocardial ischaemia may be multifactorial, related either to: reduced myocardial perfusion due to fixed coronary atherosclerosis without plaque rupture, coronary artery spasm, coronary microvascular dysfunction (which includes endothelial dysfunction, smooth muscle cell dysfunction, and the dysregulation of sympathetic innervation), coronary embolism, coronary artery dissection with or without intramural haematoma, or other mechanisms that reduce oxygen supply such as severe bradyarrhythmia, respiratory failure with severe hypoxaemia, severe anaemia, and hypotension/shock; or to increased myocardial oxygen demand due to sustained tachyarrhythmia or severe hypertension with or without left ventricular hypertrophy. In patients who undergo timely coronary angiography, description of a ruptured plaque with throm-

Circulation

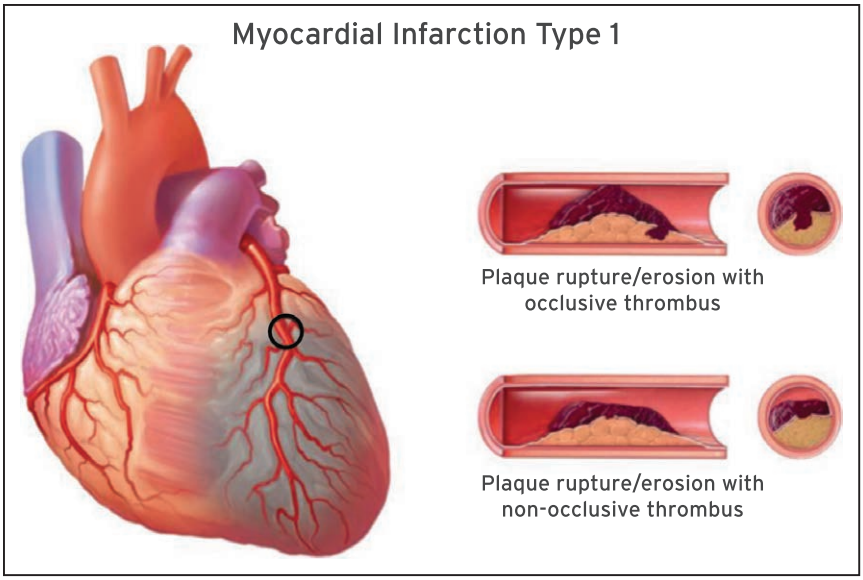

Figure 3. Myocardial infarction type 1.

bus in the infarct-related artery may be helpful in making the distinction between type 2 MI vs. type 1 MI, but angiography is not always definitive, clinically indicated, or required to establish the diagnosis of type 2 MI.

Criteria for Type 2 MI

Detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL, and evidence of an imbalance between myocardial oxygen supply and demand unrelated to coronary thrombosis, requiring at least one of the following:

- Symptoms of acute myocardial ischaemia;
- New ischaemic ECG changes;
- Development of pathological Q waves;
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology.

It appears advisable in the acute setting to treat the underlying ischaemic imbalance of oxygen supply and demand. This treatment may include volume adjustment, blood pressure management, administration of blood products, heart-rate control, and respiratory support.[47,48] Depending on the clinical situation, coronary evaluations may be indicated to assess the likelihood of CAD. If it is present, the MI Guidelines may be applied in accordance with the ECG findings of STEMI or NSTEMI.[46,47] However, if CAD is absent, the benefits of cardiovascular risk reduction strategies with type 2 MI remain uncertain.

7.3. Myocardial Infarction Type 2 and Myocardial Injury

Type 2 MI and myocardial injury are frequently encountered in clinical practice and both are related to a poor outcome.[13,14,49,51,56] A conceptual model to facilitate the clinical distinction between acute ischaemic myocardial injury with or without an acute atherothrombotic event (type 1 or type 2 MI) vs. conditions without acute ischaemic myocardial injury is displayed in *Figure 6*. Acute MI requires a rising and/or falling pattern of cTn values. Acute myocardial injury may also manifest such a pattern but if the injury is related to structural heart disease, the cTn values may be stable and unchanging. Type 2 MI and non-ischaemic myocardial injury may coexist. It should be recognized that some disease entities may be on both sides of the diagram, e.g. acute heart failure that may occur in the context of acute myocardial ischaemia. Nevertheless, abnormal cTn values in the setting of acute and/or chronic heart failure are often better categorized as a myocardial injury condition. Few studies have compared the incidence and clinical features of type 2 MI vs. myocardial injury without acute myocardial ischaemia.

7.4. Myocardial Infarction Type 3

The detection of cardiac biomarkers in the blood is fundamental for establishing the diagnosis of MI.[10,12] However, patients can manifest a typical presentation of myocardial ischaemia/infarction, including presumed new ischaemic ECG changes or ventricular fibrillation, and die before it is possible to obtain blood for cardiac biomarker determination; or the patient may succumb soon after the onset of symptoms before an elevation of biomarker values has occurred. Such patients are designated as having a type 3 MI, when suspicion for an acute myocardial ischaemic event is high, even when cardiac biomarker evidence of MI is lacking.[10,12] This category allows the separation of fatal MI events from the much larger group of sudden death episodes that

Downloaded from http://ahajournals.org by on August 25, 2018

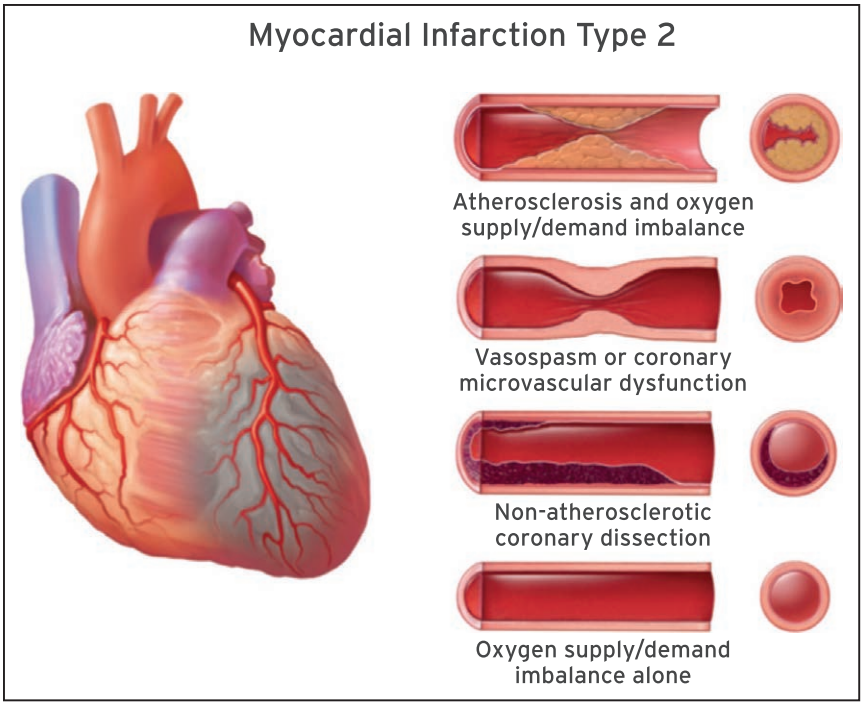

Figure 4. Myocardial infarction type 2.

may be cardiac (non-ischaemic) or non-cardiac in origin. When a type 3 MI is diagnosed and a subsequent autopsy reveals recent evidence of an MI, with a fresh or recent thrombus in the infarct-related artery, the type 3 MI should be reclassified to a type 1 MI. Original investigations addressing the incidence of type 3 MI are sparse, but a study showed an annual incidence below 10/100 000 person-years and a frequency of 3–4% among all types of MI.[60]

Criteria for Type 3 MI

Patients who suffer cardiac death, with symptoms suggestive of myocardial ischaemia accompanied by presumed new ischaemic ECG changes or ventricular fibrillation, but die before blood samples for biomarkers can be obtained, or before increases in cardiac biomarkers can be identified, or MI is detected by autopsy examination.

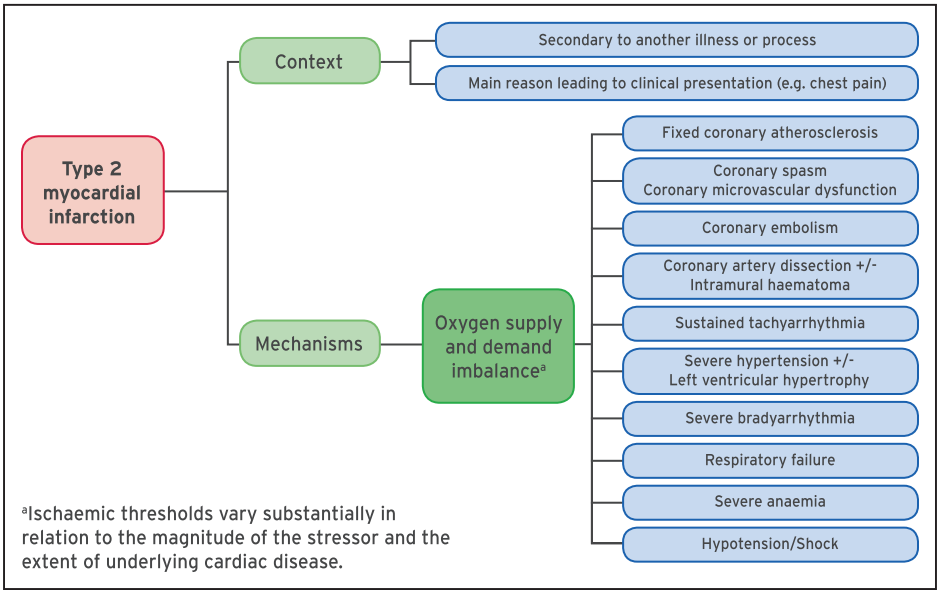

Figure 5. Framework for type 2 myocardial infarction considering the clinical context and pathophysiological mechanisms attributable to acute myocardial ischaemia.

Circulation

8. CORONARY PROCEDURE-RELATED MYOCARDIAL INJURY

Cardiac procedural myocardial injury related to coronary revascularization procedures, whether percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG), may be temporally related to the procedure itself, reflecting periprocedural issues, or may occur later reflecting complications of a device, such as early or late stent thrombosis or in-stent restenosis for PCI, or graft occlusion or stenosis with CABG. Late gadolinium enhancement (LGE) cardiac magnetic resonance (CMR) allows assessment of procedural myocardial injury[61–63] When quantifying procedural injury using LGE-CMR before and shortly after PCI or CABG, it was found that 32% of patients had evidence of procedural myocardial injury.[63] Furthermore, it has been shown that patients with elevation of cTnI values after PCI or after CABG have evidence of procedural myocardial injury on CMR imaging.[61,62] For that reason, increased cTn values detected following a coronary revascularization procedure may reflect procedural myocardial injury. Of importance, if the baseline value before the procedure is above the 99th percentile URL, it is essential that cTn levels are stable prior to the evaluation in order to reliably establish the presence of acute procedural myocardial injury. It is not possible to determine, when intervening in a patient with an acute MI event resulting in an increased cTn level, how much of any given increase is related to the MI and how much is due to the procedure.

Criteria for Cardiac Procedural Myocardial Injury

Cardiac procedural myocardial injury is arbitrarily defined by increases of cTn values (> 99th percentile URL) in patients with normal baseline values (≤ 99th percentile URL) or a rise of cTn values > 20% of the baseline value when it is above the 99th percentile URL but it is stable or falling.

A large proportion of patients have abnormal values of cTn after PCI, ranging from ~20–40% in stable CAD to 40–50% in MI.[64] The occurrence of procedural myocardial injury can be detected by the measurement of cTn before the procedure and repeated 3–6 h later. Where the second value is rising, further sampling

Downloaded from http://ahajournals.org by on August 25, 2018

should be performed to document the peak cTn value. Increasing levels after the procedure can only be attributed with certainty to procedural myocardial injury when the pre-procedural cTn values are normal (≤ 99th percentile URL), or if they are stable or falling. For patients that present with an ACS and undergo a prompt coronary revascularization procedure resulting in only a single pre-procedural baseline value that is normal or mildly elevated, followed by subsequent postprocedural values that continue to increase, the post-procedural increase should be attributed to the index event. Recent data corroborate the importance of elevated pre-procedure cTn values as a prognostic marker in patients that have values that rise after the procedure.[65] To diagnose procedural myocardial injury in the clinical setting of only a single pre-procedural cTn value, the cardiac Tn values would need to be stable or falling post-procedure, followed by a subsequent increase that exceeds the 99th percentile URL, and if the value has not returned to baseline, the increase should be > 20% with an absolute value > the 99th percentile URL.

9. MYOCARDIAL INFARCTION ASSOCIATED WITH PERCUTANEOUS CORONARY INTERVENTION (TYPE 4A MYOCARDIAL INFARCTION)

Stand-alone post-procedural increases of cTn values are sufficient to establish a diagnosis of procedural myocardial injury but not for the diagnosis of type 4a MI. Type 4a MI requires an elevation of cTn values greater than five times the 99th percentile URL in patients with normal baseline values or, in patients with elevated pre-procedure cTn in whom the cTn levels are stable (≤ 20% variation) or falling, the post-procedure cTn must rise > 20% to an absolute value more than five times the 99th percentile URL. In addition, there should be evidence of new myocardial ischaemia, either from ECG changes, imaging evidence, or from procedure-related complications associated with reduced coronary blood flow such as coronary dissection, occlusion of a major epicardial artery or a side branch occlusion/thrombus, disruption of collateral flow, slow flow or no-reflow, or distal embolization. The use of hs-cTn assays to diagnose type 4a MI (and type 5 MI) is an area of active research. Many hs-cTn assays are available, which have wide dynamic ranges. Different criteria may be required for different assays. However, it has recently been shown that the optimal hs-cTnT thresholds to predict cardiovascular events at 30 days and 1 year were very close to the five-fold increase suggested by the Third Universal Definition of Myocardial infarction.[12,66,67] These criteria are therefore retained because of a lack of new scientific evidence that identifies superior criteria for defining this MI subtype. Other criteria that meet the definition of type 4a MI, regardless of hs-cTn or cTn values, are the development of new pathological Q waves or autopsy evidence of recent procedure-related thrombus in the culprit artery.

Criteria for PCI-Related MI ≤ 48 h After the Index Procedure (Type 4a MI)

Coronary intervention-related MI is arbitrarily defined by an elevation of cTn values more than five times the 99th percentile URL in patients with normal baseline values. In patients with elevated pre-procedure cTn in whom the cTn level are stable (≤ 20% variation) or falling, the post-procedure cTn must rise by > 20%. However, the absolute post-procedural value must still be at least five times the 99th percentile URL. In addition, one of the following elements is required:

- New ischaemic ECG changes;
- Development of new pathological Q waves;[a]
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology;
- Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or a side branch occlusion/thrombus, disruption of collateral flow, or distal embolization.[b]

[a]Isolated development of new pathological Q waves meets the type 4a MI criteria if cTn values are elevated and rising but more than five times the 99th percentile URL.
[b]Post-mortem demonstration of a procedure-related thrombus in the culprit artery, or a macroscopically large circumscribed area of necrosis with or without intra-myocardial haemorrhage meets the type 4a MI criteria.

10. STENT/SCAFFOLD THROMBOSIS ASSOCIATED WITH PERCUTANEOUS CORONARY INTERVENTION (TYPE 4B MYOCARDIAL INFARCTION)

A subcategory of PCI-related MI is stent/scaffold thrombosis, type 4b MI, as documented by angiography or autopsy using the same criteria utilized for type 1 MI. It is important to indicate the time of the occurrence of the stent/scaffold thrombosis in relation to the timing of the PCI procedure. The following temporal categories are suggested: acute, 0–24 h; subacute, > 24 h to 30 days; late, > 30 days to 1 year; and very late > 1 year after stent/scaffold implantation.[68]

Circulation. 2018;138:00–00. DOI: 10.1161/CIR.0000000000000617

11. RESTENOSIS ASSOCIATED WITH PERCUTANEOUS CORONARY INTERVENTION (TYPE 4C MYOCARDIAL INFARCTION)

Occasionally MI occurs and—at angiography, in-stent restenosis, or restenosis following balloon angioplasty in the infarct territory—is the only angiographic explanation since no other culprit lesion or thrombus can be identified. This PCI-related MI type is designated as type 4c MI, defined as focal or diffuse restenosis, or a complex lesion associated with a rise and/or fall of cTn values above the 99th percentile URL applying, the same criteria utilized for type 1 MI.

12. MYOCARDIAL INFARCTION ASSOCIATED WITH CORONARY ARTERY BYPASS GRAFTING (TYPE 5 MYOCARDIAL INFARCTION)

Numerous factors can lead to procedural myocardial injury during a CABG procedure. Many of them are related to the details of the cardiac preservation, the extent of the direct traumatic injury to the myocardium, as well as any potential ischaemic injury. For that reason, increases in cTn values should be expected after all CABG procedures,[69,70] which need to be taken into account when comparing the extent of procedural myocardial injury after cardiac surgery with that associated with less invasive approaches. Depending on whether it is off-pump or on-pump surgery, procedural myocardial injury is observed among 32–44% of CABG patients when quantified by LGE-CMR.[61,63] The area under the curve (AUC) and routine cTn sampling has demonstrated an excellent linear relationship with the mass of the new injury as defined by LGE-CMR. AUC for CK-MB is also good, although clearly inferior to cTnI.[69] However, these relationships vary depending on the nature of the procedure, the nature of the cardioplegia, and the specific assay used to measure cTn. Very high cTn values are most often associated with coronary arteryrelated events.[61,63,69] Thus, although cardiac biomarkers and especially cTn appear robust for the detection of procedural myocardial injury and also, in the presence of new myocardial ischaemia, for the detection of type 5 MI, a specific cut-off value for all procedures and all cTn assays is difficult to define. However, in order to ensure consistency with the analogous standards of the preceding definition of type 5 MI[12] and because of the lack of new scientific evidence that identifies superior criteria for defining this MI subtype, it is suggested that a cTn value > 10 times the 99th percentile URL is applied as the cut-off point during the first 48 h following CABG, occurring from a normal baseline cTn value (≤ 99th percentile URL), for diagnosing type 5 MI. It is important that the post-procedural elevation of cTn values is accompanied by ECG, angiographic, or imaging evidence of new myocardial ischaemia/new loss of myocardial viability.[71] The higher cut-off of MI after CABG than after PCI (10 times vs. 5 times the 99th percentile URL) has been arbitrarily selected due to the occurrence of more unavoidable myocardial injury during surgery than during PCI.

It should be recognized that ST-segment deviation and T wave changes are common after CABG due to epicardial injury, and are not reliable indicators of myocardial ischaemia in this setting. However, ST-segment elevation with reciprocal ST-segment depression or other specific ECG patterns may be a more reliable finding of a potential ischaemic event.

Criteria for CABG-Related MI ≤ 48 h After the Index Procedure (Type 5 MI)

CABG-related MI is arbitrarily defined as elevation of cTn values > 10 times the 99th percentile URL in patients with normal baseline cTn values. In patients with elevated pre-procedure cTn in whom cTn levels are stable (≤ 20% variation) or falling, the postprocedure cTn must rise by > 20%. However, the absolute postprocedural value still must be > 10 times the 99th percentile URL. In addition, one of the following elements is required:

- Development of new pathological Q waves;[a]
- Angiographic documented new graft occlusion or new native coronary artery occlusion;
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology.

[a]Isolated development of new pathological Q waves meets the type 5 MI criteria if cTn values are elevated and rising but < 10 times the 99th percentile URL.

Marked isolated elevation of cTn values within the 48 h postoperative period, even in the absence of ECG/angiographic or other imaging evidence of MI, indicates prognostically significant cardiac procedural myocardial injury.[72] The presence of significant procedural myocardial injury in patients with operative problems (e.g. difficulty coming off bypass, technically difficult anastomoses in a heavily calcified aorta, of perioperative evidence of myocardial ischaemia, etc.) should prompt clinical review of the procedure and/or consideration of additional diagnostic testing for possible type 5 MI.

Downloaded from http://ahajournals.org by on August 25, 2018

13. OTHER DEFINITIONS OF MYOCARDIAL INFARCTION RELATED TO PERCUTANEOUS CORONARY INTERVENTION OR CORONARY ARTERY BYPASS GRAFTING

There is no universal consensus on the cTn or hs-cTn cut-off points that clearly distinguish cardiac procedural myocardial injury from MI. The distinction is made on the basis of an injury created by a flowlimiting complication during the procedure that results in sufficient myocardial ischaemia to generate a procedure-related MI. The size of the insult will determine the magnitude of the cTn release. Various groups have used multiples of the 99th percentile URL and set thresholds to diagnose periprocedural MIs for clinical trials.[68,73] Unless a standard assay is used for all analyses, given the heterogeneity of cTn assays, this approach could lead to very different values depending on the assay used locally. The Academic Research Consortium-2 (ARC-2) suggests a post-procedural cTn value ≥ 35 times the 99th percentile URL for both PCI and CABG in patients that have a normal baseline cTn value or in patients with elevated pre-procedure cTn values in whom the cTn levels are stable or falling. ARC-2 proposes that one ancillary criterion be required in addition to the ≥ 35 cTn rise to fulfill the definition of periprocedural MI. The ancillary criteria are one or more of the following: new significant Q waves (or equivalent), flow-limiting angiographic complications in a major epicardial vessel or > 1.5 mm diameter branch, or a substantial new loss of viable myocardium on echocardiography related to the procedure.[68] Furthermore, ARC-2 has defined standalone criteria for significant procedural myocardial injury if the rise in cTn is ≥ 70 times the 99th percentile URL (where the baseline is lower than the URL, elevated and stable, or falling).[68]

14. RECURRENT MYOCARDIAL INFARCTION

Incident MI is defined as the individual's first MI. When features of MI occur in the first 28 days after an incident event, the second event is not counted as a new MI for epidemiological purposes. If characteristics of MI occur after 28 days following an incident MI, it is considered to be a recurrent MI.[11]

15. RE-INFARCTION

The term re-infarction is used clinically for an acute MI that occurs within 28 days of an incident or recurrent MI.[11] The ECG diagnosis of suspected re-infarction following the initial MI may be confounded by the initial evolutionary ECG changes. Re-infarction should be considered when ST-elevation ≥ 1 mm recurs or new pathognomonic Q waves appear in at least two contiguous leads, particularly when associated with ischaemic symptoms. However, re-elevation of the STsegment can also be seen in threatened myocardial rupture or in cases of pericarditis, and should lead to additional diagnostic evaluation.

In patients where re-infarction is suspected from clinical signs or symptoms following the initial MI, an immediate measurement of cTn is recommended. A second sample should be obtained 3–6 h later or earlier with more sensitive cTn assays. If the cTn concentration is elevated, but stable or decreasing at the time of suspected re-infarction, the diagnosis of re-infarction requires a > 20% increase of the cTn value in the second sample.[74] If the initial cTn concentration is normal, the criteria for new acute MI apply.[12]

16. MYOCARDIAL INJURY AND INFARCTION ASSOCIATED WITH CARDIAC PROCEDURES OTHER THAN REVASCULARIZATION

American Heart Association.

Cardiac procedures such as transcatheter valve interventions may cause myocardial injury, both by direct trauma to the myocardium and by creating regional ischaemia secondary to coronary obstruction or embolization. Ablation of arrhythmias involves controlled procedural myocardial injury by application of warming or cooling of the tissue. The extent of procedural myocardial injury can be assessed by serial cTn measurements. Increases of cTn values in this context should be considered as a procedural myocardial injury and not labelled as an MI unless the biomarker criteria and one of the ancillary criteria for acute myocardial ischaemia listed for type 5 MI are present.[75,76]

17. MYOCARDIAL INJURY AND INFARCTION ASSOCIATED WITH NON-CARDIAC PROCEDURES

Perioperative MI is one of the most important complications in major non-cardiac surgery and it is associated with a poor prognosis.[77,78] Most patients who have a perioperative MI will not experience ischaemic symptoms due to anaesthesia, sedation, or pain relieving medications. Nevertheless, asymptomatic perioperative MI is as strongly associated with 30 day mortality as symptomatic MI.[77,78] Knowledge about hs-cTn values at baseline can help to identify patients having chronic cTn elevation before surgery, as well as those at increased risk during and after the procedure.[79,80] Measurement of hs-cTn in post-operative samples reveals

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

Circulation. 2018;138:00–00. DOI: 10.1161/CIR.0000000000000617

that as many as 35% of patients have levels above the 99th percentile URL, and 17% have an elevation and a rising pattern of values indicative of evolving myocardial injury.[81] Those with a rising pattern of elevated hs-cTn values are at particular risk; the greater the rise, the greater the risk.[82,83]

The pathophysiological mechanism of perioperative MI is subject to debate. It is recognized that the perioperative period is characterized by increased cardiac metabolic demand that may lead to MI in patients with otherwise stable CAD.[84,85] Thus, an angiographic investigation has identified demand myocardial ischaemia as the predominant aetiology of perioperative MI,[84,85] which together with a rise and/or fall of cTn values indicates type 2 MI. However, other angiographic studies have detected coronary plaque rupture in 50–60% of patients with perioperative MI,[86,87] which qualifies as type 1 MI. On the other hand, perioperative myocardial injury without ancillary ischaemic evidence indicative of MI is a common complication after non-cardiac surgery that is associated with substantial shortand long-term mortality on a level with perioperative MI.[83]

Post-operative cTn surveillance is recommended for high-risk individuals. In order to properly interpret the aetiology of elevated postoperative values, a baseline pre-operative value is necessary to determine whether the increase is acute or more chronic. However, a diagnosis of MI still requires, in addition to an increase of cTn values, evidence of myocardial ischaemia that may be evident from the periand post-operative period, e.g. ST-segment changes on telemetry/ECG, repeated episodes of hypoxia, hypotension, tachycardia, or imaging evidence of MI. In the absence of evidence for acute myocardial ischaemia, a diagnosis of acute myocardial injury is more appropriate. Ongoing research suggests the possibility that interventions may be helpful in this clinical situation.

18. MYOCARDIAL INJURY OR INFARCTION ASSOCIATED WITH HEART FAILURE

Depending on the assay used, detectable to clearly elevated cTn values being indicative of myocardial injury may be seen in patients with heart failure (HF), both with reduced ejection fraction (EF) and with preserved EF.[88] Using hs-cTn assays, measurable hs-cTn concentrations may be present in nearly all patients with HF, with a significant percentage exceeding the 99th percentile URL, particularly in those patients with more severe HF syndromes, such as in acutely decompensated HF.[87]

Beyond type 1 MI, multiple mechanisms have been proposed to explain measurable to pathologically elevated cTn concentrations in patients with HF.[88,89] For example, type 2 MI may result from increased transmural pressure, small-vessel coronary obstruction, endothelial dysfunction, anaemia, or hypotension. Besides type 1 MI or type 2 MI, cardiomyocyte apoptosis and autophagy due to wall stretch have been experimentally demonstrated. Direct cellular toxicity related to inflammation, circulating neurohormones, and infiltrative processes may present with HF and abnormal cTn measurements indicating myocardial injury. Finally, exocytosis of the early releasable cytosolic troponin pool into the blood stream from stressed cardiomyocytes has also been suggested as a cause of elevated cTn values.[89]

In the context of an acutely decompensated HF presentation, cTn should always be promptly measured and the ECG recorded, with the goal of identifying or excluding myocardial ischaemia as the precipitant. In this setting, elevated cTn values should be interpreted with a high level of suspicion for type 1 MI if a significant rise and/or fall of the marker is seen, especially if it is accompanied by chest discomfort or other symptoms suggestive of myocardial ischaemia, and/ or if new ischaemic ECG changes or loss of myocardial function on non-invasive testing are found. Shortness of breath, the cardinal symptom of acutely decompensated HF, may be an ischaemic equivalent, but in the absence of corroborating evidence for a coronary mechanism, caution is advised in its interpretation. Coronary artery anatomy may be known and this knowledge may be used to interpret abnormal cTn results. However, further information—such as renal function, myocardial perfusion studies, coronary angiography, or CMR—is often required to better understand the cause of deviant cTn values.

19. TAKOTSUBO SYNDROME

Takotsubo syndrome (TTS) can mimic MI and is found in 1–2% of patients presenting with suspected STEMI.[90] The onset of TTS is often triggered by intense emotional or physical stresses, such as bereavement. Over 90% of patients are post-menopausal women. Cardiovascular complications occur in 50% of patients presenting with TTS, and the inpatient mortality is similar to STEMI (4–5%) due to cardiogenic shock, ventricular rupture, or malignant arrhythmias.[90] TTS usually presents similar to ACS. ST-segment elevation is frequent (44%), but the extent of the ST-segment elevation is usually widespread across the lateral and precordial leads, beyond that of a single coronary artery distribution. ST-segment depression occurs in < 10% of patients and after 12–24 h, deep, symmetric T wave inversion and QTc prolongation are typically observed.[91,92]

There are usually transient elevations in cTn levels (> 95% of cases), but the peak cTn values observed are modest, and contrast with the large territory of ECG changes or left ventricular (LV) dysfunction. The rise

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

and fall in cTn levels support an acute myocardial injury, secondary to the high catecholamine surges that are known to trigger cTn release from cardiomyocytes. Coronary vasospasm, high myocardial strain hypercontractility, or high ventricular afterload may also contribute to myocardial ischaemia. The diagnosis of TTS should be suspected when the clinical manifestations and ECG abnormalities are out of proportion to the degree of elevation of cTn values, and when the distribution of the LV wall motion abnormalities does not correlate with a single coronary artery distribution. However, coronary angiography and ventriculography are often needed to secure the diagnosis.

In most cases, the coronary arteries are angiographically normal, and where CAD is present (15% cases) it is not sufficient to explain the observed pattern of regional wall motion abnormalities. Left ventriculography during catheterization and/or echocardiography may show a variety of LV regional wall motion abnormalities including apical (82% of patients), mid-ventricular (14.6%), basal (2.2%), or focal (1.5%) akinesis or hypokinesis in a circumferential pattern involving more than one coronary artery territory. Evidence of myocardial oedema is often seen on CMR imaging during the acute phase but LGE is usually absent. The recovery time for LV function varies from hours to several weeks.[93] Cardiac function may not return to normal, with persisting abnormalities of diastolic function, myocardial reserve during exercise, or rhythm disturbances at long-term follow-up in 10–15% of patients. In the absence of recovery of regional wall motion abnormalities, LGE-CMR is recommended to exclude MI with spontaneous recanalization.

The distinction between MI and TTS can be challenging, particularly when concurrent CAD is present (15% in the International Takotsubo Registry).[91] Two additional features that are helpful in distinguishing TTS from acute MI are QTc prolongation > 500 ms during the acute phase and the recovery of LV function over 2–4 weeks. There are rare cases described where MI and TTS coexist, e.g. MI-induced TTS or TTS with secondary plaque rupture, but this occurs where the acute regional wall motion abnormalities are more extensive than the culprit coronary artery territory, and fulfil the pattern and definition of TTS.[94]

20. MYOCARDIAL INFARCTION WITH NON-OBSTRUCTIVE CORONARY ARTERIES

It is increasingly recognized that there is a group of MI patients with no angiographic obstructive CAD (≥ 50% diameter stenosis in a major epicardial vessel), and the term myocardial infarction with nonobstructive coronary arteries (MINOCA) has been coined for this entity.[95,96] The diagnosis of MINOCA, like the diagnosis of MI, indicates that there is an ischaemic mechanism responsible for the myocyte injury (i.e. non-ischaemic causes such as myocarditis have been excluded). Furthermore, the diagnosis of MINOCA necessitates that obstructive CAD has not been inadvertently overlooked (e.g. spontaneous coronary artery dissection). The prevalence of MINOCA is estimated to be 6–8% among patients diagnosed with MI and more common in women than men, as well as in patients presenting with NSTEMI compared with those presenting with STEMI.[96–98] Atherosclerotic plaque disruption and coronary thrombosis may be a cause of MINOCA, i.e. type 1 MI. However, coronary spasm and spontaneous coronary dissection may be involved as well, i.e. type 2 MI, along with other possible causes. Additional coronary imaging and functional testing methods may be useful to elucidate the mechanisms of ischaemia in MINOCA.[46]

21. MYOCARDIAL INJURY AND/OR INFARCTION ASSOCIATED WITH KIDNEY DISEASE

Many patients with chronic kidney disease (CKD) have elevation of cTn values.[99,100] With hs-cTn assays, the majority of patients with end-stage renal disease will have elevation of hs-cTn values above the 99th percentile URL.[99,101] This is particularly the case for hs-cTnT, which is more often elevated compared with hs-cTnI.[99,102] It has been shown using hs-cTn assays that renal dysfunction is commonly associated with cardiovascular abnormalities.[102–104] In autopsy studies, elevation of cTn values was invariably associated with evidence of myocardial injury.[15] Recently, a minor effect on renal clearance of cTn has been shown when levels are low, but not in response to acute episodes of myocardial injury.[105] The mechanisms include increased ventricular pressure, small-vessel coronary obstruction, anaemia, hypotension, and possibly direct toxic effects on the myocardium associated with the uraemic state.[89] Cardiomyocyte apoptosis and autophagy due to acute wall stretch have been demonstrated experimentally.[18] Thus, baseline elevation of cTn values is common, and because they reflect myocardial injury, such elevation is highly prognostic over time.[99]

Diagnosing MI in patients with CKD and elevated cTn levels may be difficult if symptoms or ECG changes indicating myocardial ischaemia are absent. However, studies suggest that serial changes in cTn levels are equally effective in diagnosing MI in patients with CKD and in those with normal renal function.[106] If the level of elevated cTn values is unchanging, and the timing of the event makes a rising and/or falling pattern unlikely, the elevated level, even if substantial, is likely a reflection of chronic myocardial injury. This does not imply

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation American Heart Association

that these patients are free of CAD, since renal dysfunction and CAD are correlated. However, if a rising and/or falling pattern is present then the aetiology of the abnormal cTn values could be acute volume overload, congestive HF, or MI. If a rising and falling pattern is seen, and it is accompanied by ischaemic symptoms, new ischaemic ECG changes, or loss of viable myocardium on imaging, a diagnosis of acute MI is likely. There are no data to suggest that different criteria for the cTn decision levels are needed for these patients. At times, additional imaging studies may be necessary to determine the appropriate diagnosis. It should be noted that if CKD patients present late after the onset of chest pain, it may be difficult to observe a rise and/or fall of cTn values in the short-term, particularly when the baseline value is elevated. Such a situation should not obviate the diagnosis of MI when the clinical evidence is strong.

22. MYOCARDIAL INJURY AND/OR INFARCTION IN CRITICALLY ILL PATIENTS

Elevations of cTn values are common in patients in the intensive care unit and are associated with adverse prognosis regardless of the underlying disease state.[107,108] Some elevation of cTn values may reflect type 2 MI due to underlying CAD and increased myocardial oxygen demand,[109] whereas in other patients, type 1 MI may occur because of plaque disruption leading to thrombosis in a coronary artery. However, other patients may have elevated cTn values and marked decreases in EF due to sepsis caused by endotoxin, with myocardial function recovering completely with normal EF once the sepsis is treated. It is frequently challenging for the clinician caring for a critically ill patient with a severe single organ or multiorgan pathological condition to decide on a plan of action when the patient has elevated cTn values. If and when the patient recovers from the critical illness, clinical judgement should be employed to decide whether, and to what extent, further evaluation for CAD or structural heart disease is indicated.[110]

23. BIOCHEMICAL APPROACH FOR DIAGNOSING MYOCARDIAL INJURY AND INFARCTION

cTnI and cTnT are the preferred biomarkers recommended to both rule in and rule out myocardial injury, and thus to define MI and each specific subtype of MI.[12,22,23,31] Detection of a rise and/or fall of cTn values is essential, and a key early component along with other elements of the clinical evaluation to establish the diagnosis of acute MI. Criteria for determining a pathological rise between two serial cTn values are assay-dependent and continue to evolve. An idealized view of troponin kinetics in patients with acute MI is shown in *Figure 7*.

Circulation

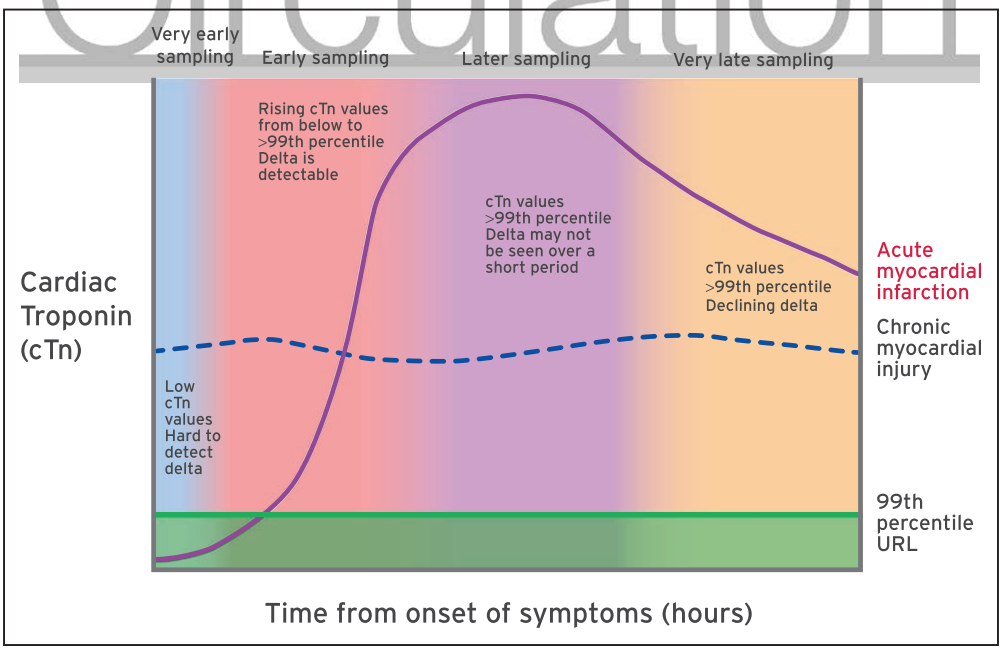

Figure 7. Illustration of early cardiac troponin kinetics in patients after acute myocardial injury including acute myocardial infarction.
The timing of biomarker release into the circulation is dependent on blood flow and how soon after the onset of symptoms samples are obtained. Thus, the ability to consider small changes as diagnostic can be problematic. In addition, many comorbidities increase cTn values and, in particular, hs-cTn values, so that elevations can be present at baseline even in those with myocardial infarction who present early after the onset of symptoms. Changes in cTn values or deltas can be used to define acute compared with chronic events, and the ability to detect these is indicated in the figure. Increased cTn values can often be detected for days after an acute event. cTn = cardiac troponin; URL = upper reference limit.

Downloaded from http://ahajournals.org by on August 25, 2018

It should be appreciated that because biomarker release is substantially dependent on blood flow,[111,112] there is significant variability in the time to peak value (velocity), the time when a normal value may become greater than the 99th percentile URL, or when a changing pattern of values can be observed. The ability to define a changing pattern will also depend on timing. For example, around peak values, it may be difficult to observe a changing pattern of values. Similarly, the downslope of the time–concentration curve is much slower than the upslope. These issues need to be taken into account when defining whether or not a changing pattern is present. In addition, it is important to make sure that a given change is greater than can be anticipated by variability alone. This is defined for conventional cTn assays as a change greater than or equal to three times the standard deviation around the measurement of the individual assay at relevant values.[12,22] For hs-cTn assays, biological variation also needs to be considered. In most studies, conjoint analytical and biological variation is in the range of 50–60%.

For that reason, this percentage has been suggested for use when initial baseline values are ≤ the 99th percentile URL.[23,31,113] However, for individuals with an initial value greater than the 99th percentile URL, a lesser degree of change during serial measurements is necessary to achieve improved clinical sensitivity (as compared with individuals with initial values ≤ the 99th percentile URL). Thus, an expert consensus group has recommended serial changes > 20% be used in this situation.[22] Absolute changes are assay dependent but appear superior to relative per cent changes with hs-cTn assays,[114] and in some studies this is especially the case when the initial value is increased.[115] The use of a fixed absolute value change criteria translates into a smaller percentage or relative change as absolute values rise, and therefore provides greater sensitivity. The use of a changing pattern is important in allowing clinicians to differentiate an acute from a chronic cTn increase above the 99th percentile URL.[113–115] Using criteria less than conjoint analytical and biological variation will reduce the clinical specificity of hs-cTn assays.[113,116] An imprecision of ≤ 10% coefficient of variation (CV) at the 99th percentile URL is also mandatory for hs-cTn assays.[31] The use of non-hs-cTn assays that do not have imprecision (≤ 10% CV at the 99th percentile URL) makes the determination of a significant serial change more difficult but does not cause false positive results. Assays with CVs between 10–20% are acceptable for clinical use. However, assays with CVs>20% at the 99th percentile URL should not be used.[117]

If a cTn assay is not available, the best alternative is CK-MB measured by a mass assay. As with cTn, an increased CK-MB value is defined as a measurement above the 99th percentile URL, which is designated as the decision level for the diagnosis of MI. Sex-specific CK-MB values should be employed.[118]

24. ANALYTICAL ISSUES OF CARDIAC TROPONINS

The analytical sensitivity [limit of detection (LoD)] of cTnI and cTnT assays varies 10-fold.[31,119] Because assays are not standardized, values from one assay cannot be directly compared with those from another assay. Furthermore, values may be different between assay generations[120] and changes can even occur when the same assay reagents are measured on different instruments.[121] Thus, clinicians must learn about their local assay and should look for reliable information, e.g. available on the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) website (http://www.ifcc.org/executive-board-and-council/eb-task-forces/task-force-on-clinical-applications-of-cardiac-bio-markers-tf-cb/), when they have questions concerning analytical issues. The current guidelines accommodate all assays, whether hs-cTn, contemporary (conventional) cTn, or point of care (POC) cTn. While hs-cTn assays are able to measure relatively low values and document small increases above the 99th percentile URL, many contemporary and POC cTn assays may not detect small increasing values within the reference interval or slightly above the 99th percentile URL, leading to substantial differences in the frequency of events based solely on the cTn assay used. These differences are amplified when multiples of the 99th percentile URL are used. At present, IFCC guidelines support the concept that hs-cTn assays are differentiated from contemporary or POC cTn assays by their ability to measure cTn values above the assay's LoD in > 50% of healthy individuals.[31,118,119,122] This provides a rough estimate of assay sensitivity. It is recommended that values for cTn assays be reported as whole numbers in nanograms per litre to avoid interpretation problems associated with multiple zeros and decimal points that can often result in confusion.[31] Clinicians should avoid mixing the units from contemporary assays with those from hs-cTn assays. All assays, including cTn assays, have some analytical problems resulting in false positive and false negative results, but these are uncommon (< 0.5%).[22] These problems are less common with hs-cTn assays.[23]

Conjoint biological and analytical variation of hs-cTn assays is in the range of 50–60%.[123] When values are elevated, analytical variation is less and a value of 20% can be used to determine that values are stable in the proper clinical context. For example, changes may be difficult to observe over short periods of time in those who present early after the onset of symptoms of acute MI, those who present late and are on the downslope of the time-concentration curve, and those who have

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

values near peak where they may be transitioning from a rising to a falling pattern.[113,123]

25. THE 99TH PERCENTILE UPPER REFERENCE LIMIT

The 99th percentile URL is designated as the decision level for the presence of myocardial injury and must be determined for each specific assay with quality control materials used at the URL to validate appropriate assay imprecision. The cTn assay 99th percentile URL values used in clinical practice and research can be found both in manufacturers' package inserts, in peer-reviewed publications, and on the IFCC website.[118–120] Clinicians should be aware that for all cTn assays, including hs-cTn assays, there is still no expert opinion or consensus about specific criteria for how the 99th percentile URL should be defined.[124] We endorse IFCC guidelines on the technical issues related to hs-cTn assays, including how studies should be configured to determine 99th percentile URLs.[120] The guidelines include the clinical or surrogate biomarker screening that may be needed to better define the 99th percentile URL and the statistical methods that can be applied, but do not include a requirement for cardiac imaging.[120] Screening of apparently healthy subjects with imaging has been shown to lower the observed 99th percentile URL value, but is not a practical standard for the *in vitro* diagnostic industry to use.[124,125] Thus, there is the possibility of false negative values using the manufacturer's reported 99th percentile URL values. hs-cTn assays demonstrate shifts to higher values for the 99th percentile URL in association with comorbidities and age over > 60 years.[101,125–127] However, at present, age-dependent cut-off points are not recommended for clinical use. Clinicians should rely instead on changing values during serial measurements of cTn for the diagnosis of acute myocardial injury, including MI. Significantly lower values are observed among women compared with men, and therefore sex-specific 99th percentile URLs are recommended for hs-cTn assays.[31,118–120] For some hs-cTn assays, sex-specific cut-off values have been reported to improve diagnostic and prognostic information in patients with possible acute MI.[128,129] However, there is controversy as to whether this approach provides valuable additional information for all hs-cTn assays.[130]

26. OPERATIONALIZING CRITERIA FOR MYOCARDIAL INJURY AND INFARCTION

Blood samples for the measurement of cTn should be drawn on first assessment (designated as 0 h) and repeated 3–6 h later, or earlier with hs-cTn assays. The sampling interval will impact the clinical cut-off at baseline and what is determined to be a pathological rise and/or fall of the biomarker. Sampling beyond 6 h may be required if further ischaemic episodes occur, or in high-risk patients. To establish the diagnosis of an acute MI, a rise and/or fall in cTn values with at least one value above the 99th percentile URL is required, coupled with a high clinical and/or ECG likelihood of myocardial ischaemia. hs-cTn assays shorten the time to diagnosis in many patients to within 3 h of onset of symptoms, but there are still some patients who may rule in late (at 6 h).[131] Furthermore, some patients with acute myocardial injury presenting late after the onset of acute MI (> 12–18 h) and who are on the downslope of the time-concentration curve may require longer periods of time for a changing pattern to be detected.[131] In addition, it should be noted that with the implementation of cTn and hs-cTn assays, the frequency of unstable angina will decrease and the diagnosis of NSTEMI will increase.[132,133] The magnitude of these changes using hs-cTn assays have been reported in the range of 18–30%.[134] Assuming proper timing of symptoms, acute ischaemia should result in a change in hs-cTn; however, there may be patients in whom it is difficult to ascertain the timing of symptom onset. Thus, despite typical chest discomfort, these patients may have hs-cTn values that are not elevated. Other patients with symptoms suggestive of unstable angina may have increased hs-cTn values as a result of structural heart disease with or without acute myocardial ischaemia. This latter group may be particularly difficult to distinguish from patients presenting with late NSTEMI with a slow decline in troponin values that can be observed in late presenters.[131] Finally, some patients may manifest a changing pattern of troponin values with a magnitude that does not exceed the delta suggested for diagnosis or who fail to manifest a value greater than the 99th percentile URL. This is a group of patients that deserves close scrutiny because they may be at high risk. The triage of these patients can only be accomplished based on clinical evaluation.

Strategies employing either very low levels of hs-cTn on presentation or the lack of any change and persistently normal hs-cTn values over a 1–2 h period after presentation have been advocated to exclude acute myocardial injury, and MI as well. A single sample rule out strategy using a very low value (in many cases the LoD of the assay) has high sensitivity for myocardial injury and therefore high negative predictive value to exclude MI.[135] This strategy should not be used in those who present early, i.e. < 2 h after the onset of chest discomfort. Some studies indicate that the single sample approach provides optimal sensitivity and negative predictive accuracy in patients otherwise at low risk and those with a normal ECG.[136–138] However, one concern about very short rule out periods is that

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

the precision of the assays may not permit small differences to be distinguished.[139–142] These criteria have not, and should not, be applied to patients with hs-cTn elevations.

The clinical specificity and positive predictive value of such 1–2 h sampling approaches for ruling in MI are limited by the substantial proportion of individuals who meet the proposed biomarker criteria with diagnoses other than MI.[136,141] Thus, the use of a rapid rule in/ out MI protocol does not absolve the clinician from considering other causes of acute myocardial injury.[142] In addition, considering a broader population of patients—inclusive of those who present atypically, those with end-stage renal disease, and the critically ill—the cut-off points to be used will likely need to be altered.[139] Such patients have been excluded from the majority of emergency department evaluation studies.[108,136,142]

The demonstration of a rising and/or falling pattern is needed to distinguish acute injury from chronic conditions associated with structural heart disease that can have chronic increases of cTn values. For example, patients with renal failure[99,143,144] or LV hypertrophy[145] can have significant chronic increases in cTn values. These increases can be marked but do not change acutely during serial sampling. However, a falling pattern may take longer to be observed in patients with a high pre-test risk of MI who present late after symptom onset.[146] These patients who have cTn values on the downslope of the time–concentration curve have a slow decline in values (*Figure 7*). Thus, detecting a changing pattern over short periods of time may be difficult.[117] Depending on the extent of myocardial injury, cTn values may remain above the 99th percentile URL for a longer period of time.[22,23] An increased cTn value above the 99th percentile URL, with or without a dynamic change of values, or in the absence of clinical evidence of ischaemia, should prompt a search for other diagnoses associated with myocardial injury, as shown in *Table 1*.

27. ELECTROCARDIOGRAPHIC DETECTION OF MYOCARDIAL INFARCTION

The ECG is an integral part of the diagnostic workup of patients with suspected MI, and should be acquired and interpreted promptly (i.e. target within 10 min) after first medical contact.[47,147] Pre-hospital ECGs reduce the time to diagnosis and treatment, and can facilitate the triage of STEMI patients to hospitals with PCI capability if within the recommended time interval (120 min from STEMI diagnosis).[46,148] Acute myocardial ischaemia is often associated with dynamic changes in ECG waveform and serial ECG acquisition can provide critical information, particularly if the ECG at initial presentation is non-diagnostic. Recording several standard ECGs with fixed electrode positions at 15–30 min intervals for the initial 1–2 h, or the use of continuous computer-assisted 12-lead ECG recording (if available) to detect dynamic ECG changes, is reasonable for patients with persistent or recurrent symptoms or an initial non-diagnostic ECG.[149] Serial or continuous ECG recordings may be helpful in determining reperfusion or reocclusion status. Reperfusion is usually associated with a large and prompt reduction in ST-segment elevation.

More profound ST-segment shifts or T wave inversions involving multiple leads/territories are associated with a greater degree of myocardial ischaemia, and a worse prognosis. For example, ST-segment depression ≥ 1 mm in six leads, which may be associated with ST-segment elevation in leads aVR or lead V_1 and haemodynamic compromise, is suggestive evidence of multivessel disease or left main disease. Pathologic Q waves increase the prognostic risk. Other ECG signs associated with acute myocardial ischaemia include cardiac arrhythmias, intraventricular bundle branch blocks, atrioventricular conduction delays, and loss of precordial R wave amplitude, a less specific finding. The ECG by itself is often insufficient to diagnose acute myocardial ischaemia or infarction, since ST deviation may be observed in other conditions, such as acute pericarditis, LV hypertrophy (LVH), left bundle branch block (LBBB), Brugada syndrome, TTS, and early repolarization patterns.[150] A prior ECG is often helpful in distinguishing a new from a chronic finding, but should not delay the decision for treatment.

Prolonged new convex ST-segment elevation, particularly when associated with reciprocal ST-segment depression, usually reflects acute coronary occlusion and results in myocardial injury with necrosis. Reciprocal changes can help to differentiate STEMI from pericarditis or early repolarization changes. As in cardiomyopathy, Q waves may also occur due to myocardial fibrosis in the absence of CAD. Some of the earlier manifestations of myocardial ischaemia are typical T wave and ST-segment changes. Increased hyperacute T wave amplitude, with prominent symmetrical T waves in at least two contiguous leads, is an early sign that may precede the elevation of the ST-segment. In general, the development of new Q waves indicates myocardial necrosis, which starts minutes/hours after the myocardial insult. Transient Q waves may be observed during an episode of acute ischaemia or (rarely) during acute MI with successful reperfusion. *Table 2* lists ST-segment–T wave (ST-T) criteria suggestive of acute myocardial ischaemia that may or may not lead to MI. The J-point (junction between QRS termination and ST-segment onset) is used to determine the magnitude of the ST-segment shift with the onset of the QRS serving as the reference point. In patients with a stable baseline, the TP segment (isoelectric interval) is a more accurate method to assess

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

the magnitude of ST-segment shift, and in distinguishing pericarditis (PTa depression) from acute myocardial ischaemia. Tachycardia and baseline shift are common in the acute setting and can make this determination difficult. Therefore, QRS onset is recommended as the reference point for J-point determina-tion (*Figure 8*).

New, or presumed new, J-point elevation ≥ 1 mm (1 mm = 0.1 mV) is required in all leads other than V_2 and V_3 as an ischaemic response. In healthy men under age 40, J-point elevation can be as much as 2.5 mm in leads V_2 or V_3, but it decreases with increasing age. Sex differences require different cut-off points for women, since J-point elevation in healthy women in leads V_2 and V_3 is less than in men.[5] The criteria in *Table 2* require that the ST shift be present in two or more contiguous leads. For example, ≥ 2 mm of ST-elevation in lead V_2 and ≥ 1 mm in lead V_1 would meet the criteria of two abnormal contiguous leads in a man ≥40 years old. However, ≥ 1mm and < 2 mm of ST-elevation, seen only in leads V_2–V_3 in men (or < 1.5 mm in women), may represent a normal finding.

It should be noted that lesser degrees of ST displacement or T wave inversion than those described in *Table 2* can also represent anacute myocardial ischaemic response. In patients with known or high likelihood of CAD, the clinical presentation is critical to enhance the specificity of these findings.

Absence of ST-elevation in the precordial leads, tall, prominent, symmetrical T waves in the precordial leads, upsloping ST-segment depression > 1 mm at the J-point in the precordial leads, and in most cases ST-segment elevation (> 1 mm) in lead aVR or the symmetrical, often deep (> 2 mm), T wave inversions in the anterior precordial leads are associated with significant left anterior descending artery (LAD) occlusion.[151–153] ST-elevation in lead aVR > 1 mm may accompany anterior or inferior STEMI, and is associated with increased 30 day mortality in patients with acute MI.[154] Pulmonary embolism, intracranial processes, electrolyte abnormalities, hypothermia, or perimyocarditis may also result in ST-T abnormalities and should be considered in the differential diagnosis.

The ECG diagnosis of atrial infarction should be suspected in the context of ventricular infarction (particularly when the right ventricle is involved) if small, transient elevations and reciprocal depressions of the PR (PTa) segment are noted associated with changes in configuration of the P wave.

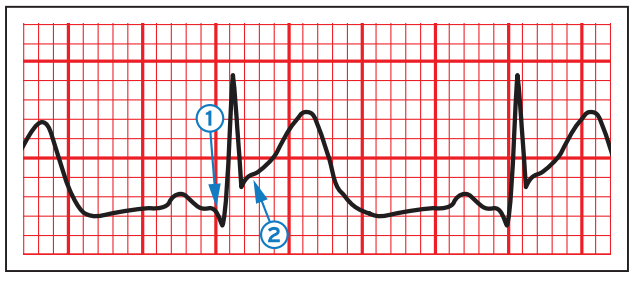

Figure 8. Electrocardiogram example of ST-segment elevation.
The initial onset of the Q wave shown by arrow 1 serves as the reference point and arrow 2 shows the onset of the ST-segment or J-point. The difference between the two identifies the magnitude of displacement. Measurements of both arrows should be made from the top of the electrocardiogram line tracing.

Table 2. Electrocardiographic Manifestations Suggestive of Acute Myocardial Ischaemia (In the Absence of Left Ventricular Hypertrophy and Bundle Branch Block)

ST-elevation
New ST-elevation at the J-point in two contiguous leads with the cut-point: ≥ 1 mm in all leads other than leads V_2–V_3 where the following cut-points apply: ≥ 2 mm in men ≥ 40 years; ≥ 2.5 mm in men < 40 years, or ≥ 1.5 mm in women regardless of age.[a]
ST-depression and T wave changes
New horizontal or downsloping ST-depression ≥ 0.5 mm in two contiguous leads and/or T inversion > 1 mm in two contiguous leads with prominent R wave or R/S ratio > 1.

[a]When the magnitudes of J-point elevation in leads V_2 and V_3 are registered from a prior electrocardiogram, new J-point elevation ≥ 1 mm (as compared with the earlier electrocardiogram) should be considered an ischaemic response. For bundle branch block, see section below.

28. APPLICATION OF SUPPLEMENTAL ELECTROCARDIOGRAM LEADS

Supplemental leads, as well as serial ECG recordings, should be deployed with a very low threshold in patients who present with ischaemic chest pain and a non-diagnostic initial ECG.[155,156] ECG evidence of myocardial ischaemia in the distribution of a left circumflex artery is often overlooked. Isolated ST-segment depression ≥ 0.5 mm in leads V_1–V_3 may indicate left circumflex occlusion and can best be captured using posterior leads at the fifth intercostal space (V_7 at the left posterior axillary line, V_8 at the left mid-scapular line, and V_9 at the left paraspinal border). Recording of these leads is strongly recommended in patients with high clinical suspicion of acute circumflex occlusion (e.g. initial ECG non-diagnostic or ST-segment depression in leads V_1–V_3).[156] A cut-off point of 0.5 mm ST elevation is recommended in leads V_7–V_9; specificity is increased at a cut-off point ≥ 1 mm ST-elevation and this cut-off point should be used in men < 40 years old. ST-segment depression in leads V_1–V_3 may be suggestive of inferobasal myocardial ischaemia (previously termed posterior infarction), especially when the terminal T wave is positive (ST-elevation equivalent); however, this is non-specific.

In patients with inferior and suspected right ventricular infarction, leads aVR or V_1 may exhibit ST-segment elevation ≥1 mm. The early recording of right precordial leads V_3R and V_4R should be performed, since ST-elevation ≥ 0.5 mm (≥ 1 mm in men < 30 years old) provides supportive criteria for the diagnosis.[157] Changes in right

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

precordial leads may be transient, and an absence of ECG changes in leads V_3R and V_4R does not exclude right ventricular infarction. Myocardial imaging can be helpful in this clinical setting.

29. ELECTROCARDIOGRAPHIC DETECTION OF MYOCARDIAL INJURY

It is not possible to initially distinguish ECG manifestations of acute or chronic myocardial injury from acute myocardial ischaemia. Rapidly developing dynamic ECG changes that temporally match the clinical presentation may be helpful in diagnosing a symptomatic patient with elevated cTn values as having acute myocardial ischaemia resulting in MI. However, ECG abnormalities are also common in patients who have myocardial injury, e.g. myocarditis or TTS.[158–160]

30. PRIOR OR SILENT/UNRECOGNIZED MYOCARDIAL INFARCTION

Q wave criteria associated with MI and an increased relative risk of death are illustrated in *Table 3*, and are contained in Q wave coding algorithms such as the Minnesota Code and the WHO MONItoring of trends and determinants in CArdiovascular disease (MONICA) code[11,161,162]

The specificity of the ECG diagnosis for MI is greatest when Q waves occur in several leads or lead groupings, or are > 0.04 s. When the Q waves are associated with ST deviations or T wave changes in the same leads, the likelihood of MI is increased; for example, minor Q waves ≥ 0.02 s and < 0.03 s that are ≥ 1 mm deep are suggestive of prior MI if accompanied by inverted T waves in the same lead group. Non-invasive imaging techniques also provide important supportive evidence of prior MI. In the absence of non-ischaemic causes, regional myocardial thinning, scar or reduced wall motion shown by echocardiography, myocardial perfusion scintigraphy (MPS) with single photon emission computed tomography (SPECT) or positron emission tomography (PET), or magnetic resonance imaging provide strong evidence for prior MI, particularly when ECG criteria are equivocal.

Table 3. Electrocardiographic Changes Associated With Prior Myocardial Infarction (In the Absence of Left Ventricular Hypertrophy and Left Bundle Branch Block)

Any Q wave in leads V_2–V_3 > 0 .02 s or QS complex in leads V_2–V_3.
Q wave ≥ 0 .03 s and ≥ 1 mm deep or QS complex in leads I, II, aVL, aVF or V_4–V_6 in any two leads of a contiguous lead grouping (I, aVL; V_1–V_6; II, III, aVF).[a]
R wave > 0 .04 s in V_1–V_2 and R/S > 1 with a concordant positive T wave in absence of conduction defect.

[a]The same criteria are used for supplemental leads V_7–V_9. s = seconds.

Asymptomatic patients who develop new Q wave criteria for MI detected during routine ECG follow-up, or reveal evidence of MI by cardiac imaging that cannot be directly attributed to an interim coronary revascularization procedure or an ACS admission, should be termed 'silent or unrecognized MI'. In studies where serial ECG analysis was applied, silent or unrecognized Q wave MI accounted for 9–37% of all non-fatal MI events and was associated with a significantly increased mortality risk.[163,164] Improper lead placement, QRS abnormalities, or technical errors (e.g. lead reversal) may result in the appearance of new Q waves or QS complexes, as compared with a prior tracing. Thus, the diagnosis of a new silent Q wave MI should be confirmed by a repeat ECG recording with correct lead placement, focused questioning about potential interim ischaemic symptoms, or by an imaging study. Imaging techniques are useful if there is abnormal myocardial motion, thickening, or thinning in the region of interest, but the absence of these does not exclude MI.[165]

Criteria for Prior or Silent/Unrecognized MI

Any one of the following criteria meets the diagnosis for prior or silent/unrecognized MI:

- Pathological Q waves as described in *Table 3*, with or without symptoms, in the absence of non-ischaemic causes;
- Imaging evidence of loss of viable myocardium in a pattern consistent with ischaemic aetiology;
- Pathological findings of a prior MI.

31. CONDITIONS THAT CONFOUND THE ELECTROCARDIOGRAPHIC DIAGNOSIS OF MYOCARDIAL INFARCTION

A QS complex in lead V_1 is normal. A Q wave < 0.03 s and < 0.25 of the R wave amplitude in lead III is normal if the frontal QRS axis is between –30° and 0°. A Q wave may also be normal in aVL if the frontal QRS axis is between 60–90°. Septal Q waves are small, nonpathological Q waves < 0.03 s and < 0.25 of the R-wave amplitude in leads I, aVL, aVF, and V_4–V_6. Preexcitation, cardiomyopathy, TTS, cardiac amyloidosis, LBBB, left anterior hemiblock, LVH, right ventricular hypertrophy, myocarditis, acute cor pulmonale, or hyperkalaemia may be associated with Q waves or QS complexes in the absence of MI. Clinicians should be aware of confounders to the ECG diagnosis of myocardial ischaemia, since ST-T wave abnormalities are commonly observed with different pathological cardi-

Downloaded from http://ahajournals.org by on August 25, 2018

ac conditions, such as pre-excitation, pericarditis, and cardiomyopathy.

32. CONDUCTION DISTURBANCES AND PACEMAKERS

The diagnosis of MI is more difficult in the presence of conduction disturbances, related in part to ST-T wave changes caused by the conduction disturbance and the fact that the conduction disturbance itself may be heart-rate dependent.[166,167] Comparison to a preadmission ECG may be helpful in determining if the conduction defect or ST-T wave changes are new, as long as it does not delay time to treatment. Ischaemic symptoms, and presumed new LBBB or right bundle branch block (RBBB) that is not rate-related, are associated with an adverse prognosis. In patients with LBBB, ST-segment elevation ≥ 1 mm concordant with the QRS complex in any lead may be an indicator of acute myocardial ischaemia. Similar findings can be useful in detecting ECG evidence for acute myocardial ischaemia in patients with right ventricular paced rhythms.[167] Recording an ECG trace with the pacemaker temporarily switched off may also be useful in patients who are not pacemaker dependent, but careful interpretation of repolarization is needed due to the possible presence of stimulation-induced changes (electrical memory). The ECG diagnosis of acute myocardial ischaemia in patients with biventricular pacing is more difficult. In patients with RBBB, new or presumed new STsegment elevation ≥ 1 mm, or ST-segment or T wave abnormalities (excluding leads V_1–V_4) (*Table 2*), may indicate acute myocardial ischaemia. New, or presumed new, RBBB without associated STsegment or T wave changes is associated with thrombolysis in myocardial infarction (TIMI) 0–2 flow in as many as 66% of patients (compared with > 90% in those with ST-segment or T wave changes).[168]

33. ATRIAL FIBRILLATION

In patients with atrial fibrillation and rapid ventricular rate or paroxysmal supraventricular tachycardia, ST-segment depression or T wave inversion may occur in the absence of CAD.[169,170] The causes are not completely understood. Cardiac memory, an electrical remodelling phenomenon characterized by marked diffuse T wave inversions following periods of abnormal ventricular activation, which may also be caused by transient rate-related conduction disturbances or pacing, may explain these findings. In some patients, the tachycardia may result in an insufficient increase in coronary flow to match myocardial oxygen demand, resulting in cellular hypoxia and abnormal repolarization.[171,172] For these reasons, a patient with new-onset atrial fibrillation, elevated baseline cTn concentration, and new ST-segment depression should not automatically be classified as type 2 MI without additional information. In this clinical setting, signs of overt ischaemic symptoms, the timing of symptoms relative to atrial fibrillation onset, a changing pattern of cTn, and imaging and/or angiographic findings may be helpful in establishing the diagnosis. However, in the absence of evidence for myocardial ischaemia, the aetiology of the elevated cTn values should be attributed to myocardial injury.

34. IMAGING TECHNIQUES

Non-invasive imaging plays many roles in patients with known or suspected MI, but this section concerns only its role in the diagnosis and characterization of myocardial injury and MI. The underlying rationale is that regional myocardial hypoperfusion and ischaemia lead to a cascade of events including myocardial dysfunction, cell death, and healing by fibrosis. Important imaging parameters are therefore myocardial perfusion, myocyte viability, myocardial thickness, thickening and motion, and the effects of myocyte loss on the kinetics of paramagnetic or radio-opaque contrast agents indicating myocardial fibrosis or scar.

Commonly used imaging techniques in acute and prior MI are echocardiography, MPS using SPECT or PET, CMR, and possibly computed tomography (CT).[173] There is considerable overlap in their capabilities and each of the techniques can assess myocardial viability, perfusion, and function to a greater or lesser extent. Only the radionuclide techniques provide a direct assessment of myocyte viability because of the inherent properties of the tracers used. Other techniques provide indirect assessments of myocardial viability, such as the contractile response to dobutamine by echocardiography, or increased extracellular space secondary to myocyte loss by CMR or CT.

34.1. Echocardiography

The strength of echocardiography is the combined assessment of cardiac structure and function, in particular myocardial thickness, thickening/thinning, and motion. Regional wall motion abnormalities induced by ischaemia can be detected by echocardiography almost immediately after onset when > 20% transmural myocardial thickness is affected.[174–176] These abnormalities, when new and without alternative aetiology, support the diagnosis of MI when cTn values show a rising and/or falling pattern. Echocardiography also allows detection of non-coronary cardiac pathologies known to cause chest pain, e.g. acute pericarditis, severe aortic stenosis, and hypertrophic cardiomyopathy among others. The technique is useful in diagnosing mechanical complications in patients with MI and haemodynamic compromise (shock), or other potentially fatal entities

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

such as acuteaortic dissection or massive pulmonary embolism where the clinical presentation might be similar to that seen with acute MI.

Intravenous echocardiographic contrast agents can improve visualization of the endocardial border, and can be used to assess myocardial perfusion and microvascular obstruction. Tissue Doppler and strain imaging permit the quantification of global and regional function.[177,178] Intravascular echocardiographic contrast agents that are targeted at specific molecular processes have been developed, but these techniques have not yet been applied in the setting of MI.[179]

34.2. Radionuclide Imaging

Several radionuclide tracers allow viable myocytes to be imaged directly, including the SPECT tracers ^{201}TI chloride, ^{99m}Tc sestamibi, and tetrofosmin, and the PET tracers ^{18}F 2-fluorodeoxyglucose and ^{82}Rb.[173] A strength of the radionuclide techniques is that they are the only commonly available methods for assessing viability directly, although the relatively low resolution of the images limits them for detecting the smallest areas of MI. Phantom studies suggest that myocyte loss as little as 4% of the myocardium can be detected, corresponding to 5–10 g of muscle.[180] ECG-gated imaging provides a reliable assessment of myocardial motion, thickening, and global function. Evolving radionuclide techniques relevant to the assessment of MI include imaging of sympathetic innervation using ^{123}I-labelled meta-iodobenzylguanidine,[181] imaging of matrix metalloproteinase activation in ventricular remodelling,[182,183] and the assessment of myocardial metabolism.[184]

34.3. Cardiac Magnetic Resonance Imaging

The high tissue contrast and resolution of CMR provides an accurate assessment of myocardial structure and function. Although less commonly used in the acute setting, it has similar capabilities to echocardiography in suspected MI. Paramagnetic contrast agents can be used to assess myocardial perfusion and the increase in extracellular space that is associated with the fibrosis of prior MI (detected by LGE-CMR). These techniques have been used in the setting of acute MI[185,186] and localized delay in contrast enhancement is able to detect even small areas of subendocardial MI, thought to be as little as 1 g.[187] CMR also has the ability to identify the presence and extent of myocardial oedema/inflammation, allowing the distinction of acute vs. chronic myocardial injury. The patterns of LGE when reflecting ischaemic and non-ischaemic myocardial injury are shown in *Figure 9*.

The gadolinium-based contrasts wash out slowly from myocardium with increased extracellular space such as fibrosis, thus enhancing areas of scarring (white arrows). The different patterns of scarring are divided into ischaemic and non-ischaemic. Typically, an ischaemic scar/fibrosis (upper panel) extends from the subendocardium to the epicardium (subendocardial, non-transmural scar vs. transmural scar). Conversely, a non-ischaemic fibrosis/scar can be encountered at the epicardium, in the mid-wall, or at the insertion points of the right ventricle (lower panel).

34.4. Computed Tomographic Coronary Angiography

Infarcted myocardium is initially visible as a focal area of decreased LV myocardial enhancement, but later imaging shows hyperenhancement as with LGE-CMR.[188] This finding is clinically relevant because contrastenhanced CT may be performed for suspected pulmonary embolism and aortic dissection, conditions with clinical features that overlap with those of acute MI, but the technique is not used routinely. Similarly, CT assessment of myocardial perfusion is technically feasible but not widely applied.[189] CT coronary angiography (CTCA) may be used to diagnose CAD in patients with an ACS in the emergency department or chest pain unit, particularly in low- to intermediate-risk patients with normal cTn at presentation.[189–193] The only randomized trial in these patients that included both hs-cTn and CTCA found that imaging did not reduce the length of stay in hospital, but it did decrease subsequent outpatient testing and costs.[189] A diagnosis of MI cannot be established based on a CTCA scan alone.

35. APPLYING IMAGING IN ACUTE MYOCARDIAL INFARCTION

Imaging techniques can be useful in the diagnosis of acute MI because of the ability to detect wall motion abnormalities or loss of viable myocardium in the presence of elevated cardiac biomarker values. Demonstration of new loss of myocardial viability in the absence of non-ischaemic causes supports the diagnosis of MI. Normal function practically excludes significant MI, but a small MI cannot be ruled out.[194] Thus, imaging techniques are useful for early triage and discharge of patients with suspected MI. However, if biomarkers have been measured at appropriate times and are normal, this excludes acute MI and takes precedence over the imaging criteria.

Abnormal regional myocardial motion and thickening may be caused by acute MI, or by one or more of several other conditions including prior infarction,

Downloaded from http://ahajournals.org by on August 25, 2018

Circulation

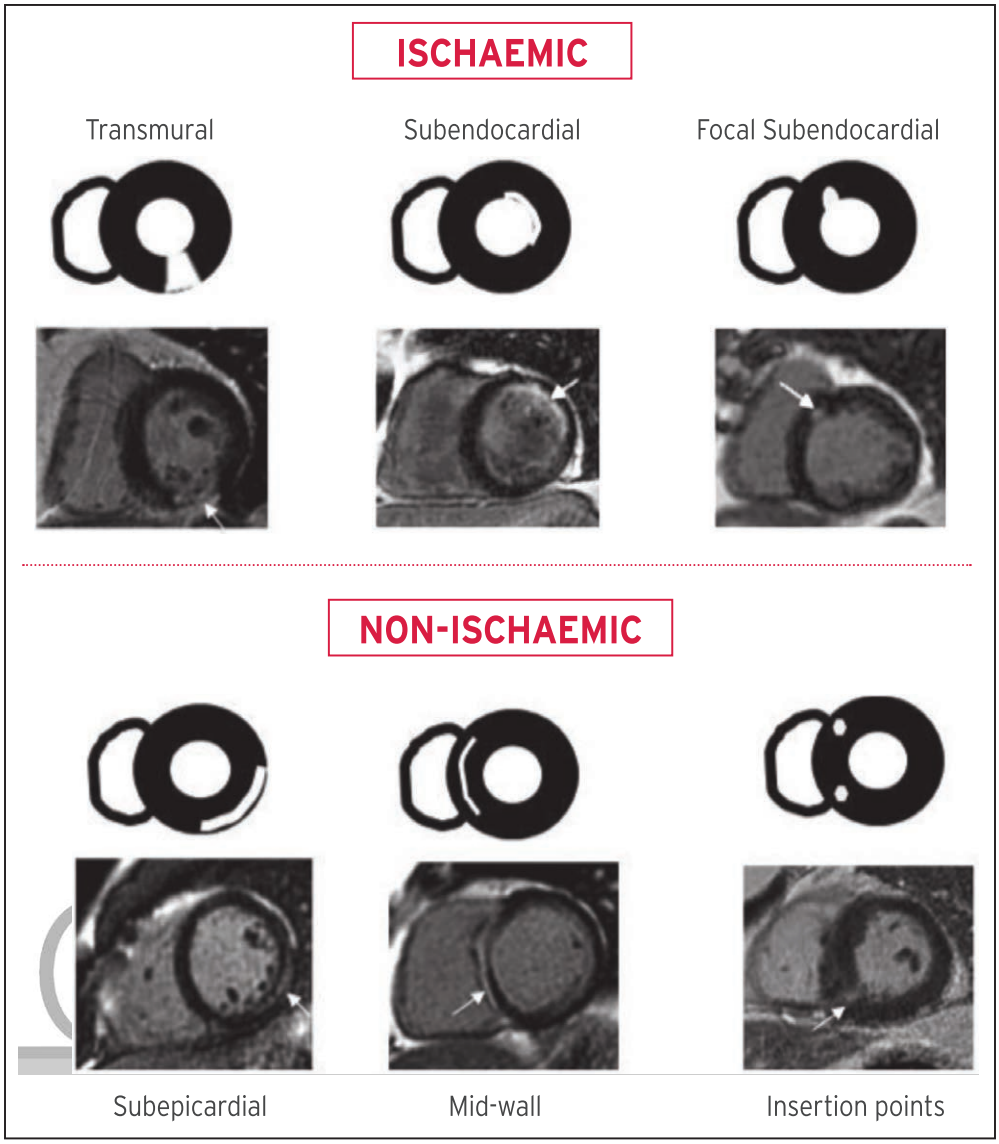

Figure 9. Post-contrast cardiac magnetic resonance images.
The gadolinium-based contrasts wash out slowly from myocardium with increased extracellular space such as fibrosis, thus enhancing areas of scarring (white arrows). The different patterns of scarring are divided into ischaemic and non-ischaemic. Typically, an ischaemic scar/fibrosis (upper panel) extends from the subendocardium to the epicardium (subendocardial, non-transmural scar vs. transmural scar). Conversely, a non-ischaemic fibrosis/scar can be encountered at the epicardium, in the mid-wall, or at the insertion points of the right ventricle (lower panel).

acute ischaemia, stunning, or hibernation. Non-ischaemic conditions such as cardiomyopathy, and inflammatory or infiltrative diseases, can also lead to regional loss of viable myocardium or functional abnormality. Therefore, the positive predictive value of imaging for acute MI is not high unless these conditions can be excluded, and unless a new abnormality is detected or can be presumed to have arisen in the setting of other features of acute MI.

In the setting of acute MI, CMR can also be used to assess the presence and extent of myocardium at risk (myocardial oedema), myocardial salvage, microvascular obstruction, intramyocardial haemorrhage, and infarct size, all markers of myocardial injury that have prognostic value.[190] In patients with possible acute MI but unobstructed coronary arteries, CMR can help to diagnose alternative conditions such as myocarditis, TTS, embolic infarction, or MI with spontaneous recanalization.[189]

36. APPLYING IMAGING IN LATE PRESENTATION OF MYOCARDIAL INFARCTION

In the case of late presentation after suspected MI, the presence of a regional abnormality of myocardial motion, thickening, thinning, or scar in the absence of a non-ischaemic cause provides supportive evidence of past MI. The resolution and specificity of CMR for the

Downloaded from http://ahajournals.org by on August 25, 2018

detection of myocardial scarring has made this a valuable technique. In particular, the ability to distinguish between subendocardial and other patterns of scars helps to differentiate between ischaemic heart disease and other myocardial pathologies. Imaging techniques are also useful for risk stratification after a definitive diagnosis of MI.

37. REGULATORY PERSPECTIVE ON MYOCARDIAL INFARCTION IN CLINICAL TRIALS

In drug and device development programmes, MI may be an entry criterion or be used as an efficacy endpoint, commonly as a component of the primary endpoint, as well as a safety endpoint of interest in drug development programmes.[195,196] A universal definition of MI is of great benefit for clinical studies, since it will allow a standardized approach for meaningful interpretation and comparison across different trials, or the pooling of results for the detection of safety signals. For the harmonization of the MI definition it is important to standardize the reporting of MI events by clinical events committees. This would allow a more optimal comparison of MI rates among drug and device trials.

One cannot presume that values from one cTn assay are equivalent to those of another. These differences are amplified when multiples of the values are used. This could affect results, especially in trials that compare strategies such as PCI and CABG. The use of one single assay and/or a central core laboratory within a trial could help to decrease this variability, and might be particularly relevant in decreasing variability in trials of a drug or intervention in which cTn concentration is a principal safety endpoint. However, the uniform use of a single assay is generally not feasible in trials with follow-up post-discharge, since recurrent ischaemic events may occur in different hospitals using different cTn assays. In clinical trials, a standardized approach to establish the 99th percentile URL for a particular assay should be established. One approach in large multicentre trials is to use the manufacturer's recommended 99th percentile URL for a particular assay to reduce site-to-site variability in the selection of the MI decision cut-off point.

Multiples for hs-cTn vs. conventional cTn could have markedly different prognostic implications. The assay types should be reported when possible. Multiples of the 99th percentile URL should be indicated and reported, both for those with cardiac procedural myocardial injury and those diagnosed with types 4a and 5 MI. Cumulative frequency distribution of peak cTn measurements for MI endpoint assessments by treatment group should also be provided. This will facilitate the comparison of trials and meta-analyses.

38. SILENT/UNRECOGNIZED MYOCARDIAL INFARCTION IN EPIDEMIOLOGICAL STUDIES AND QUALITY PROGRAMMES

ECG monitoring for unrecognized or silent Q wave MI is usually acquired annually in epidemiological studies and clinical trials that assess cardiovascular endpoints. These events are associated with adverse outcomes.[197] There is no firm consensus on how frequently to monitor for ECG evidence of silent Q wave MI or whether surveillance for silent MI events should be routinely implemented. Serial monitoring of patients who have had a symptomatic Q wave MI event revealed Q wave regression in a substantial number of patients.[198] An annual ECG is reasonable in clinical trials to monitor for silent Q wave MI events if the study population is expected to have an accelerated rate of atherosclerotic events. The review should consider the baseline tracing, interim event ECG tracings, and protocolmandated annual tracings, along with the review of imaging studies if available.

39. INDIVIDUAL AND PUBLIC IMPLICATIONS OF THE MYOCARDIAL INFARCTION DEFINITION

Revision of the definition of MI has a number of implications for individuals, health professionals, and society at large. A tentative or final diagnosis is the basis for advice about further diagnostic testing, lifestyle changes, treatment, and prognosis for the patient. The aggregate of patients with a particular diagnosis is the basis for healthcare planning, and policy and resource allocation.

One of the goals of good clinical practice is to reach a definitive and specific diagnosis, which is supported by current scientific knowledge. The approach to the definition of myocardial injury and MI outlined in this document meets this goal. In general, the conceptual meaning of the term myocardial infarction has not changed, although new sensitive methods have been developed to diagnose this entity. Thus, the diagnosis of an acute MI is a clinical diagnosis based on patient symptoms, ECG changes, and highly sensitive biochemical markers, as well as information gleaned from various imaging techniques.

It should be appreciated that the universal definition of MI may be associated with consequences for patients and their families with respect to psychological status, life and health insurance, and professional career, as well as driving and pilot licences. The diagnosis is also associated with societal implications with regards to diagnosis-related coding, hospital reimbursement, public health statistics, sick leave, and disability attestation. In order to meet these challenges, physicians must be adequately informed of the diagnostic criteria. Hence,

Circulation

educational materials will need to be created and treatment guidelines must be appropriately adapted.

40. GLOBAL PERSPECTIVES OF THE DEFINITION OF MYOCARDIAL INFARCTION

Cardiovascular disease is a global health problem and prevalence is increasing in the developing world. Understanding the burden and effects of CAD in populations is of critical importance. Changing clinical definitions, criteria, and biomarkers add challenges to our understanding and ability to improve the health of the public. For clinicians, the definition of MI has important and immediate therapeutic implications. For epidemiologists, the data are often retrospective, so consistent case definitions are critical for comparisons and trend analysis. The standards described in this report are suitable for epidemiology studies and for international classification of diseases.[199] However, to analyse trends over time, it is important to have consistent definitions and to quantify adjustments when biomarkers or other diagnostic methods change,[200] considering that the advent of cTn has dramatically increased the number of diagnosable MIs for epidemiologists.[11,201]

In countries with limited economic resources, cardiac biomarkers and imaging techniques may not be available except in a few centres, and even the option of ECG recordings may be lacking. The WHO recommends the use of the ESC/ACC/AHA/WHF Universal Definition of MI in countries without resource constraints, but recommends more flexible standards in resource-constrained locations. Thus, when the only information available is the clinical history and ECG, and when data on cardiac biomarkers are not available or incomplete, the diagnosis of MI can be confirmed by the development of pathological Q waves.[11]

41. USING THE UNIVERSAL DEFINITION OF MYOCARDIAL INFARCTION IN THE HEALTHCARE SYSTEM

Arriving at a diagnosis of MI using the criteria set forth in this document requires the integration of clinical findings, patterns on the ECG, laboratory data, observations from imaging procedures, and on occasion pathological findings, all viewed in the context of the time horizon over which the suspected event unfolds. Contemporary healthcare systems are increasingly using electronic medical records where medical information is entered, curated, and available for retrieval at a later date. This evolution offers the advantages of a modern electronic database that is useful for a variety of purposes, including scientific discovery and quality improvement in clinical care, but carries with it the challenges of sifting through variable locations and formats where key data elements for confirming a diagnosis of MI are located. Also, use of the electronic medical record as an epidemiological and research tool of the future is likely to require efforts to verify the accuracy of an acute MI diagnosis, rather than accepting the coded diagnoses used for administrative and billing purposes. Such an effort to create a computable phenotype of MI (further categorized as types 1–5 MI) will require input from informaticians and experts in implementation science to translate the recommendations from this Universal Definition of MI into the routine practice of healthcare delivery and documentation.

Given the evolution of biomarker assays used to support the diagnosis of MI, it is important that a consistent approach be used in the construction of the computable phenotype of MI so as to reliably make comparisons across institutions and track epidemiological trends. Ideally, the information provided should include the assay used to make the diagnosis of MI, the 99th percentile of the URL, and the full sequence of values obtained to discern a rise and fall in biomarker levels.[196]

CVD DURING PREGNANCY

Guidelines for the Management of Cardiovascular Diseases during Pregnancy

ESC
European Society of Cardiology

www.escardio.org/guidelines

Figure 1 Selected revised and new recommendations

A) Selected revised recommendations

Comment, comparison with 2011	2018
Strengthening modified World Health Organization (mWHO) classification of maternal risk.	It is recommended to perform risk assessment in all women with cardiac diseases in childbearing age and before conception, using the mWHO classification of maternal risk. (IC)
Upgrade in class of recommendation - Patients with severe MS should undergo intervention before pregnancy.	Intervention is recommended before pregnancy in patients with MS and valve area <1.0 cm^2. (IC)
2011, OACs were recommended during the 2nd and 3rd trimesters until the 36th week. Now separate recommendations for women with low and high dose are given for VKA use during the 2nd and 3rd trimesters.	During the 2nd and 3rd trimesters until the 36th week, VKA are recommended in women needing a low dose. (Low dose VKA: warfarin <5 mg/day (or phenprocoumon <3 mg/day or acenocoumarol <2 mg/day.) (IC)
Sotalol deleted.	Flecainide† or propafenone† are recommended for prevention of SVT in patients with WPW syndrome. (IC)
Changed in high-risk patients from UFH to LMWH. Dosing based on body weight introduced.	LMWH is the drug of choice for the prevention and treatment of VTE in all pregnant patients. (IB) It is recommended that the therapeutic dose of LMWH is based on body weight. (IC)
Changes: dose adjustment of UFH or LMWH dose within 36 hours now recommended.	In pregnant women on LMWH or UFH, it is recommended to perform weekly anti-Xa level monitoring or aPTT monitoring with dose adjustment (within 36 hours). (IC)
Upgrade of recommendation, IIb to IIa.	Catheter ablation with electroanatomic systems should be considered in experienced centres in case of drug- refractory and poorly tolerated SVT. (IIaC)
Changed from D-dimers to imaging as the first line of investigation as D-dimers are unreliable in pregnancy.	If compression ultrasound is negative, magnetic resonance venography should be considered to diagnose VTE. (IIaC)
FDA categories A to X were used for all drugs in 2011.	Decision-making based on former FDA categories is no longer recommended. (IIIC)
“Pre-pregnancy surgery” is now deleted. Now also information on Turner syndrome with aortic diameter corrected for BSA.	Pregnancy is not recommended in patients with severe dilatation of the aorta (heritable thoracic aortic disease such as Marfan syndrome >45 mm, bicuspid aortic valve >50 mm or >27 mm/m^2 body surface area, Turner syndrome ASI >25 mm/m^2 body surface area). (IIIC)

B) Selected new recommendations

Right heart catheterization is recommended to confirm the diagnosis of PAH. This can be performed during pregnancy but with very strict indications. (IC)
LMWH in therapeutic dose is recommended in pregnant patients with chronic thromboembolic pulmonary hypertension. (IC)
In patients with pulmonary embolism, thrombolytic therapy is recommended only in severe hypotension or shock. (IC)
In women at high-risk for thromboembolism, it is recommended to convert LMWH to UFH at least 36 hours prior to delivery and stop the UFH infusion 4–6 hours prior to anticipated delivery. aPTT should be normal before regional anaesthesia. (IC)
In women at low-risk for thromboembolism on therapeutic LMWH, induction or caesarean section is recommended to be performed 24 hours after the last dose of LMWH. (IC)
In women considering pregnancy and requiring heart valve surgery, it is recommended to choose the prosthesis in consultation with a pregnancy heart team. (IC)
It is recommended to manage pregnancy in women with mechanical heart valves in a centre with a pregnancy heart team (IC)
In treatment naive pregnant PAH patients, initiating treatment should be considered. (IIaC)
In patients with (history of) aortic dissection caesarean delivery should be considered. (IIaC)
β-blocker therapy throughout pregnancy should be considered in women with Marfan syndrome and other heritable thoracic aortic diseases. (IIaC)
Induction of labour should be considered at 40 weeks gestation in all women with cardiac disease. (IIaC)
In patients with PPCM, bromocriptine treatment may be considered to stop lactation and enhance recovery (LV function). (IIbB)
Pregnancy is not recommended in patients with vascular Ehlers–Danlos syndrome. (IIIC)
Breastfeeding is not recommended in mothers who take antiplatelet agents other than low-dose aspirin (from Chapter 7, see Chapter 12) (III C)

C) New concepts

Enforcing mWHO classification of maternal risk.
Introduction of the pregnancy heart team.
More attention for assisted reproductive therapy.
Discussion of the use of bromocriptine in PPCM.
Introducing specific levels of surveillance based on low/medium/high-risk for arrhythmia with haemodynamic compromise at delivery.
New information on pharmacokinetics in pregnancy, more detailed information on pharmacodynamics in animal experiments on all drugs (Supplementary Data).
Perimortem caesarean section is discussed.
Advice on contraception and termination of pregnancy in women with cardiac disease is now provided.

ASI = aortic size index; aPTT = activated partial thromboplastin time; BSA = body surface area; FDA = US Food and Drug Administration; LMWH = low molecular weight heparin; LV = left ventricular; MS = mitral stenosis; mWHO = modified World Health Organization; OAC = oral anticoagulant; PAH = pulmonary arterial hypertension; PPCM = peripartum cardiomyopathy; UFH = unfractionated heparin.

Hypertensive disorders are the most frequent cardiovascular disorders during pregnancy, occurring in 5–10% of all pregnancies (see Chapter here). Among the other disease conditions, congenital heart disease is most frequent present during pregnancy in the western world (75–82%). Rheumatic valvular disease dominates in non-western countries, comprising 56–89% of all CVDs in pregnancy. Cardiomyopathies are rare, but represent severe causes of cardiovascular complications in pregnancy.

Pregnancy induces changes in the cardiovascular and coagulation system. The risk of pregnancy depends on the underlying cardiac diagnosis and individual conditions. Risk estimation should be individualized and be based on the modified World Health Organization (mWHO) classification (Table 3)

Table 3 Modified World Health Organization classification of maternal cardiovascular risk

	mWHO I
Diagnosis (if otherwise well and uncomplicated)	Small or mild • pulmonary stenosis • patent ductus arteriosus • mitral valve prolapse Successfully repaired simple lesions (atrial or ventricular septal defect, patent ductus arteriosus, anomalous pulmonary venous drainage) Atrial or ventricular ectopic beats, isolated
Risk	No detectable increased risk of maternal mortality and no/mild increased risk in morbidity
Maternal cardiac event rate	2.5–5%
Counselling	Yes
Care during pregnancy	Local hospital
Minimal follow-up visits during pregnancy	Once or twice
Location of delivery	Local hospital

Table 3 Modified World Health Organization classification of maternal cardiovascular risk (continued)

	mWHO II
Diagnosis (if otherwise well and uncomplicated)	Unoperated atrial or ventricular septal defect Repaired tetralogy of Fallot Most arrhythmias (supraventricular arrhythmias) Turner syndrome without aortic dilatation
Risk	Small increased risk of maternal mortality or moderate increase in morbidity
Maternal cardiac event rate	5.7–10.5%
Counselling	Yes
Care during pregnancy	Local hospital
Minimal follow-up visits during pregnancy	Once per trimester
Location of delivery	Local hospital

WHO classification of maternal CV risk

Table 3 Modified World Health Organization classification of maternal cardiovascular risk (continued)

	mWHO III
Diagnosis (if otherwise well and uncomplicated)	Moderate left ventricular impairment (EF 30–45%) Previous peripartum cardiomyopathy without any residual left ventricular impairment Mechanical valve Systemic right ventricle with good or mildly decreased ventricular function Fontan circulation. If otherwise the patient is well and the cardiac condition uncomplicated Unrepaired cyanotic heart disease Other complex heart disease Moderate mitral stenosis Severe asymptomatic aortic stenosis Moderate aortic dilatation (40–45 mm in Marfan syndrome or other HTAD; 45–50 mm in bicuspid aortic valve, Turner syndrome ASI 20–25 mm/m^2, tetralogy of Fallot <50 mm) Ventricular tachycardia
Risk	Significantly increased risk of maternal mortality or severe morbidity
Maternal cardiac event rate	19–27%
Counselling	Yes: expert counselling required
Care during pregnancy	Expert centre for pregnancy and cardiac disease
Minimal follow-up visits during pregnancy	Monthly or bimonthly
Location of delivery	Expert centre for pregnancy and cardiac disease

Table 3 Modified World Health Organization classification of maternal cardiovascular risk (continued)

	mWHO IV
Diagnosis	Pulmonary arterial hypertension Severe systemic ventricular dysfunction (EF <30% or NYHA class III–IV) Previous peripartum cardiomyopathy with any residual left ventricular impairment Severe mitral stenosis Severe symptomatic aortic stenosis Systemic right ventricle with moderate or severely decreased ventricular function Severe aortic dilatation (>45 mm in Marfan syndrome or other HTAD, >50 mm in bicuspid aortic valve, Turner syndrome ASI >25mm/m^2, tetralogy of Fallot >50 mm) Vascular Ehlers-Danlos Severe (re)coarctation Fontan with any complication
Risk	Extremely high-risk of maternal mortality or severe morbidity
Maternal cardiac event rate	40–100%
Counselling	Yes: pregnancy contra-indicated. If pregnancy occurs termination should be discussed
Care during pregnancy	Expert centre for pregnancy and cardiac disease
Minimal follow-up visits during pregnancy	Monthly
Location of delivery	Expert centre for pregnancy and cardiac disease

ASI = aortic size index; EF = ejection fraction; HTAD= heritable thoracic aortic disease; mWHO = modified World Health Organization classification; NYHA = New York Heart Association; WHO = World Health Organization.

Table 4 Predictors of maternal and neonatal events

Predictors of maternal cardiovascular events
Prior cardiac event (heart failure, transient ischaemic attack, stroke, arrhythmia)
NYHA Class III/IV
Left heart obstruction (moderate to severe)
Reduced systemic ventricular systolic function (ejection fraction <40%)
Reduced subpulmonary ventricular function (TAPSE <16 mm)
Systemic atrioventricular valve regurgitation (moderate to severe)
Pulmonary atrioventricular valve regurgitation (moderate to severe)
Pulmonary arterial hypertension
Cardiac medication before pregnancy
Cyanosis (O_2 saturation <90%)
Natriuretic peptide levels (NT-proBNP >128 pg/mL at 20 weeks predictive of event later in pregnancy)
Smoking history
Mechanical valve prosthesis
Repaired or unrepaired cyanotic heart disease
Predictors of neonatal events
NYHA Class III/IV or cyanosis during baseline pre-natal visit
Maternal left heart obstruction
Smoking during pregnancy
Low maternal oxygen saturation (<90%)
Multiple gestations
Use of anticoagulants throughout pregnancy
Cardiac medication before pregnancy
“At birth” cyanotic heart disease
Mechanical valve prosthesis
Maternal cardiac event during pregnancy
Maternal decline in cardiac output during pregnancy
Abnormal uteroplacental Doppler flow

NT-proBNP = N-terminal pro B-type natriuretic peptide; NYHA = New York Heart Association; TAPSE = tricuspid annular plane systolic excursion. Predictors identified in references (See Full Text).

In women with a moderate or high-risk of complications during pregnancy (mWHO II–III, III and IV), pre-pregnancy counselling and management during pregnancy and around delivery should be conducted in an expert centre by a multidisciplinary team, the pregnancy heart team. The minimum team requirements are a cardiologist, obstetrician and anaesthetist, all with expertise in the management of high-risk pregnancies in women with heart disease. The conclusions and recommendations should be filed and made available 24 hours per day.

Transthoracic echocardiography is the preferred imaging method in pregnancy. Physiological exercise testing is an integral part of follow-up in grown-up congenital heart disease and valve disease, and should be performed in patients with known heart disease who plan pregnancy.

If possible, procedures using ionizing radiation should be delayed until at least the completion of the period of major organogenesis (>12 weeks after menses). Cardiac catheterisation and MRI can be necessary to guide diagnosis and interventional procedures.

Presently, options for pre-natal genetic testing are increasingly available for those patients with an identified genetic defect (either chromosomal defects such as insertions/deletions/ translocations or single gene defects). This includes (i) pre-gestational diagnosis or (ii) pre-natal diagnosis, chorionic villus sampling or amniocentesis. Counselling should be provided by an experienced centre with an interdisciplinary expert team.

Measurement of nuchal fold thickness around the 12th week of pregnancy to screen for chromosome abnormalities also screens for foetal congenital heart disease.

All women with congenital heart disease should be offered foetal echocardiography in the 19th to 22nd week of pregnancy with 45% of all congenital cardiac malformations identified.

If an intervention is absolutely necessary, the best time is after the fourth month in the second trimester. Maternal mortality during cardiopulmonary by-pass is now similar to that in non-pregnant women. However, foetal mortality remains high (around 20%). Cardiac surgery is recommended only when medical therapy or interventional procedures fail and the mother's life is threatened. Delivery before necessary surgery should be considered when the fetus is viable.

A delivery plan should be made with details of induction, management of labour, delivery, and post-partum surveillance.

Vaginal delivery is associated with less blood loss and lower risk of infection, venous thrombosis and embolism, and should be advised for most women. Caesarean section should be considered for obstetric indications and for patients presenting in labour on oral anticoagulants (OACs), with aggressive aortic pathology and in acute intractable HF and is advised in severe forms of pulmonary hypertension (PH) (including Eisenmenger syndrome).

Antibiotic prophylaxis is not recommended during vaginal or caesarean delivery. IE should be diagnosed and treated in the same way as in the non-pregnant patient. Antibiotics should be given according to guidelines, guided by culture and antibiotic sensitivity results considering the potential fetotoxic effects of antibiotics (see Table 7: Drugs and safety data).

The risk of using a particular type of contraception needs to be balanced against the risk of pregnancy, estimated using the modified WHO classification. Advice on contraception should be provided to all women with heart disease.

The rates of subfertility are likely to be as similar in most women with heart disease as in the general population, but their management is more complex. Hysteroscopy and laparoscopy can be life-threatening procedures in women with some forms of heart disease (PH, Fontan) and should be undertaken in an experienced centre with appropriate support. Assisted reproduction has added risks above those of pregnancy alone.

General recommendations		
	Class[a]	Level[b]
Pre-pregnancy risk assessment and counselling is indicated in all women with known or suspected congenital or acquired cardiovascular and aortic disease.	I	C
It is recommended to perform risk assessment in all women with cardiac diseases in childbearing age and after conception, using the mWHO classification of maternal risk.	I	C
It is recommended to treat high-risk patients in specialized centres by a multidisciplinary pregnancy heart team.	I	C
Foetal echocardiography by experienced specialists is recommended when there is an elevated risk of foetal abnormalities.	I	C
Echocardiography is recommended in any pregnant patient with unexplained or new cardiovascular signs or symptoms.	I	C
If cardiac surgery is to be performed after 24 weeks and before 37 weeks of gestation, then corticosteroids are recommended for the mother.	I	C
Vaginal delivery is recommended as first choice in most patients; for most important exceptions see below.	I	C
Induction of labour should be considered at 40 weeks of gestation in all women with cardiac disease.	IIa	C
Genetic counselling should be considered in women with congenital heart disease or congenital arrhythmia, cardiomyopathies, aortic disease or genetic malformations associated with CVD.	IIa	C
MRI (without gadolinium) should be considered if echocardiography is insufficient for a definite diagnosis.	IIa	C
In patients with severe hypertension, vaginal delivery with epidural analgesia and elective instrumental delivery should be considered.	IIa	C
Delivery before necessary surgery should be considered when gestational age is ≥26 weeks.	IIa	C
Caesarean delivery should be considered for obstetric indications or for patients with dilatation of the ascending aorta >45 mm, severe aortic stenosis, pre-term labour while on oral anticoagulants, Eisenmenger syndrome or severe heart failure.	IIa	C
A chest radiograph may be considered if other methods are not successful in clarifying the cause of dyspnoea.	IIb	C
Cardiac catheterization may be considered with very strict indications.	IIb	C
CT and electrophysiological studies may be considered in selected patients for vital indications.	IIb	C
Coronary bypass surgery or valvular surgery may be considered during pregnancy when conservative and medical therapy has failed, in situations that threaten the mother's life and that are not amenable to percutaneous treatment.	IIb	C
Prophylactic antibiotic therapy to prevent endocarditis during delivery is not recommended.	III	C

CT = computed tomography; CVD = cardiovascular disease; MRI = magnetic reso-

Introduction

In most women with congenital heart disease, pregnancy is well tolerated. Maternal cardiac complications are present in approximately 10% of completed pregnancies and are more frequent in mothers with complex disease.

PH has many causes and is defined by an elevation in mean pulmonary arterial pressure (PAP) ≥25 mmHg at right heart catheterization.

Maternal outcome, which varies according to the PH subset, has improved but mortality remains high in women with PAH (16–30% maternal mortality). Therefore, the recommendation to avoid pregnancy remains and when pregnancy occurs, termination should be discussed.

There is increased foetal and neonatal (0–30%) mortality particularly if there is preterm delivery, reduced maternal cardiac output (CO) and/or hypoxaemia.

Eisenmenger patients require special consideration because of the additional complications of cyanosis, right-to-left shunting, and paradoxical embolism. Maternal mortality is high (20–50%) and termination of pregnancy should be discussed. However, termination also carries a risk.

Foetal and neonatal risks are increased and relate to maternal CO and cyanosis. Miscarriage is common. Maternal hypoxaemia is the most important predictor of outcome.

Many of the principles of caring for non-Eisenmenger PAH apply. However, patients with Eisenmenger syndrome are at increased risk of thrombocytopenia, deficiencies in vitamin K-dependent clotting factors, and bleeding. Caution is therefore needed if prescribing antiplatelet therapy or LMWH.

Maternal complications (HF, thrombosis, arrhythmias, endocarditis) occur in at least 15% of cyanotic pregnant patients.

If oxygen saturation is >90%, then there is usually a better foetal outcome (10% foetal loss). If oxygen saturation is <85%, foetal growth restriction, prematurity, and foetal death are common and pregnancy should be discouraged (live birth rate of only 12%).

The principles for managing supravalvular or subvalvular LV outflow tract obstruction are the same as those for valvular aortic stenosis (AS) (see Chapter here). Balloon valvuloplasty is not, however, a therapeutic option.

Pregnancy is well tolerated by most women with repaired atrial septal defect (ASD) (WHO risk Class I).

For a secundum defect, catheter device closure can be performed during pregnancy but is rarely indicated.

Small or repaired ventricular septal defects (VSDs) (without left heart dilatation or ventricular dysfunction) have a low-risk of complications during pregnancy (mWHO I and II).

The risk of HF is low and only exists in women with severe regurgitation or impaired ventricular function.

Offspring mortality has been reported in 6% of cases, primarily due to the recurrence of congenital heart disease.

Pregnancy is often well tolerated in women after repair of coarctation of the aorta (CoA) (WHO risk class II).

In women with unrepaired CoA and those repaired who have systemic hypertension, residual CoA or aortic aneurysms have an increased risk of complications including dissection. Other risk factors include aortic dilatation and bicuspid aortic valve.

Pulmonary stenosis (PS) is generally well tolerated. However, severe stenosis may result in complications including RV failure and arrhythmias.

In severely symptomatic PS which is unresponsive to medical therapy and bed rest, percutaneous valvuloplasty can be appropriate.

Women with repaired tetralogy of Fallot usually tolerate pregnancy well (WHO risk class II). Cardiac complications have been reported in 8% of repaired patients.

In women with uncomplicated Ebstein's anomaly, pregnancy is often tolerated well (WHO risk class II). Symptomatic patients with cyanosis and/or HF should be counselled against pregnancy.

In patients with transposition of the great arteries (TGA), the risks associated with pregnancy are mainly attributable to women with a previous atrial (Senning and Mustard) switch, not arterial switch.

Though many women with an atrial switch operation tolerate pregnancy relatively well, there is an increased risk of developing arrhythmias (sometimes life- threatening) and HF (WHO risk class III). An irreversible decline in RV function and worsening TR are also described. Patients with more than moderate impairment of RV function or greater than moderate TR should be advised against pregnancy.

The risk of low birth weight and preterm delivery is 38%.

Complications include arrhythmias and HF (WHO risk class III). These patients are also predisposed to developing AV block. Some 10% of patients have an irreversible decline in RV function. Patients in New York Heart Association (NYHA) class III or IV, ventricular dysfunction (ejection fraction [EF] <40%), or severe TR should be counselled against pregnancy.

The rate of foetal loss is increased, especially if there is cyanosis.

Patients with a Fontan circulation have an increased risk of fertility issues but successful pregnancy can occur. However, these are high- to very high-risk pregnancies (WHO risk class III or IV). Patients with saturations <85%, depressed ventricular function, moderate to severe AV regurgitation, refractory arrhythmia or protein-losing enteropathy should be counselled against pregnancy (mWHO IV). Fontan patients have a high-risk of miscarriage (30%). Antenatal and peripartum bleeding is common. There is an increased risk of premature birth, small for gestational age, and neonatal death.

Fontan patients are at risk of thromboembolic complications and therapeutic anticoagulation should be considered (balanced with the risk of bleeding). Atrial arrhythmias should be treated promptly and this often requires electrical cardioversion.

Pregnancy and pulmonary arterial hypertension		
Recommendations	**Class[a]**	**Level[b]**
Right heart catheterization is recommended to confirm the diagnosis of PAH (group 1). This can be performed during pregnancy but with very strict indications.	I	C
Treatment dose LMWH is recommended in pregnant patients with chronic thromboembolic pulmonary hypertension.	I	C
If a PAH patient conceives on targeted PH therapies consideration should be given to withdrawing embryotoxic drugs taking into account the risks of withdrawal.	IIa	C
In treatment naive pregnant PAH patients, initiating treatment should be considered.	IIa	C
Pregnancy is not recommended in patients with PAH.	III	B

LMWH = low molecular weight heparin; PAH = pulmonary arterial hypertension; PH = pulmonary hypertension.

[a] Class of recommendation

[b] Level of evidence.

Congenital heart disease

Recommendations	Class[a]	Level[b]
Patients with a systemic right ventricle (Mustard/Senning or congenitally corrected TGA), in NYHA Class III/IV, systemic ventricular dysfunction (EF <40%), or severe TR should be advised against pregnancy.	IIa	C
Anticoagulation treatment should be considered during pregnancy in Fontan patients.	IIa	C
Symptomatic patients with Ebstein's anomaly with saturations <85% and/or heart failure should be advised against pregnancy.	IIa	C
In patients with a Fontan circulation and saturations <85%, depressed ventricular function, moderate to severe AV regurgitation, refractory arrhythmia or protein-losing enteropathy pregnancy is not recommended.	III	C

AV = atrioventricular; EF = ejection fraction; NYHA = New York Heart Association; TGA = transposition of the great arteries; TR = tricuspid regurgitation.

[a] Class of recommendation.

[b] Level of evidence.

Aortic diseases

Due to haemodynamic and hormonal changes, pregnancy is a high-risk period for all patients with aortic pathology, which is rare during pregnancy but associated with very high mortality. Dissection occurs most often in the last trimester of pregnancy (50%) or the early post-partum period (33%).

The overall risk of a woman with Marfan syndrome having an aortic dissection associated with pregnancy is approximately 3%. Pregnancy should be avoided in Marfan patients with an aortic root diameter >45 mm. When the aorta is 40–45 mm, other factors should be considered such as family history of dissection and rate of aortic growth.

In patients with a bicuspid aortic valve, if the ascending aorta is not visible with echocardiography, an MRI or CT should be performed pre-pregnancy. The risk of dissection is small. Risk factors are type of bicuspid aortic valve morphology, aortic dilatation, and CoA. Pregnancy should be avoided when the aorta diameter is >50 mm.

In patients with Ehlers-Danlos syndrome, serious vascular complications occur almost exclusively in type IV (vascular). Maternal mortality is significant. Pregnancy is therefore considered as a very high-risk undertaking and not advised.

Turner syndrome is associated with an increased risk of congenital heart disease, aortic dilatation, hypertension, diabetes and atherosclerotic events. Risk factors for aortic dissection include aortic dilation, bicuspid aortic valve and CoA. Pregnancy should be avoided when the aortic size index (ASI) is >25 mm/m^2.

Table 5 Aortic diseases

	Marfan	**Bicuspid aortic valve**
Location of aneurysm/ dissection	Everywhere (sinus of Valsalva)	Ascending aorta
Risk of dissection	High: 1–10%	Low: <1%
Comorbidity	Dural abnormalities Mitral regurgitation Heart failure Arrhythmias	Aortic stenosis or regurgitation
Advise not to become pregnant	Ascending aorta >45 mm (or >40 mm in family history of dissection or sudden death)	Ascending aorta >50 mm

Risk of dissection	High: 1–10%
Comorbidity	Dural abnormalities Uterine rupture
Advise not to become pregnant	All patients

ASI = aortic size index

Recommendations	Class[a]	Level[b]
All aortic diseases		
It is recommended that women with aortic disease have counselling about the risk of aortic dissection.	I	C
Imaging of the entire aorta (CT/MRI) is recommended before pregnancy in patients with a genetically proven aortic syndrome or known aortic disease.	I	C
In bicuspid aortic valve patients imaging of the ascending aorta is recommended before pregnancy.	I	C
When a woman with known aortic dilatation, (history of) dissection or genetic predisposition for dissection becomes pregnant, strict blood pressure control is recommended.	I	C
Repeated echocardiographic imaging every 4–12 weeks (depending on diagnosis and severity of dilatation) is recommended during pregnancy and 6 months post-partum in patients with ascending aorta dilatation.	I	C
For imaging of pregnant women with dilatation of distal ascending aorta, aortic arch or descending aorta, MRI (without gadolinium) is recommended.	I	C
It is recommended to deliver all women with aortic dilatation or (history of) aortic dissection in an experienced centre with a pregnancy heart team, where cardiothoracic surgery is available.	I	C
In patients with an ascending aorta <40 mm vaginal delivery is recommended.	I	C
In patients with an ascending aorta >45 mm caesarean delivery should be considered.	IIa	C
In patients with (history of) aortic dissection, caesarean delivery should be considered.	IIa	C
Prophylactic surgery should be considered during pregnancy if the aorta diameter is >45 mm and increasing rapidly.	IIa	C
When the foetus is viable, delivery before necessary surgery should be considered.	IIa	C
In patients with an aorta 40–45 mm vaginal delivery with epidural anaesthesia and expedited second stage should be considered.	IIa	C
In patients with an aorta 40–45 mm caesarean section may be considered.	IIb	C
Pregnancy is not recommended in patients with (or history of) aortic dissection.	III	C
When possible the use of ergometrine is not recommended in women with aortic disease.	III	C
Specific syndromes		
In patients with vascular Ehlers–Danlos syndrome celiprolol is recommended.	I	C
β-blocker therapy throughout pregnancy should be considered in women with Marfan syndrome and other heritable thoracic aortic diseases.	IIa	C
Pregnancy is not recommended in patients with severe dilatation of the aorta (heritable thoracic aortic disease such as Marfan syndrome >45 mm, bicuspid aortic valve >50 mm or >27 mm/m^2 BSA, Turner syndrome ASI >25 mm/m^2 BSA).	III	C
Pregnancy is not recommended in patients with vascular Ehlers– Danlos syndrome.	III	C

In stenotic valve diseases, increased CO causes an increase in transvalvular gradient of approximately 50%, mainly between the first and second trimesters, which increases the risk of maternal and foetal complications. Mechanical valve prostheses raise specific problems during pregnancy.

Heart failure occurs in one-third of pregnant women with moderate mitral stenosis and in half of those with severe mitral stenosis, most often during the second trimester. Atrial fibrillation, NYHA Class ≥II, systolic PAP >30 mmHg, severe stenosis and older age are associated with maternal complications. Prematurity rates are 20–30%, intrauterine growth retardation 5–20%, and foetal death 1–5%.

When symptoms or clinically significant PH (echocardiographically estimated systolic PAP ≥50 mmHg) develop, activity should be restricted and β-1 selective blockers (preferably metoprolol or bisoprolol) commenced. Diuretics may be used if symptoms persist. The persistence of severe symptoms or PH under medical therapy should lead to consider percutaneous mitral commissurotomy during pregnancy. Anticoagulation is recommended in the case of paroxysmal or permanent AF, left atrial thrombosis, or prior embolism.

All patients with significant MS should be counselled against pregnancy and intervention should be considered pre-pregnancy, favouring percutaneous intervention, even if asymptomatic, and even more so if the valve area is <1.0 cm^2.

The main cause of AS is bicuspid aortic valve followed by rheumatic heart disease. Cardiac morbidity is related to baseline severity of AS and symptoms. Even in patients with severe AS, pregnancy is often well tolerated if prior exercise tolerance was normal. Pre-term birth, intrauterine growth retardation, and low birth weight occur in 20–25% of the offspring of mothers with moderate and severe AS and are increased in severe AS.

All symptomatic patients with severe AS or asymptomatic patients with impaired LV function or a pathological exercise test should be counselled against pregnancy, and surgery should be performed pre-pregnancy.

During pregnancy in patients who are severely symptomatic despite medical therapy, percutaneous valvuloplasty can be undertaken by an experienced operator.

Women with severe regurgitation and symptoms or compromised LV function are at high-risk of HF. Heart failure occurs in 20–25% of women with moderate or severe rheumatic MR. Acute severe regurgitation is poorly tolerated.

Ascending aortic diameters should be measured in women with bicuspid valves. Pre-pregnancy surgery favouring valve repair should be performed according to guidelines.

In acute severe regurgitation with therapy-refractory HF, surgery is sometimes unavoidable during pregnancy. If the foetus is sufficiently mature, delivery should be undertaken prior to cardiac surgery (see Table "General Recommendations").

A high thromboembolic risk is associated with AF in native heart valve disease, in particular in clinically significant MS. Immediate anticoagulation is required.

In young women who wish to become pregnant in the future, the pregnancy heart team should be involved in the choice of a specific prosthesis, taking into account the advantages and disadvantages of the different options for that woman.

The risk of maternal cardiovascular complications in women with a bioprosthesis is low in those with no or minimal bioprosthesis dysfunction and uncompromised ventricular function. When significant bioprosthesis dysfunction is present, the risk of complications can be significant. In women with mechanical valves, pregnancy is associated with a very high-risk of complications (WHO risk classification III). A recent study from the UK reported a favourable outcome for mother and baby in only 28% of cases. The main risks are related to the need for anticoagulation therapy (valve thrombosis and haemorrhagic complications). Additional risks are related to ventricular and valvular dysfunction.

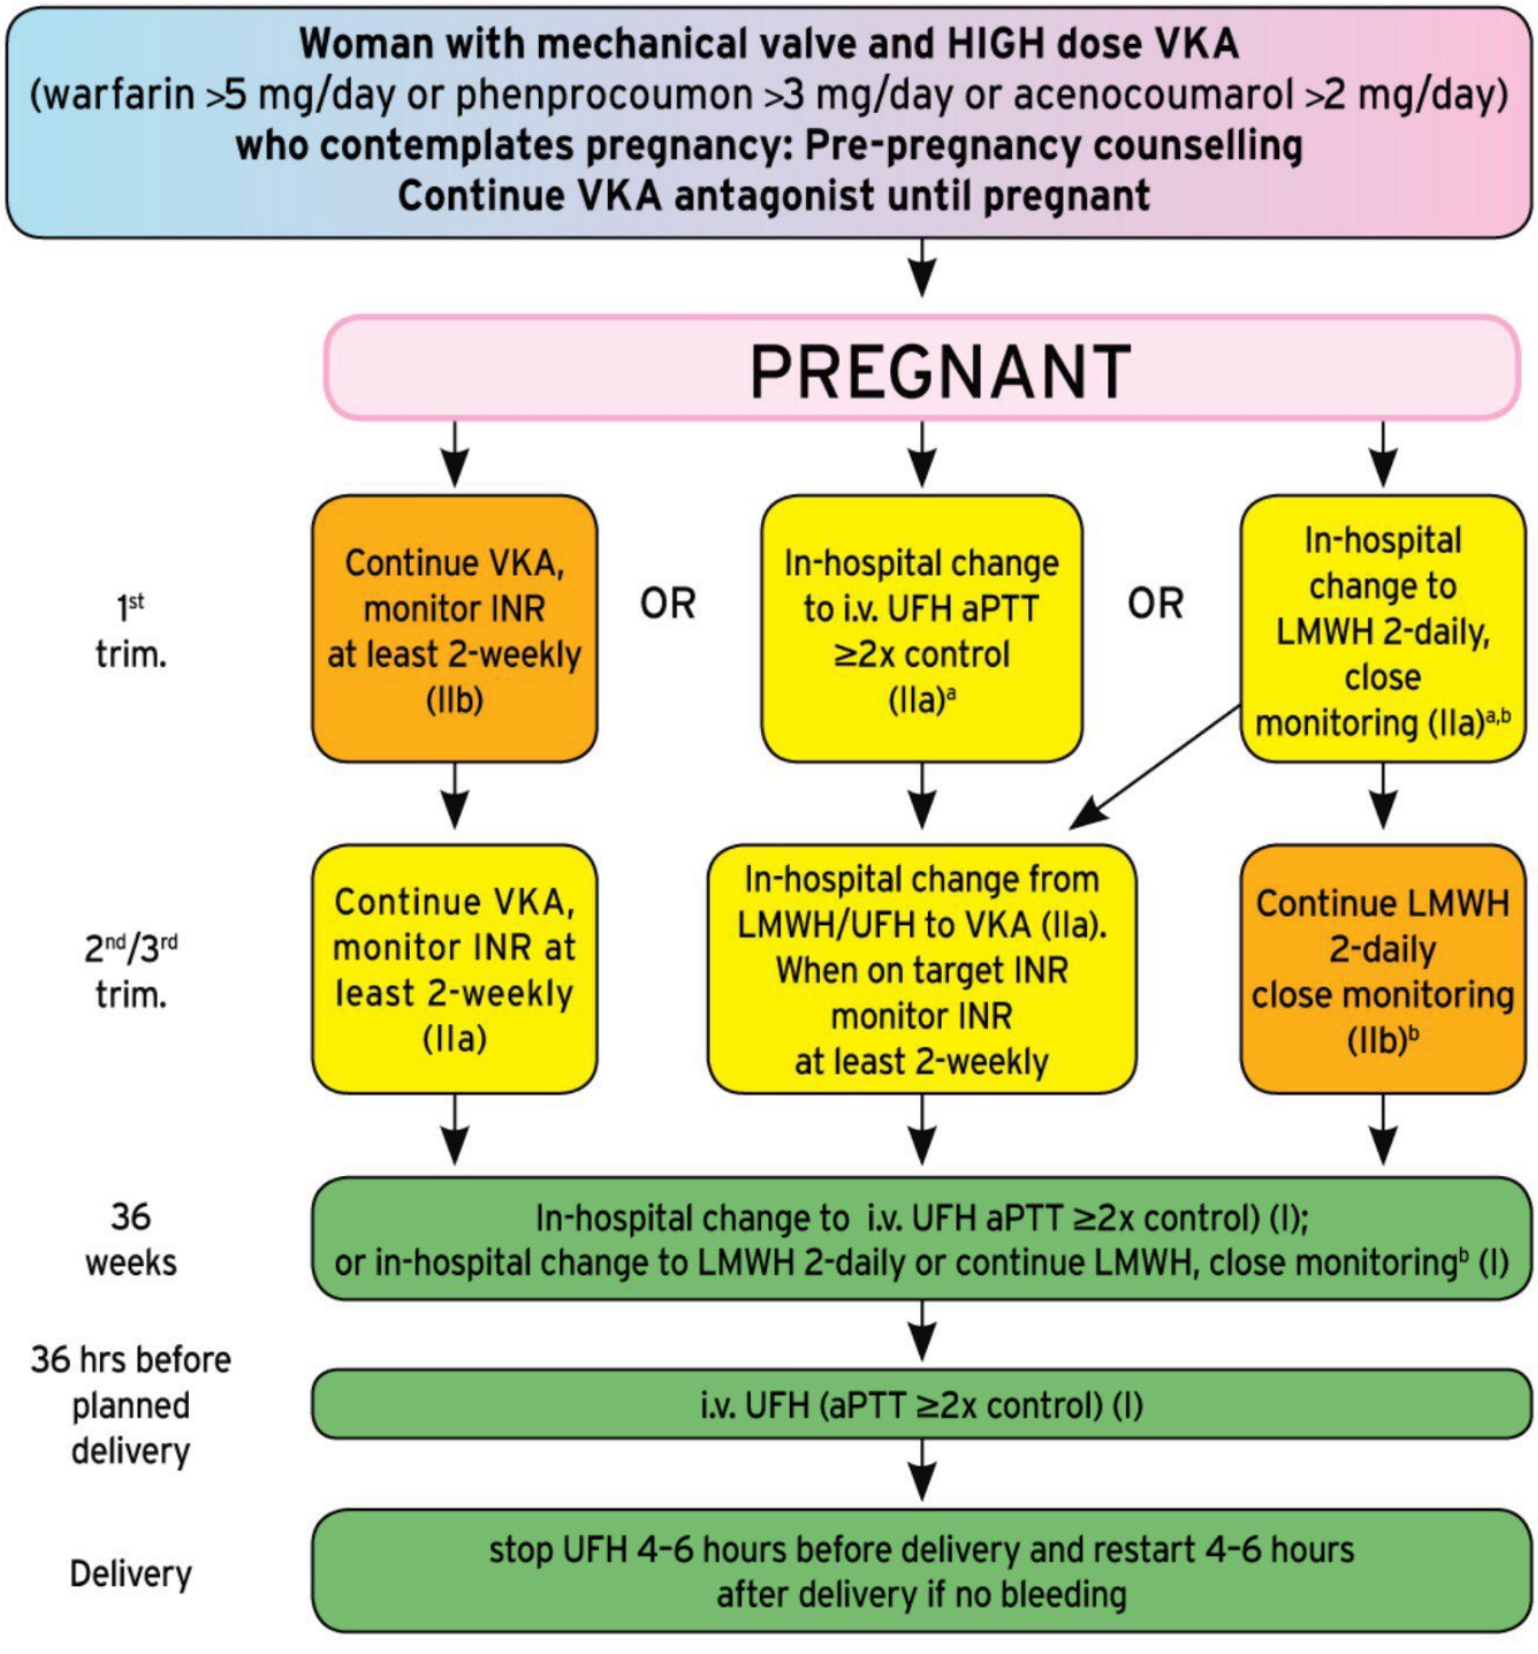
Current evidence (lacking adequate randomized studies) indicates that VKAs throughout pregnancy, under strict INR control, is the safest regimen to prevent valve thrombosis. LMWH is possibly superior to UFH for preventing valve thrombosis. All anticoagulation regimens carry an increased risk of miscarriage and haemorrhagic complications, including post-partum haemorrhage and retroplacental bleeding leading to premature birth and foetal death. VKAs during the first trimester are associated with an increased risk of miscarriage compared to LMWH or UFH, and the live birth rate is lower, Vaginal delivery while the mother is on VKAs is contra-indicated because of the risk of foetal intracranial bleeding. The option to avoid pregnancy should be discussed with women who have a mechanical valve prosthesis.

These high-risk pregnancies should be managed by a pregnancy heart team in an expert centre. The effectiveness of the anticoagulation regimen should be monitored weekly or every 2 weeks depending on the anticoagulation regimen (see Table 7: Drugs and safety data) and clinical follow-up including echocardiography should be performed monthly.

Dyspnoea and/or an embolic event are reasons for immediate transthoracic echocardiography to search for valve thrombosis, usually followed by transoesophageal echocardiography.

Planned delivery is necessary. Vaginal delivery requires a prior switch to i.v. heparin. The use of epidural anaesthesia requires a prolonged interruption of anticoagulant therapy, which may contra-indicate its use in women with a mechanical prosthesis. A planned caesarean section may therefore be considered as an alternative. Caesarean section should be performed if labour onset occurs while the patient is still on VKAs.

VKA



aPTT = activated partial thromboplastic time; INR, international normalized ratio; i.v. = intravenous; LMWH = low molecular weight heparin; LVEF = left ventricular ejection fraction; UFH = unfractionated heparin; VKA = vitamin K antagonist.

[a] Weeks 6–12 - [b] Monitoring LMWH: - starting dose for LMWH is 1 mg/kg body weight for enoxaparin and 100 IU/kg for dalteparin, twice daily subcutaneously; -In-hospital daily anti-Xa levels until target, then weekly (I); -target anti-Xa levels: 1.0–1.2 U/mL (mitral and right sided valves) or 0.8–1.2 U/mL (aortic valves) 4–6 hrs post-dose (I); -pre-dose anti-Xa levels >0.6 U/mL (IIb).

Management of native valvular heart disease		
Recommendations	**Class[a]**	**Level[b]**
Pre-pregnancy evaluation, including echocardiography, and counselling is recommended for any woman with known or suspected valvular disease.	I	C
Mitral stenosis		
In patients with symptoms or pulmonary hypertension, restricted activities and β-1 selective blockers are recommended.	I	B
Diuretics are recommended when congestive symptoms persist despite β-blockers.	I	B
Intervention is recommended before pregnancy in patients with MS and valve area <1.0 cm^2.	I	C
Therapeutic anticoagulation using heparins or VKA is recommended in case of atrial fibrillation, left atrial thrombosis, or prior embolism.	I	C
Intervention should be considered before pregnancy in patients with MS and valve area <1.5 cm^2.	IIa	C
Percutaneous mitral commissurotomy should be considered in pregnant patients with severe symptoms or systolic pulmonary artery pressure >50 mmHg despite medical therapy.	IIa	C
Aortic stenosis		
Intervention is recommended before pregnancy in patients with severe AS if:		
• they are symptomatic	I	B
• OR LV dysfunction (LVEF <50%) is present	I	C
• OR when they develop symptoms during exercise testing.	I	C
Intervention should be considered before pregnancy in asymptomatic patients with severe AS when a fall in blood pressure below baseline during exercise testing occurs.	IIa	C
Balloon aortic valvuloplasty should be considered during pregnancy in patients with severe AS and severe symptoms.	IIa	C
Chronic regurgitant lesions		
Surgical treatment is recommended before pregnancy in patients with severe aortic or mitral regurgitation and symptoms or impaired ventricular function or ventricular dilatation.	I	C
Medical therapy is recommended in pregnant women with regurgitant lesions when symptoms occur.	I	C

AS = aortic stenosis; LV = left ventricular; LVEF = left ventricular ejection fraction; MS = mitral stenosis; VKA = vitamin K antagonist. [a]Class of recommendation - [b]Level of evidence.

Management of native valvular heart disease		
Recommendations	**Class[a]**	**Level[b]**
Pre-pregnancy evaluation, including echocardiography, and counselling is recommended for any woman with known or suspected valvular disease.	I	C
Mitral stenosis		
In patients with symptoms or pulmonary hypertension, restricted activities and β-1 selective blockers are recommended.	I	B
Diuretics are recommended when congestive symptoms persist despite β-blockers.	I	B
Intervention is recommended before pregnancy in patients with MS and valve area <1.0 cm^2.	I	C
Therapeutic anticoagulation using heparins or VKA is recommended in case of atrial fibrillation, left atrial thrombosis, or prior embolism.	I	C
Intervention should be considered before pregnancy in patients with MS and valve area <1.5 cm^2.	IIa	C
Percutaneous mitral commissurotomy should be considered in pregnant patients with severe symptoms or systolic pulmonary artery pressure >50 mmHg despite medical therapy.	IIa	C
Aortic stenosis		
Intervention is recommended before pregnancy in patients with severe AS if:		
• they are symptomatic	I	B
• OR LV dysfunction (LVEF <50%) is present	I	C
• OR when they develop symptoms during exercise testing.	I	C
Intervention should be considered before pregnancy in asymptomatic patients with severe AS when a fall in blood pressure below baseline during exercise testing occurs.	IIa	C
Balloon aortic valvuloplasty should be considered during pregnancy in patients with severe AS and severe symptoms.	IIa	C
Chronic regurgitant lesions		
Surgical treatment is recommended before pregnancy in patients with severe aortic or mitral regurgitation and symptoms or impaired ventricular function or ventricular dilatation.	I	C
Medical therapy is recommended in pregnant women with regurgitant lesions when symptoms occur.	I	C

AS = aortic stenosis; LV = left ventricular; LVEF = left ventricular ejection fraction; MS = mitral stenosis; VKA = vitamin K antagonist. [a]Class of recommendation - [b]Level of evidence.

Management of prosthetic heart valves		
Recommendations	**Class[a]**	**Level[b]**
In women contemplating pregnancy, selection of a valve prosthesis should be undertaken in consultation with a pregnancy heart team.	I	C
It is recommended to manage pregnancy in women with mechanical valves in a centre with a pregnancy heart team.	I	C
If delivery starts while on VKA or in less than 2 weeks after discontinuation of VKA caesarean section is recommended.	I	C
It is recommended to discontinue VKA and start adjusted-dose intravenous UFH (aPTT ≥2x control) or adjusted-dose LMWH[c] (see separate recommendations) at the 36th week of gestation.	I	C
In pregnant women on LMWH or UFH, it is recommended to perform weekly anti-Xa level monitoring or aPTT monitoring with dose- adjustment (within 36 hours).	I	C
In pregnant women on VKA, it is recommended to perform INR monitoring weekly or every 2 weeks.	I	C
In pregnant women with LMWH, it is recommended to target anti-Xa levels 4–6 hours post-dose at 0.8–1.2 U/l (aortic valve prosthesis) or 1.0–1.2 IU/mL (mitral and right-sided valve prostheses).	I	C
It is recommended to replace LMWH with intravenous UFH (aPTT ≥2x control) at least 36 hours before planned delivery. UFH should be continued until 4–6 hours before planned delivery and restarted 4–6 hours after delivery if there are no bleeding complications.	I	C
It is recommended to anticipate timing of delivery to ensure safe and effective peripartum anticoagulation.	I	C
Immediate echocardiography is recommended in women with mechanical valves presenting with dyspnoea and/or an embolic event.	I	C
It is recommended to implement changes in the anticoagulation regimen during pregnancy in hospital.	I	C
During the second and third trimester until the 36th week VKAs are recommended in women needing a low dose.	I	C
A bioprosthesis should be considered in young women contemplating pregnancy.	IIa	C
During the second and third trimester until the 36th week VKAs should be considered in women needing a high dose.	IIa	C
Continuation of VKAs should be considered during the first trimester if the warfarin dose required for therapeutic anticoagulation is <5 mg/day (or phenprocoumon <3 mg/day or acenocoumarol <2 mg/day), after patient information and consent.	IIa	C

During the second and third trimester until the 36th week VKAs should be considered in women needing a high dose.	IIa	C
Continuation of VKAs should be considered during the first trimester if the warfarin dose required for therapeutic anticoagulation is <5 mg/day (or phenprocoumon <3 mg/day or acenocoumarol <2 mg/day), after patient information and consent.	IIa	C
Discontinuation of VKA between weeks 6 and 12 and replacement with adjusted-dose intravenous UFH (aPTT ≥2x control) or adjusted- dose LMWHc twice daily (see separate recommendations) should be considered in patients with a warfarin dose >5 mg/day (or phenprocoumon >3 mg/day or acenocoumarol >2 mg/day).	IIa	C
During the second and third trimesters, LMWH with anti-Xa level monitoring and dose adjustment (see separate recommendations) may be considered in women who need a high dose of VKA[e] after patient information and consent.	IIb	C
In pregnant women with LMWH, in addition to monitoring peak anti-Xa levels, monitoring predose levels targeted at ≥0.6 IU/mL may be considered.	IIb	C
LMWH is not recommended when weekly anti-Xa level monitoring and dose-adjustment is not available.	III	C

aPTT = activated partial thromboplastin time; INR = international normalized ratio; LMWH = low molecular weight heparin; UFH = unfractionated heparin; VKA = vitamin K antagonist.

[a]Class of recommendation - [b]Level of evidence - [c]The starting dose for LMWH is 1 mg/kg body weight for enoxaparin and 100 IU/kg for dalteparin, twice daily subcutaneously - [d]Low dose VKA: warfarin <5 mg/day (or phenprocoumon <3 mg/day or acenocoumarol <2 mg/day) - [e]High dose VKA: warfarin >5 mg/day (or phenprocoumon >3 mg/day or acenocoumarol >2 mg/day).

Pregnancy is associated with a three- to four-fold increase in AMI risk compared with age-matched non-pregnant women. The majority of CAD are of non-atherosclerotic causes, including pregnancy-related spontaneous coronary artery dissection (P-SCAD) (43%), angiographically normal coronary arteries (18%) and coronary thrombosis (17%).

Clinical presentation is the same as the non-pregnant population. Serum troponin rise should suggest myocardial ischaemia. Where the ECG is non-diagnostic, echocardiography may be helpful.

Management

AMI management in pregnancy is similar to that in the general population, including revascularization techniques. In P-SCAD, enhanced vascular vulnerability should be considered when applying revascularization strategies.

Therapy

Low-dose aspirin appears to be safe, but there is little information regarding P2Y inhibitors. Clopidogrel should be used only when strictly necessary. The effects of ionizing radiation should not prevent primary PCI in pregnant patients with standard indications for revascularization in AMI. The majority of reports regarding STEMI management in pregnancy relate to bare metal stents, however, new generation drug-eluting stents (DES) are recommended according to the 2017 AMI STEMI Guidelines. Stents usage has been reported in spontaneous coronary artery dissection; however, currently there is no evidence to recommend them in pregnancy.

Pregnancy may be considered in patients with known CAD in the absence of residual ischaemia and clinical signs of LV dysfunction.

Management of coronary artery disease

Recommendations	Class[a]	Level[b]
ECG and measurement of troponin levels are recommended when a pregnant woman has chest pain.	I	C
Primary coronary angioplasty is recommended as the preferred reperfusion therapy for STEMI during pregnancy.	I	C
An invasive management strategy should be considered for NSTE-ACS with high-risk criteria.	IIa	C
Conservative management should be considered for stable NSTE-ACS with low-risk criteria.	IIa	C
Follow-up should be considered over at least the next 3 months after NSTE-ACS	IIa	C
Breastfeeding is not recommended in mothers who take antiplatelet agents other than low-dose aspirin due to lack of data (see Chapter here).	III	C

ECG = electrocardiogram; LV = left ventricular; NSTE-ACS = non-ST-elevation acute coronary syndrome; NSTEMI = non-ST-elevation myocardial infarction; STEMI = ST-elevation myocardial infarction.

[a] Class of recommendation - [b] Level of evidence.

Management of native valvular heart disease		
Recommendations	**Class[a]**	**Level[b]**
Pre-pregnancy evaluation, including echocardiography, and counselling is recommended for any woman with known or suspected valvular disease.	I	C
Mitral stenosis		
In patients with symptoms or pulmonary hypertension, restricted activities and β-1 selective blockers are recommended.	I	B
Diuretics are recommended when congestive symptoms persist despite β-blockers.	I	B
Intervention is recommended before pregnancy in patients with MS and valve area <1.0 cm^2.	I	C
Therapeutic anticoagulation using heparins or VKA is recommended in case of atrial fibrillation, left atrial thrombosis, or prior embolism.	I	C
Intervention should be considered before pregnancy in patients with MS and valve area <1.5 cm^2.	IIa	C
Percutaneous mitral commissurotomy should be considered in pregnant patients with severe symptoms or systolic pulmonary artery pressure >50 mmHg despite medical therapy.	IIa	C
Aortic stenosis		
Intervention is recommended before pregnancy in patients with severe AS if:		
• they are symptomatic	I	B
• OR LV dysfunction (LVEF <50%) is present	I	C
• OR when they develop symptoms during exercise testing.	I	C
Intervention should be considered before pregnancy in asymptomatic patients with severe AS when a fall in blood pressure below baseline during exercise testing occurs.	IIa	C
Balloon aortic valvuloplasty should be considered during pregnancy in patients with severe AS and severe symptoms.	IIa	C
Chronic regurgitant lesions		
Surgical treatment is recommended before pregnancy in patients with severe aortic or mitral regurgitation and symptoms or impaired ventricular function or ventricular dilatation.	I	C
Medical therapy is recommended in pregnant women with regurgitant lesions when symptoms occur.	I	C

AS = aortic stenosis; LV = left ventricular; LVEF = left ventricular ejection fraction; MS = mitral stenosis; VKA = vitamin K antagonist. [a]Class of recommendation - [b]Level of evidence

The aetiology of pregnancy-associated cardiomyopathy includes acquired and inherited diseases, such as peripartum cardiomyopathy (PPCM), toxic cardiomyopathies, hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM), Takotsubo cardiomyopathy, and storage diseases.

Important predisposing factors include multiparity, African ethnicity, smoking, diabetes, pre-eclampsia, malnutrition, advanced age, and teenage pregnancy. PPCM presents with HF secondary to LV systolic dysfunction towards the end of pregnancy and in the months following delivery, with the majority diagnosed post-partum. The LV may be non-dilated, but the EF is usually <45%. Although symptoms and signs are often typical for HF, diagnosis is frequently delayed. Echocardiography is the imaging modality of choice. Initial LVEF <30%, marked LV dilatation (LV end diastolic diameter ≥6.0 cm), and RV involvement are associated with adverse outcomes. 6-month mortality ranges from 2.0% in Germany to 12.6% in a large cohort from South Africa or 24% over 24 months in Turkey. When the EF has not recovered to >50–55%, subsequent pregnancy should be discouraged.

Although PPCM and DCM are distinct disease entities, patients may share a genetic predisposition, and differentiation during pregnancy may be impossible. Pregnancy is poorly tolerated in some women with pre-existing DCM, with the potential for significant deterioration in LV function.

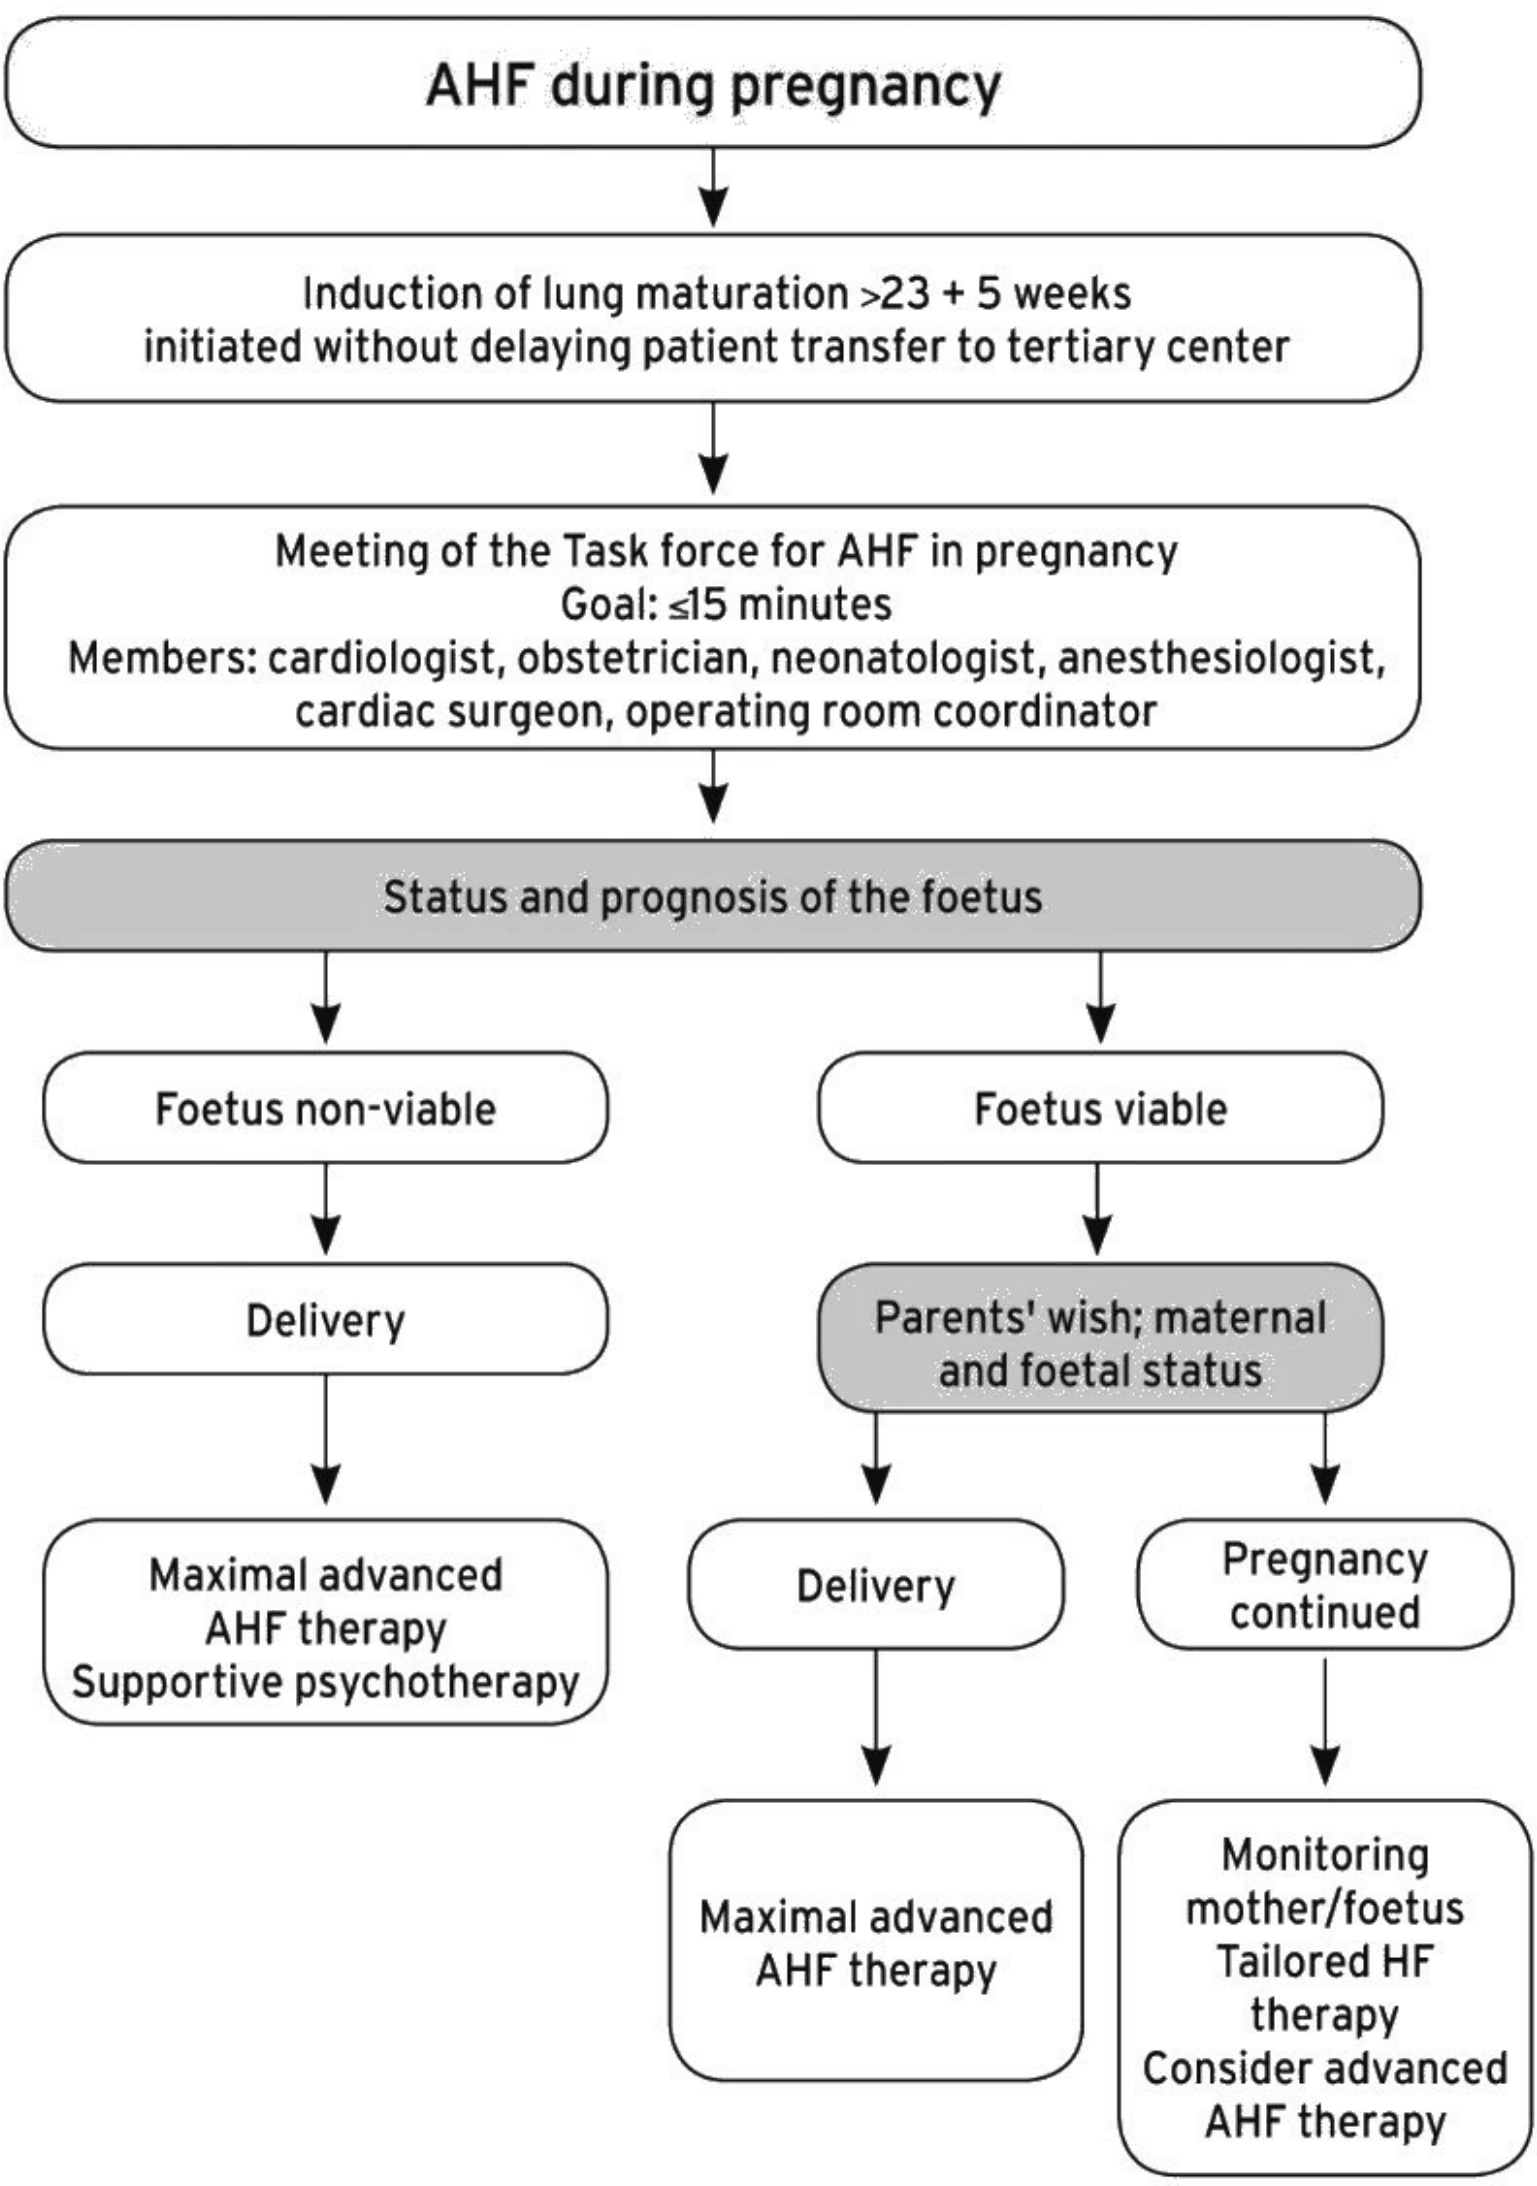
Pre-pregnancy management includes modification of existing HF medications to avoid foetal harm. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), angiotensin receptor neprilysin inhibitors (ARNIs), mineralocorticoid receptor antagonists (MRAs) and ivabradine are contra-indicated and should be stopped prior to conception. β- blockers should be switched to β-1-selective blockers.

HF in DCM or PPCM can develop rapidly and guidelines for the management of acute HF and cardiogenic shock apply. (Figures 3 and 4). Patients with symptoms and signs of acute HF should be evaluated according to acute HF guidelines.

If a patient is in cardiogenic shock or dependent on inotropes or vasopressors, mechanical circulatory support and urgent delivery by caesarean section (irrespective of gestation) should be considered.

Management goals are similar to non-pregnant acute HF, while avoiding fetotoxic agents (ACE inhibitors, ARB, ARNI, MRA, ivabradine, and atenolol) during pregnancy. HF with pulmonary congestion is treated with loop diuretics and thiazides if required. Standard indications for anticoagulation in PPCM and DCM apply during and after pregnancy. Addition of bromocriptine to standard HF therapy may improve LV recovery and clinical outcome in women with acute severe PPCM. Given the high rate of improvement of LV function during optimal HF drug therapy, early implantation of an implantable cardioverter-defibrillator (ICD) in patients with newly diagnosed PPCM or DCM is not appropriate. Cardiac transplantation is reserved for patients where mechanical circulatory support is not possible or desirable.

Figure 3 Management of acute heart failure (AHF) during pregnancy

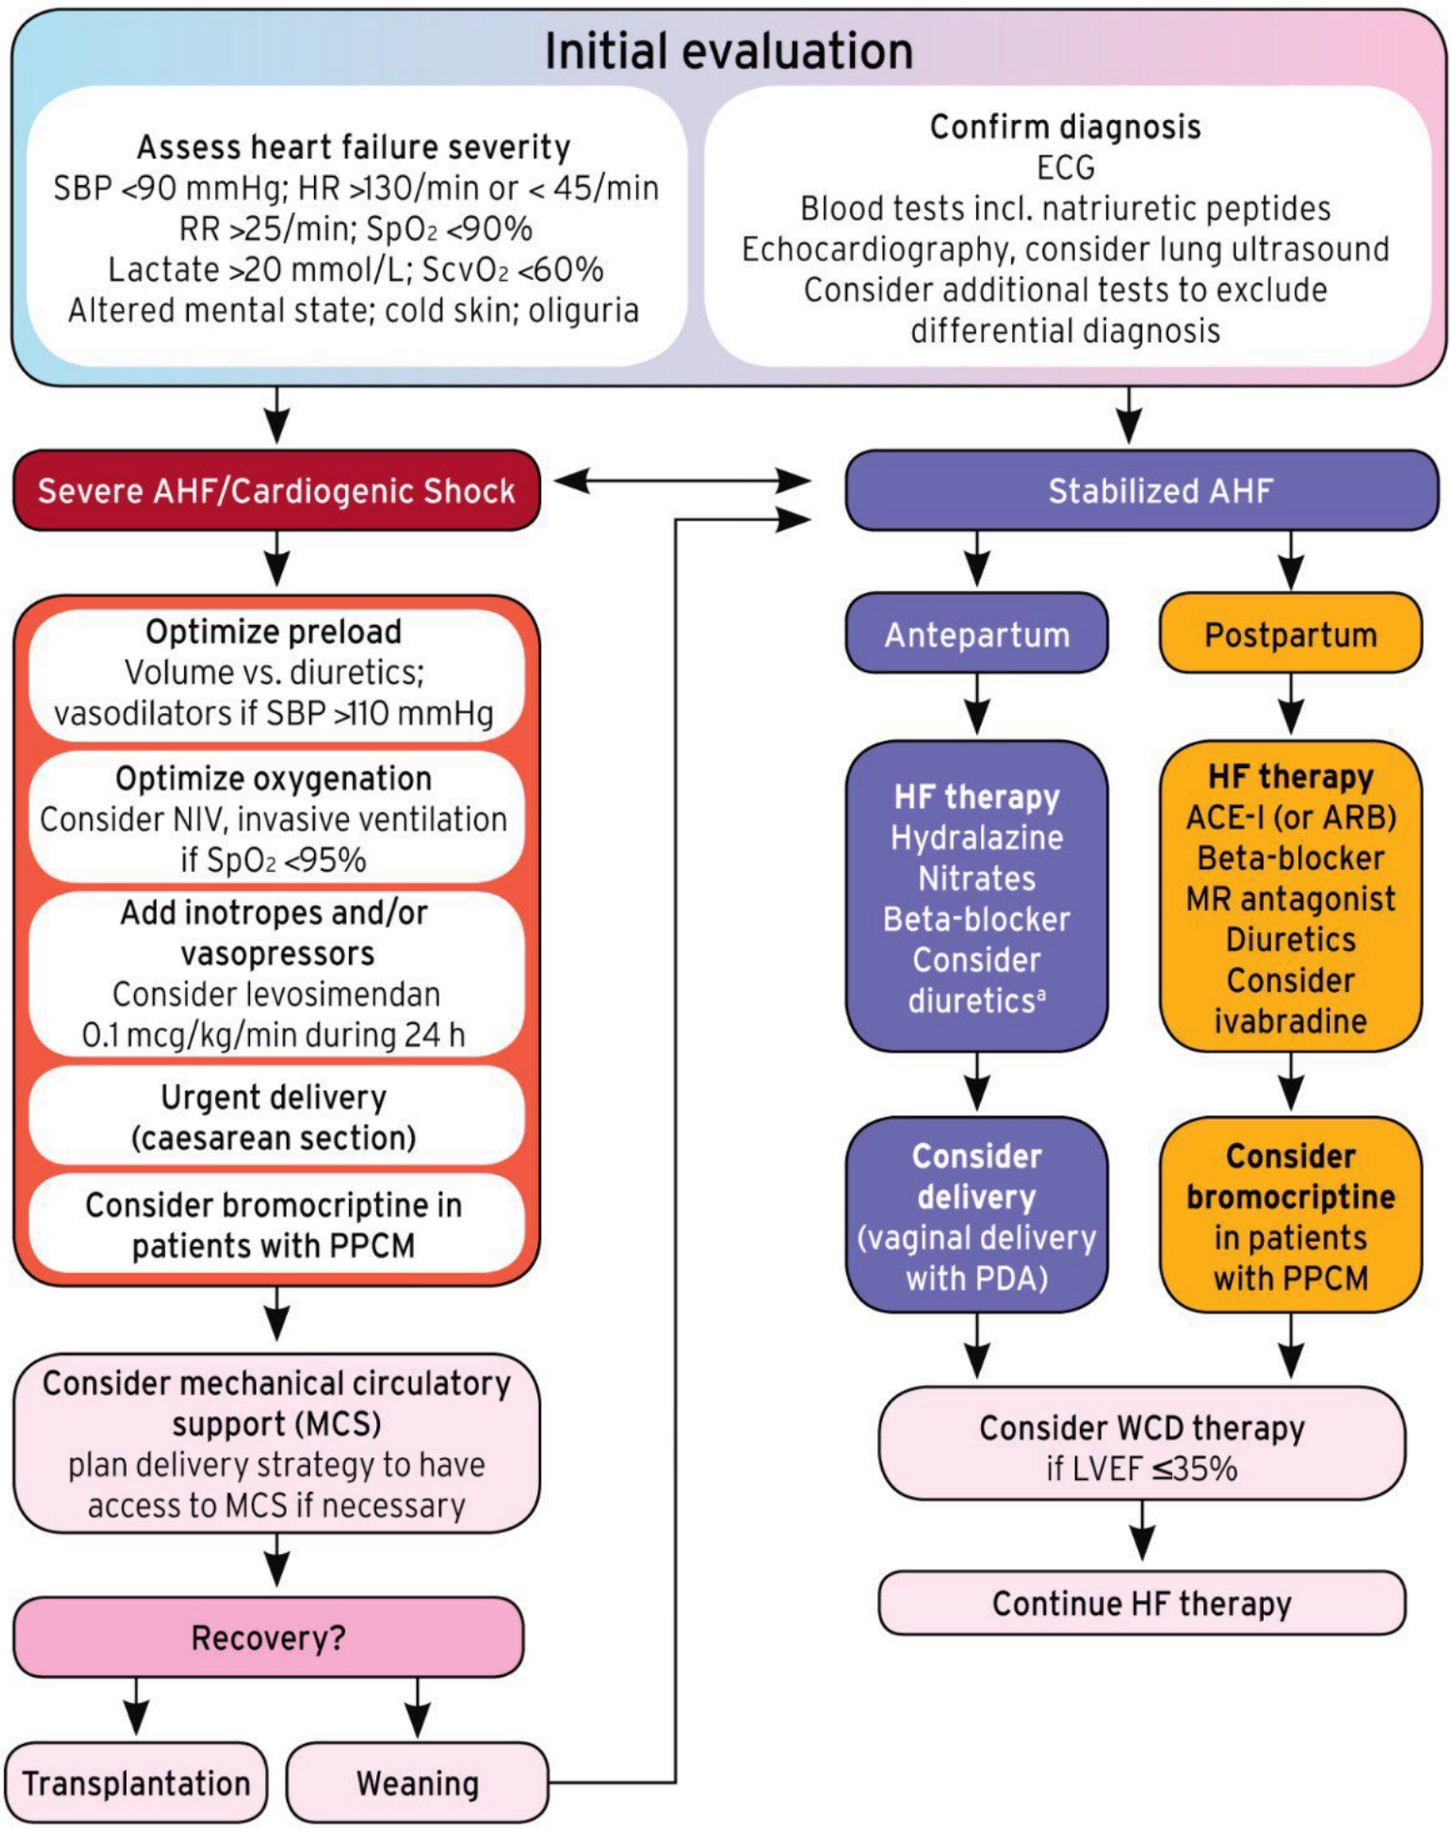


Example of a prespecified protocol of interdisciplinary work-up (modified from Bauersachs et al, EJHF 2016)

For interactivity see here

Figure 4 Management of acute heart failure (AHF) during/after pregnancy

Figure 4 Management of acute heart failure (AHF) during/after pregnancy



[a]Diuretics have to be used with caution due to potential reduction in placental blood flow.

Modified from Bauersachs et al, EJHF 2016: 18, 1096–1105

ACE-I = angiotensin converting enzyme inhibitor; ARB = angiotensin receptor blocker; (A)HF = (acute) heart failure; HR = heart rate; NIV = non-invasive ventilation; MR = mineralocorticoid receptor; PDA = peridural analgesia; PPCM = peripartum cardiomyopathy; RR = respiratory rate; SBP = systolic blood pressure; $ScvO^2$ = central venous oxygen saturation; SpO^2 = peripheral oxygen saturation; WCD = wearable cardioverter-defibrillator.

In stable congestive HF vaginal delivery is preferred with spinal/epidural analgesia. Urgent delivery by Caesarean section should be considered in women with advanced HF and haemodynamic instability. Epidural anaesthesia may be the method of choice.

In HF with reduced EF (HFrEF), breastfeeding is discouraged in more severe cases (e.g. NYHA III/IV).

Women with HCM usually tolerate pregnancy well (maternal mortality 0.5%, complication or worsening of symptoms in 29%). Foetal mortality by spontaneous abortion (15%), therapeutic abortion (5%), or stillbirth (2%) is comparable to the general population.

Cardioversion should be considered for poorly tolerated persistent AF. Therapeutic anticoagulation is recommended for those with paroxysmal or persistent arrhythmias. Patients with a past history or family history of sudden death need close surveillance.

Low-risk cases may have a spontaneous labour and vaginal delivery. Caesarean section should be considered in patients with severe LV outflow tract obstruction, pre-term labour while on OAC, or severe HF.

Management of cardiomyopathies and heart failure		
Recommendations	**Class[a]**	**Level[b]**
Anticoagulation is recommended in patients with intracardiac thrombus detected by imaging or with evidence of systemic embolism.	I	A
It is recommended to treat women with HF during pregnancy according to current guidelines for non-pregnant patients, respecting contraindications for some drugs in pregnancy (see Table 7).	I	B
It is recommended to inform women with HFrEF about the risk of deterioration of the condition during gestation and peripartum.	I	C
Therapeutic anticoagulation with LMWH or vitamin K antagonists according to stage of pregnancy is recommended for patients with atrial fibrillation.	I	C
In HFrEF it is recommended that β-blockers are continued in women who used them before pregnancy or are installed with caution, if clinically indicated.	I	C
In patients with PPCM and DCM counselling for recurrence risk during subsequent pregnancy is recommended in all cases, even if LV function has recovered.	I	C
As rapid diagnosis and decision making is crucial for all pregnant women with acute HF, a prespecified management algorithm and an interdisciplinary team should be established.	IIa	C
Patients in cardiogenic shock/dependent on inotropes should be transferred early to a facility where mechanical circulatory support is available.	IIa	C
Bromocriptine treatment should be accompanied by prophylactic (or therapeutic) anticoagulation (see Chapter here).	IIa	C
Due to high metabolic demands of lactation and breastfeeding, preventing lactation may be considered in patients with severe HF.	IIb	B
In patients with PPCM, bromocriptine treatment may be considered to stop lactation and enhance recovery (LV function).	IIb	B
In women with PPCM and DCM subsequent pregnancy is not recommended if LVEF does not normalize.	III	C
Hypertrophic cardiomyopathy (HCM)		
In patients with HCM the same risk stratifications as for non- pregnant women is recommended.	I	C
In patients with HCM, it is recommended that β-blockers are continued in women who used them before pregnancy.	I	C
In patients with HCM, β-blockers should be started in women who develop symptoms due to outflow tract obstruction or arrhythmia during pregnancy.	IIa	C
In HCM, cardioversion should be considered for persistent atrial fibrillation.	IIa	C

DCM = dilated cardiomyopathy; HCM = hypertrophic cardiomyopathy; HF = heart failure; HFrEF = heart failure with reduced ejection fraction; LMWH = low molecular weight heparin; LV = left ventricular; LVEF = left ventricular ejection fraction; PPCM = peripartum cardiomyopathy.

[a] Class of recommendation - [b] Level of evidence.

AF (27/100 000) and paroxysmal supraventricular tachycardia (PSVT) are, apart from premature beats, the most frequent arrhythmias. AF is associated with an increased mortality risk. Patients with a known history of any symptomatic supraventricular or ventricular tachycardia should be considered for catheter ablation prior to pregnancy.

Pregnant PSVT subjects have worse obstetric and foetal outcomes, with higher adjusted ORs (1.54–3.52) for severe maternal morbidity, caesarean delivery, low birth weight, preterm labour, foetal stress and foetal abnormalities, than those without PSVT.

Recommendations for acute termination of PSVT are outlined in the tables below. Intravenous administration of adenosine is recommended as first drug of choice for acute conversion of PSVT. For prevention of PSVT, β-blockers (exception for atenolol) or verapamil are first-line agents, except for patients with Wolff-Parkinson-White (WPW) syndrome.

Electrical cardioversion is recommended whenever ongoing AF is haemodynamically unstable or a considerable risk for the mother or the foetus. Cardioversion should generally be preceded by anticoagulation (see here). Intravenous β-blockers are recommended for rate control.

SCD is recognized as an increasing risk factor in pregnancy. Inherited arrhythmogenic disorders should always be looked for with appropriate diagnostic tests during or after pregnancy. Women with congenital LQTS are at substantial risk of cardiac events during the post-partum period. The choice of prophylactic antiarrhythmic drug therapy relates to the presence of underlying structural heart disease and LV function.

ICD implantation is recommended if an indication emerges during pregnancy. Non- selective β-blockers should be continued throughout pregnancy and during the post-partum period (at least 40 weeks after delivery) in patients with congenital LQTS and those with catecholaminergic polymorphic VT.

Bradyarrhythmias and conduction disturbances usually have a favourable outcome in the absence of underlying heart disease.

Sinus node dysfunction

Rare cases of sinus bradycardia may be related to the supine hypotensive syndrome of pregnancy. Symptomatic bradycardia should be managed by changing the position of the mother to a left lateral decubitus position. For persistent symptoms, a temporary pacemaker may be necessary.

Atrioventricular block

Isolated congenital complete heart block in the mother has a favourable outcome during pregnancy, especially when the escape rhythm has a narrow QRS complex.

Electrical cardioversion

Cardioversion seems safe in all phases of pregnancy as it does not compromise foetal blood flow and the risk of inducing foetal arrhythmias or initiating preterm labour seems small. The foetal heart rate should routinely be controlled after cardioversion.

Catheter ablation

Catheter ablation should be postponed to the second trimester if possible and performed at an experienced centre using non-fluoroscopic electroanatomic mapping and catheter navigation systems.

Implantable cardioverter-defibrillator and pacing

The implantation of an ICD should be considered prior to pregnancy in patients with high-risk factors for SCD. Treatment with an ICD during pregnancy does not cause an increased risk of major ICD-related complications and is recommended if an indication emerges. Implantations, for ICD preferably one chamber, can be performed safely, especially if the foetus is beyond 8 weeks' gestation. Echocardiographic guidance or electro-anatomical mapping may be helpful.

Table 6 Recommended surveillance levels at time of delivery in women with arrhythmias

	Level of surveillance[a]	Class[b]	Level[c]
Risk for arrhythmia with haemodynamic compromise at delivery: Low-risk			
PSVT, AF, idiopathic VT, low-risk LQTS, WPW syndrome.	1	I	C
Risk for arrhythmia with haemodynamic compromise at delivery: Medium-risk			
Unstable SVT, VT, those with an implanted ICD, VT and structural heart disease, Brugada syndrome. Moderate risk: LQTS, catecholaminergic polymorphic VT.	2	I	C
Risk for arrhythmia with haemodynamic compromise at delivery: High-risk for life threatening arrhythmia			
Unstable VT in structural heart disease/congenital heart disease, unstable VT/TdP in high-risk LQTS patients, short QT syndrome, high-risk catecholaminergic polymorphic ventricular tachycardia.	3	I	C

Descriptions of actions to be planned	**Surveillance level**

AF = atrial fibrillation; ICD = implantable cardioverter-defibrillator; LQTS = long QT syndrome; PSVT = paroxysmal supraventricular tachycardia; SVT = supraventricular tachycardia; TdP = torsade de pointes; VT = ventricular tachycardia, WPW = Wolfe-Parkinson-White.

[a] The risk stratification should follow published Guidelines for the particular disease.

[b] Class of recommendation - [c] Level of evidence.

Management of arrhythmias		
Recommendations	**Class[a]**	**Level[b]**
Acute management (intravenous administration of drugs) of SVT and AF		
Vagal manoeuvres, and if these fails, adenosine, are recommended for acute conversion of PSVT.	I	C
Immediate electrical cardioversion is recommended for any tachycardia with haemodynamic instability and for pre-excited AF.	I	C
β-1-selective blockers should be considered for acute conversion of PSVT.	IIa	C
Ibutilide or flecainide may be considered for termination of atrial flutter and AF in stable patients with structurally normal hearts[c].	IIb	C
Long-term management (oral administration of drugs) of SVT and AF		
β-1-selective blockers or verapamil[d] is recommended for prevention of SVT in patients without pre-excitation on resting ECG.	I	C
Flecainide[e] or propafenone[e] are recommended for prevention of SVT in patients with WPW syndrome.	I	C
β-selective blockers are recommended for rate control of AT or AF.	I	C
Flecainide[e], propafenone[e] or sotalol[f] should be considered to prevent SVT, AT and AF if AV nodal blocking agents fail.	IIa	C
Digoxin[d], verapamil[d] should be considered for rate control of AT or AF if β-blockers fail.	IIa	C
Catheter ablation with electroanatomic systems should be considered in experienced centres in case of drug-refractory and poorly tolerated SVT.	IIa	C
Acute management (intravenous administration of drugs) of Ventricular tachyarrhythmias		
Immediate electrical cardioversion is recommended for sustained both unstable and stable VT.	I	C
For acute conversion of sustained, haemodynamically stable, monomorphic VT (e.g. idiopathic VT), a β-blocker, sotalol[f], flecainide[e], procainamide or overdrive ventricular pacing should be considered.	IIa	C
Long-term management (oral administration of drugs) of Ventricular tachyarrhythmias		

case of drug-refractory and poorly tolerated SVT.		
Acute management (intravenous administration of drugs) of Ventricular tachyarrhythmias		
Immediate electrical cardioversion is recommended for sustained both unstable and stable VT.	I	C
For acute conversion of sustained, haemodynamically stable, monomorphic VT (e.g. idiopathic VT), a β-blocker, sotalol[f], flecainide[e], procainamide or overdrive ventricular pacing should be considered.	IIa	C
Long-term management (oral administration of drugs) of Ventricular tachyarrhythmias		
ICD (preferably one chamber) is recommended prior to pregnancy if clinically indicated. If indication emerges during pregnancy, ICD implantation is recommended using echocardiographic guidance or mapping, especially if foetus is beyond 8 weeks' gestation.	I	C
β-blocking agents are recommended during pregnancy and post- partum in patients with long QT syndrome or catecholaminergic polymorphic ventricular tachycardia.	I	C
β-blocking agents or verapamil[d,e] are recommended for prevention of idiopathic sustained VT if associated with severe symptoms or haemodynamic compromise.	I	C
In idiopathic sustained VT sotalol[f] or flecainide[e] should be considered for prevention if other drugs fail.	IIa	C
Catheter ablation with electroanatomic mapping systems may be considered in experienced centres in sustained drug-refractory and poorly tolerated VT if there are no other alternatives.	IIb	C

AF = atrial fibrillation; AT = atrial tachycardia; AV = atrioventricular; ECG = electrocardiogram; ICD = implantable cardioverter-defibrillator; PSVT = paroxysmal supraventricular tachycardia; SVT = supraventricular tachycardia; TdP = torsade de pointes; VT = ventricular tachycardia; WPW = Wolff-Parkinson-White.

[a] Class of recommendation - [b] Level of evidence - [c] Cardioversion of AF and atrial flutter should generally be preceded by anticoagulation (see below). - [d] AV nodal blocking agents should not be used in patients with pre-excitation on resting ECG or pre-excited AF - [e] Flecainide and propafenone should be combined with AV nodal blocking agents for certain atrial tachycardias, but structural heart disease, reduced left ventricular function and bundle branch block should be excluded - [f] Vaughan Williams class III antiarrhythmic drugs should not be used in patients with prolonged QTc.

Hypertensive disorders in pregnancy are the most common medical complications, affecting 5–10% of pregnancies worldwide.

Repeated BP readings should be performed, preferably on two occasions in the sitting position (or the left lateral recumbent during labour) with an appropriately- sized arm cuff at heart level and using Korotkoff V for diastolic BP (DBP). The diagnosis of hypertension in pregnancy by ambulatory BP monitoring (ABPM) is superior to routine BP measurement for the prediction of pregnancy outcome. Only devices validated according to recognized protocols should be used in pregnancy. Basic laboratory investigations include urinalysis, blood count, haematocrit, liver enzymes, serum creatinine, and serum uric acid. All pregnant women should be assessed for proteinuria in early pregnancy to detect pre-existing renal disease and, in the second half of pregnancy, to screen for pre-eclampsia.

The definition of hypertension in pregnancy is based only on office (or in-hospital) BP values (systolic BP [SBP] ≥140 mmHg and/or DBP ≥90 mmHg) and distinguishes mildly (140–159/90–109 mmHg) or severely (≥160/110 mmHg) elevated BP. Hypertension in pregnancy is not a single entity but comprises:

- Pre-existing hypertension: precedes pregnancy or develops before 20 weeks' gestation. It usually persists for more than 42 days post-partum and may be associated with proteinuria.
- Gestational hypertension: develops after 20 weeks' gestation and usually resolves within 42 days post-partum.
- Pre-eclampsia: gestational hypertension with significant proteinuria (>0.3 g/24h or ≥30 mg/mmol albumin/creatinine ratio). It occurs more frequently during the first pregnancy, in multiple pregnancy, in hydatidiform mole, in antiphospholipid syndrome, or with pre-existing hypertension, renal disease or diabetes. The only cure is delivery.
- Pre-existing hypertension plus superimposed gestational hypertension with proteinuria.
- Antenatally unclassifiable hypertension

Women at high or moderate risk of pre-eclampsia should be advised to take 100–150 mg of aspirin daily from week 12 to weeks 36–37.

Overview

Management of hypertension in pregnancy depends on BP, gestational age and the presence of associated maternal and foetal risk factors.

Most women with pre-existing hypertension and normal renal function have non- severe hypertension (140–159/90–109 mmHg) and are at low-risk for cardiovascular complications. Some are able to withdraw their medication in the first half of pregnancy because of the physiological fall in BP.

Evidence-based data regarding treatment of hypertension in pregnancy are lacking. In terms of treatment benefit, tight versus less tight control of hypertension in pregnancy in the Control of Hypertension in Pregnancy Study (CHIPS) was associated with less severe maternal hypertension, but no difference in the risk of adverse perinatal outcomes and overall serious maternal complications.

Non-pharmacological management of hypertension during pregnancy has a limited role to play with randomized studies of dietary and lifestyle interventions showing minimal effects on pregnancy outcome. Regular exercise might be continued with caution and obese women (≥30 kg/m^2) are advised to avoid a weight gain of more than 6.8 kg.

While the goal of treating hypertension is to reduce maternal risk, the agents selected must be effective and safe for the foetus.

Treatment of severe hypertension

There is no agreed definition of severe hypertension, with values ranging between 160 and 180 mmHg/>110 mmHg. This Task Force recommends considering an SBP ≥170 mmHg or DBP ≥110 mmHg in a pregnant woman an emergency, and hospitalization is indicated. The selection of the antihypertensive drug and its route of administration depend on the expected time of delivery. ACE inhibitors, ARBs and direct renin inhibitors are strictly contraindicated (see Chapter 12). Pharmacological treatment with i.v. labetalol, oral methyldopa, or nifedipine should be initiated; i.v. hydralazine is no longer the drug of choice. However, hydralazine is still commonly used when other treatment regimens have failed. Intravenous urapidil can also be considered. Sodium nitroprusside should only be used as the drug of last choice. The drug of choice when pre-eclampsia is associated with pulmonary oedema is nitroglycerin (glyceryl trinitrate).

Treatment of mild-to-moderate hypertension

Despite lack of evidence, the European guidelines recommend to initiate drug treatment in all women with persistent elevation of BP ≥150/95 mmHg and at values >140/90 mmHg in women with: gestational hypertension (with or without proteinuria); with pre-existing hypertension with the superimposition of gestational hypertension and hypertension with subclinical organ damage or symptoms at any time during pregnancy.

Methyldopa, β-blockers (most data available for labetalol) and calcium antagonists (most data available for nifedipine) are the drugs of choice. β-blockers appear to be less effective than calcium antagonists and may induce foetal bradycardia, growth retardation and hypoglycaemia. Women with pre-existing hypertension may continue their current antihypertensive medication unless on ACE inhibitors, ARBs, and direct renin inhibitors, which are contra-indicated due to adverse foetal and neonatal outcomes. Diuretic therapy is best avoided unless in the context of oliguria when low-dose furosemide may be considered. Intravenous magnesium sulfate is recommended for the prevention of eclampsia and treatment of seizures.

Delivery is indicated in pre-eclampsia with visual disturbances or haemostatic disorders and at 37 weeks in asymptomatic women. Breastfeeding does not increase BP in the nursing mother.

Post-partum hypertension is common in the first week. Methyldopa should be avoided because of the risk of post-partum depression.

Women experiencing hypertension in their first pregnancy are at increased risk in a subsequent pregnancy. The earlier the onset of hypertension in the first pregnancy, the higher the risk of recurrence in a subsequent pregnancy.

Women who develop gestational hypertension or pre-eclampsia are at increased risk of hypertension, stroke, and ischaemic heart disease in later adult life. Lifestyle modifications are primarily indicated to avoid complications in subsequent pregnancies and to reduce maternal cardiovascular risk in the future. Therefore, regular visits to a primary care physician to check BP and metabolic factors are recommended.

Management of hypertension		
Recommendations	**Class[a]**	**Level[b]**
Low-dose aspirin (100–150 mg daily) is recommended in women at high or moderate risk of pre-eclampsia from week 12 to weeks 36–37.	I	A
In women with gestational hypertension or pre-existing hypertension superimposed by gestational hypertension or with hypertension and subclinical organ damage or symptoms, initiation of drug treatment is recommended at SBP >140 mmHg or DBP >90 mmHg. In all other cases, initiation of drug treatment is recommended if SBP ≥150 mmHg or DBP ≥95 mmHg.	I	C
SBP ≥170 mmHg or DBP ≥110 mmHg in a pregnant woman is an emergency, and hospitalization is recommended.	I	C
Methyldopa, labetalol, and calcium antagonists are recommended for the treatment of hypertension in pregnancy.	I	B methyldopa C (labetalol, calcium antagonists)
In women with gestational hypertension or mild pre-eclampsia, delivery is recommended at 37 weeks.	I	B
It is recommended to expedite delivery in pre-eclampsia and with adverse conditions such as visual disturbances or haemostatic disorders.	I	C
In pre-eclampsia associated with pulmonary oedema, nitroglycerin given as an intravenous infusion is recommended.	I	C
In severe hypertension, drug treatment with intravenous labetalol or oral methyldopa or nifedipine is recommended.	I	C
Limitation of weight gain to <6.8 kg should be considered in obese women.	IIa	C
ACE inhibitors, ARBs or direct renin inhibitors are not recommended.	III	C

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; BP = blood pressure; DBP = diastolic blood pressure; SBP = systolic blood pressure.
[a] Class of recommendation - [b] Level of evidence.

VTE, encompassing PE and deep vein/venous thrombosis (DVT), represents a significant cause of pregnancy-related morbidity and mortality. The risk of VTE is highest in the immediate post-partum period with rates of nearly 0.5% reported. In women with previous VTE, recurrence rates are 7.6% despite the use of LMWH.

All women should undergo a documented assessment of risk factors for VTE before pregnancy or in early pregnancy. Based on this, women can be classified as being at high, intermediate or low-risk of VTE and preventative measures applied accordingly. Previous unprovoked recurrent VTEs and previous VTE—unprovoked or oestrogen related—are considered high-risk factors.

LMWH has become the drug of choice for the prevention and treatment of VTE in pregnant patients. The initial dose of LMWH for thromboprophylaxis should be based on the booking weight (body weight at the first antenatal appointment with the gynaecologist) Patients at high-risk for VTE should receive prophylactic enoxaparin at 0.5 IU/kg of body weight once daily or other LMWH at equivalent doses, according to local practice. In morbidly obese women a weight-based dosing instead of a fixed dosing is more appropriate in order to achieve adequate anti-Xa concentrations.

Pulmonary embolism

For diagnosis, a high index of suspicion is important and all pregnant women with signs and symptoms suggestive of VTE should have objective testing performed urgently and receive therapeutic anticoagulation until the diagnosis is established. D-dimer levels increase physiologically with each trimester. Thus, a positive D-dimer test in pregnancy is not necessarily indicative of VTE and normal D-dimer concentrations have been reported in pregnant women with VTE, meaning that imaging remains the diagnostic test of choice during pregnancy.

LMWH: In suspected DVT or PE, therapeutic LMWH should be given until the diagnosis is excluded by objective testing The recommended therapeutic dose is calculated on early pregnancy body weight aiming for 4–6 hour peak anti-Xa values of 0.6–1.2 IU/mL.

UFH: Typically, UFH is used in the acute treatment of massive pulmonary emboli. (Chapter here).

Thrombolysis: Thrombolytics should only be used in patients with severe hypotension or shock

Fondaparinux: Fondaparinux (7.5 mg once a day in normal-weight pregnant woman) can be considered if there is an allergy or adverse response to LMWH (Chapter here).

Post-partum management:

In patients with recent PE, pre-partum heparin treatment should be restarted 6 hours after a vaginal birth and 12 hours after a caesarean delivery, if no significant bleeding has occurred, with subsequent overlap with VKAs for at least 5 days. VKAs may be started on the second day after delivery and continued for at least 3 months or for 6 months if PE occurred late in pregnancy. The INR should be between 2 and 3 and needs regular monitoring, ideally every 1–2 weeks.

Acute deep vein thrombosis

Leg swelling is a frequent finding in pregnancy, giving rise to the suspicion of DVT. Since DVT is left sided in >85% of cases swelling of the left leg is more suspicious. Three clinical variable – left leg presentation, >2 cm calf circumference difference, and first trimester – allowed a negative predictive value of 100% if ultrasound of the legs was negative.

Compression ultrasound is the diagnostic imaging procedure of choice for suspected DVT in pregnancy with a high sensitivity and specificity for proximal DVT. In acute DVT, treatment with therapeutic doses of weight adjusted LMWH should be given twice daily (as in PE).

Prevention and treatment of venous thromboembolism		
Recommendations	**Class[a]**	**Level[b]**
LMWH is recommended for the prevention and treatment of VTE in pregnant patients.	I	B
For high-risk women it is recommended to give a weight-related prophylactic dose of LMWH (e.g. enoxaparin 0.5 mg/kg once daily).	I	B
A documented assessment of risk factors for VTE before pregnancy or in early pregnancy is recommended in all women.	I	C
It is recommended that the therapeutic dose of LMWH is based on body weight.	I	C
Thrombolytics to manage patients with pulmonary embolism is only recommended in patients with severe hypotension or shock.	I	C
In high-risk women, it is recommended to convert LMWH to UFH at least 36 hours prior to delivery and stop the UFH infusion 4–6 hours prior to anticipated delivery. aPTT should be normal before regional anaesthesia.	I	C
In low-risk women on therapeutic LMWH, induction or caesarean section is recommended to be performed 24 hours after the last dose of LMWH.	I	C
For women after in vitro fertilization complicated by OHSS thromboprophylaxis with LMWH is recommended during the first trimester.	I	C
In women who are on antenatal anticoagulation it should be considered to actively manage the third stage of labour with oxytocin.	IIa	C
If compression ultrasound is negative, using magnetic resonance venography should be considered to diagnose pelvic thrombosis before using computed tomography pulmonary angiography or ventilation perfusion scanning.	IIa	C
In women on therapeutic LMWH, planned delivery should be considered at around 39 weeks to avoid the risk of spontaneous labour while fully anticoagulated (LMWH is only partially reversed with protamine).	IIa	C
Direct oral anticoagulants are not recommended in pregnancy.	III	B

aPTT = activated partial thromboplastin time; LMWH = low molecular weight heparin; OHSS = ovarian hyperstimulation syndrome; UFH = unfractionated heparin; VTE = venous thromboembolism.

[a] Class of recommendation - [b] Level of evidence.

There are no uniform recommendations for the treatment of pregnant women yet. In case of emergency, drugs that are not recommended by international agencies during pregnancy and breastfeeding should not be withheld from the mother. The potential risk of a drug and the possible benefit of the therapy must be weighed against each other.

US Food and Drug Administration classification

On 30 June 2015 the US Food and Drug Administration (FDA) changed the previously used classification system for counselling of pregnant women and nursing mothers requiring drug therapy. The former A to X categories have been replaced by the Pregnancy and Lactation Labelling Rule (PLLR), which provides a descriptive risk summary and detailed information on animal and clinical data. PLLR applies immediately for prescription drugs approved after 30 June 2015, and the former FDA categories have to be removed for all other drugs until 29 June 2018. However, the former FDA categories will be present in the literature for a longer period of time, and therefore Table 7 (Drugs and safety data) provides information on both systems.

The previous classification consisted of category A (safest) to Category D (evidence of human foetal risk) and, X (known danger—do not use!).

Drug use in pregnancy

Recommendations	Class[a]	Level[b]
Before pharmacological treatment in pregnancy is started, it is recommended to check drug Table 7 for clinical safety data.	I	C
In the absence of clinical safety data it is recommended to check electronic drug table (www.safefetus.com) for preclinical safety data.	I	C
In the absence of adequate human safety data, decision-making should be based on individual drug efficacy and safety profile, and available animal data, and the decision must be made together with the patient.	IIa	C
Decision-making based on former FDA categories alone is no longer recommended.	III	C

FDA = Food and Drug Administration.
[a] Class of recommendation - [b] Level of evidence.

Table 7: Drugs and safety data is available in the Full text of the ESC Guidelines for cardiovascular Diseases during pregnancy at: www.escardio.org/guidelines

2017 ESC Pocket Guidelines

Committee for Practice Guidelines

VHD

2017 ESC/EACTS Guidelines for the Management of Valvular Heart Disease

ESC
European Society of Cardiology

EACTS

www.escardio.org/guidelines

Since the previous version of the Guidelines on the management of VHD was published, in 2012, new evidence has accumulated, particularly on percutaneous interventional techniques and on risk stratification with regard to timing of intervention in VHD making the present update necessary. This document focuses on acquired VHD and is oriented towards management. It does not deal with endocarditis or congenital valve disease, including pulmonary valve disease, as separate guidelines have been published by the ESC on these topics.

Patient evaluation

Essential questions in the evaluation

The aims of the evaluation of patients with VHD are to diagnose, quantify, and assess the mechanism of VHD as well as its consequences. Decision-making for intervention should be made by a "Heart Team" with a particular expertise in VHD, comprising cardiologists, cardiac surgeons, imaging specialists, anaesthetists, and if needed, general practitioners, geriatricians, and heart failure, electrophysiology or intensive care specialists. The "Heart Team" approach is particularly advisable in the management of high-risk patients and is also important for other subsets, such as asymptomatic patients where the evaluation of valve reparability is a key component in decision-making. The essential questions in the evaluation of a patient for valvular intervention are summarized in Table 3.

Table 3 Essential questions in the evaluation of patients for valvular intervention

Questions
• How severe is VHD?
• What is the aetiology of VHD?
• Does the patient have symptoms?
• Are symptoms related to valvular disease?
• Are any signs present in asymptomatic patients that indicate a worse outcome if the intervention is delayed?
• What are the patient's life expectancy[a] and expected quality of life?
• Do the expected benefits of intervention (versus spontaneous outcome) outweigh its risks?
• What is the optimal treatment modality? Surgical valve replacement (mechanical or biological), surgical valve repair, or catheter intervention?
• Are local resources (local experience and outcome data for a given intervention) optimal for the planned intervention?
• What are the patient's wishes?

[a]Life expectancy should be estimated according to age, sex, comorbidities, and country-specific life expectancy.

Overview

Precise evaluation of the patient's history and symptomatic status as well as proper physical examination, in particular auscultation and search for heart failure signs, are crucial for the diagnosis and management of VHD. In addition, assessment of the extracardiac condition – comorbidities and general condition – require particular attention. Echocardiography is the key technique to diagnose VHD and to assess its aetiology, severity, mechanisms, pathophysiologic consequences (cardiac chamber size, ventricular function, pulmonary artery pressure) and prognosis. Other non-invasive investigations such as stress testing, CMR, CT, fluoroscopy, and biomarkers are complementary, and invasive investigation beyond preoperative coronary angiography is restricted to situations where non-invasive evaluation is inconclusive.

Echocardiographic criteria for the definition of severe valve stenosis are indicated in the corresponding sections, and quantification of regurgitant lesions is summarized in Table 4. An integrated approach including various criteria is strongly recommended instead of referring to single measurements. Indications for coronary angiography are summarized in the Table "Management of CAD in patients with VHD".

Risk stratification

Risk stratification applies to any sort of intervention and is required for weighing the risk of intervention against the expected natural history of VHD as a basis for decision-making. Most experience relates to surgery and TAVI. While EuroSCORE I markedly overestimates 30-day mortality and should therefore be replaced by the better performing EuroSCORE II with this regard, it is nevertheless provided in this document for comparison as it has been used in many TAVI studies/ registries and may still be useful to identify the subgroups of patients for decision between intervention modalities and to predict 1-year mortality. Both scores have, however, major limitations for practical use by insufficiently considering disease severity and not including major risk factors such as frailty, porcelain aorta, chest radiation etc. It remains essential not to rely on a single risk score figure when assessing patients, nor to determine unconditionally the indication and type of intervention. Patient's life expectancy, expected quality of life, and patient preference should be considered, as well as local resources and results. The futility of interventions in patients unlikely to benefit from the treatment has to be taken into consideration, particularly for TAVI and mitral edge-to- edge repair. The role of the Heart Team is essential to take all of these data into account and adopt a final decision on the best treatment strategy.

Table 4 Echocardiographic criteria for the definition of severe valve regurgitation: an integrative approach (adapted from Lancellotti *et al.*)		
Aortic regurgitation		
Qualitative		
Valve morphology	Abnormal/flail/large coaptation defect	
Colour flow regurgitant jet	Large in central jets, variable in eccentric jets[a]	
CW signal of regurgitant jet	Dense	
Other	Holodiastolic flow reversal in descending aorta (EDV >20 cm/s)	
Semiquantitative		
Vena contracta width (mm)	>6	
Upstream vein flow[c]	–	
Inflow	–	
Other	Pressure half-time <200 ms[f]	
Quantitative		
EROA (mm^2)	≥30	
Regurgitant volume (mL/beat)	≥60	
+ enlargement of cardiac chambers/vessels	LV	
Mitral regurgitation		
Qualitative		
Valve morphology	Flail leaflet/ruptured papillary muscle/large coaptation defect	
Colour flow regurgitant jet	Very large central jet or eccentric jet adhering, swirling, and reaching the posterior wall of the LA	
CW signal of regurgitant jet	Dense/triangular	
Other	Large flow convergence zone[a]	
Semiquantitative		
Vena contracta width (mm)	≥7 (>8 for biplane)[b]	
Upstream vein flow[c]	Systolic pulmonary vein flow reversal	
Inflow	E-wave dominant ≥1.5 m/s[d]	
Other	TVI mitral/TVI aortic >1.4	
Quantitative	**Primary**	**Secondary[h]**
EROA (mm^2)	≥40	≥20
Regurgitant volume (mL/beat)	≥60	≥30
+ enlargement of cardiac chambers/vessels	LV,LA	

Tricuspid regurgitation	
Qualitative	
Valve morphology	Abnormal/flail/large coaptation defect
Colour flow regurgitant jet	Very large central jet or eccentric wall impinging jet[a]
CW signal of regurgitant jet	Dense/triangular with early peaking (peak <2 m/s in massive TR)
Other	–
Semiquantitative	
Vena contracta width (mm)	≥7[a]
Upstream vein flow[c]	Systolic hepatic vein flow reversal
Inflow	E-wave dominant ≥1 m/s[e]
Other	PISA radius >9 mm[g]
Quantitative	
EROA (mm^2)	≥40
Regurgitant volume (mL/beat)	≥45
+ enlargement of cardiac chambers/vessels	RV, RA, inferior vena cava

CW = continuous wave; EDV = end-diastolic velocity; EROA = effective regurgitant orifice area; LA = left atrium/ atrial; LV = left ventricle/ventricular; PISA = proximal isovelocity surface area; RA = right atrium/right atrial; RV = right ventricle; TR = tricuspid regurgitation; TVI = time-velocity integral.

[a]At a Nyquist limit of 50–60 cm/s - [b]For average between apical four- and two-chamber views - [c]Unless other reasons for systolic blunting (atrial fibrillation, elevated atrial pressure) - [d]In the absence of other causes of elevated LA pressure and of mitral stenosis - [e]In the absence of other causes of elevated RA pressure - [f]Pressure half-time is shortened with increasing LV diastolic pressure, vasodilator therapy, and in patients with a dilated compliant aorta, or lengthened in chronic aortic regurgitation - [g]Baseline Nyquist limit shift of 28 cm/s- [h]Different thresholds are used in secondary mitral regurgitation where an EROA >20 mm^2 and regurgitant volume >30 mL identify a subset of patients at increased risk of cardiac events.

Management of coronary artery disease in patients with VHD (adapted from Windecker *et al.*)

Recommendations	Class[a]	Level[b]
Diagnosis of coronary artery disease		
Coronary angiography[c] is recommended before valve surgery in patients with severe VHD and any of the following: • history of cardiovascular disease • suspected myocardial ischaemia[d] • LV systolic dysfunction • in men aged over >40 years and postmenopausal women • one or more cardiovascular risk factors.	I	C
Coronary angiography is recommended in the evaluation of moderate to severe secondary mitral regurgitation.	I	C
CT angiography should be considered as an alternative to coronary angiography before valve surgery in patients with severe VHD and low probability of CAD or in whom conventional coronary angiography is technically not feasible or associated with a high-risk.	IIa	C
Indications for myocardial revascularization		
CABG is recommended in patients with a primary indication for aortic/ mitral valve surgery and coronary artery diameter stenosis ≥70%.[e]	I	C
CABG should be considered in patients with a primary indication for aortic/mitral valve surgery and coronary artery diameter stenosis ≥50–70%.	IIa	C
PCI should be considered in patients with a primary indication to undergo TAVI and coronary artery diameter stenosis >70% in proximal segments.	IIa	C
PCI should be considered in patients with a primary indication to undergo transcatheter mitral valve interventions and coronary artery diameter stenosis >70% in proximal segments.	IIa	C

CABG = coronary artery bypass grafting; CAD = coronary artery disease; CT = computed tomography; LV = left ventricular; MSCT = multislice computed tomography; PCI = percutaneous coronary intervention; TAVI = transcatheter aortic valve implantation;VHD = valvular heart disease.

[a]Class of recommendation - [b]Level of evidence - [c]MSCT may be used to exclude CAD in patients who are at low risk of atherosclerosis - [d]Chest pain, abnormal non-invasive testing - [e]≥50% can be considered for left main stenosis.

Special considerations in elderly patients

Poor mobility, as assessed by the 6-minute walk test, and oxygen dependency are the main factors associated with increased mortality after TAVI and other VHD treatments. The combination of severe lung disease, post-operative pain from sternotomy or thoracotomy, and prolonged time under anaesthesia in patients undergoing traditional surgical aortic valve replacement may contribute to pulmonary complications. There is a gradual relationship between the impairment of renal function and increased mortality after surgical and catheter interventions. Coronary, cerebrovascular, and peripheral artery disease have a negative impact on early and late survival.

Endocarditis prophylaxis

Antibiotic prophylaxis should be considered for high-risk procedures in patients with prosthetic valves including transcatheter valves or repairs using prosthetic material and those with previous episodes of infective endocarditis. Detailed recommendations are given in dedicated guidelines.

Prophylaxis for rheumatic fever

Prevention of rheumatic heart disease should preferably be orientated to preventing the first attack of acute rheumatic fever. Antibiotic treatment of Group A Streptococcus sore throat is key in primary prevention. In patients with rheumatic heart disease, secondary long-term prophylaxis against rheumatic fever is recommended. Lifelong prophylaxis should be considered in high-risk patients according to the severity of VHD and exposure to Group A Streptococcus.

Heart Team and heart valve centres

The main purpose of heart valve centres as centres of excellence in the treatment of VHD is to deliver better quality of care. This is achieved through greater volumes associated with specialization of training, continuing education, and clinical interest. Specialization will also result in timely referral of patients before irreversible adverse effects occur, and evaluation of complex VHD conditions. Techniques with a steep learning curve may be performed with better results in hospitals with high volumes and more experience. These main aspects are presented in Table 5.

Table 5 Recommended requirements of a heart valve centre (modified from Chambers *et al.*)

Requirements
Multidisciplinary teams with competencies in valve replacement, aortic root surgery, mitral, tricuspid and aortic valve repair, as well as transcatheter aortic and mitral valve techniques including reoperations and reinterventions. The Heart Teams must meet on a regular basis and work with standard operating procedures.
Imaging, including 3D and stress echocardiographic techniques, perioperative TOE, cardiac CT, MRI, and positron emission tomography-CT.
Regular consultation with community, other hospitals, and extracardiac departments, and between non-invasive cardiologists and surgeons and interventional cardiologists.
Back-up services including other cardiologists, cardiac surgeons, intensive care and other medical specialties.
Data review: • Robust internal audit processes including mortality and complications, repair rates, durability of repair, and reoperation rate with a minimum of 1-year follow-up. • Results available for review internally and externally. • Participation in national or European quality databases.

Management of CAD and atrial fibrillation are summarized in the according tables.

Management of atrial fibrillation in patients with VHD

Recommendations	Class[a]	Level[b]
Anticoagulation		
NOACs should be considered as an alternative to VKAs in patients with aortic stenosis, aortic regurgitation, and mitral regurgitation presenting with atrial fibrillation.	IIa	B
NOACs should be considered as alternative to VKAs after the thirdmonth of implantation in patients who have atrial fibrillation associated with a surgical or transcatheter aortic valve bioprosthesis.	IIa	C
The use of NOACs is not recommended in patients with atrial fibrillation and moderate to severe mitral stenosis.	III	C
NOACS are contra-indicated in patients with a mechanical valve.	III	B
Surgical interventions		
Surgical ablation of atrial fibrillation should be considered in patients with symptomatic atrial fibrillation who undergo valve surgery.	IIa	A
Surgical ablation of atrial fibrillation may be considered in patients with asymptomatic atrial fibrillation who undergo valve surgery, if feasible, with minimal risk.	IIb	C
Surgical excision or external clipping of the LA appendage may be considered in patients undergoing valve surgery.	IIb	B

Aortic regurgitation

Overview

Aortic regurgitation (AR) can be caused by primary disease of the aortic valve cusps and/or abnormalities of the aortic root and ascending aortic geometry. Degenerative tricuspid and bicuspid AR are the most common aetiologies in Western countries. Other causes include infective and rheumatic endocarditis. Acute severe AR is mostly caused by infective endocarditis and less frequently by aortic dissection, and is addressed iin the relevant guidelines.

Evaluation

Echocardiography is the key examination to describe valve anatomy, quantify AR, evaluate its mechanisms, define the morphology of the aorta, and determine the feasibility of valve-sparing aortic surgery or valve repair. Essential aspects of this evaluation include:

- Assessment of valve morphology: tricuspid, bicuspid, unicuspid, or quadricuspid valve.
- Determination of the direction of the AR jet in the long-axis view (central or eccentric) and its origin in the short-axis view (central or commissural).
- Identification of the mechanism, following the same principle as for MR: normal cusps but insufficient coaptation due to dilatation of the aortic root with central jet (type 1); cusp prolapse with eccentric jet (type 2); retraction with poor cusp tissue quality and large central or eccentric jet (type 3).
- Quantification of AR should follow an integrated approach considering all qualitative, semiquantitative, and quantitative parameters (Table 4).
- Measurement of LV function and dimensions. Indexing LV diameters for body surface area (BSA) is recommended in patients with small body size (BSA <1.68 m^2). New parameters obtained by three-dimensional (3D) echocardiography, tissue Doppler, and strain rate imaging may be useful, particularly in patients with borderline left ventricular ejection fraction (LVEF) where they may help in the decision for surgery.
- Measurement of the aortic root and ascending aorta in the 2-dimensional (2D) mode at four levels: annulus, sinuses of Valsalva, sinotubular junction, and tubular ascending aorta. Measurements are taken in the parasternal long- axis view from leading edge to leading edge at end diastole except forthe aortic annulus, which is measured in mid systole. As it will have surgical consequences, it is of importance to differentiate three phenotypes of the ascending aorta:1) aortic root aneurysms (sinuses of Valsalva >45 mm); 2) tubular ascending aneurysm (sinuses of Valsalva <40–45 mm); 3) isolated AR (all diameters <40 mm). The calculation of indexed values has been recommended to account for body size.
- Definition of the anatomy of the aortic valve cusps and assessment of valve reparability should be provided by preoperative TOE if aortic valve repair or a valve-sparing surgery of the aortic root is considered.

CMR should be used to quantify regurgitant fraction when echocardiographic measurements are equivocal. In patients with aortic dilatation, gated MSCT is recommended to assess the maximum diameter. CMR can be used for follow-up but indication for surgery should preferably be based on CT measurements.

The indications for intervention in chronic AR are summarized in the table of recommendations on indications for surgery in severe AR and aortic root disease and in Figure 1, and may be related to symptoms, status of the LV, or dilatation of the aorta.

Indications for surgery in (A) severe aortic regurgitation and (B) aortic root disease (irrespective of the severity of aortic regurgitation)

Indications for surgery	Class[a]	Level[b]
A. Severe aortic regurgitation		
Surgery is indicated in symptomatic patients.	I	B
Surgery is indicated in asymptomatic patients with resting LVEF ≤50%.	I	B
Surgery is indicated in patients undergoing CABG or surgery of the ascending aorta or of another valve.	I	C
Heart Team discussion is recommended in selected patients[c] in whom aortic valve repair may be a feasible alternative to valve replacement.	I	C
Surgery should be considered in asymptomatic patients with resting ejection fraction >50% with severe LV dilatation:LVEDD >70 mm,or LVESD >50 mm (or LVESD >25 mm/m^2 BSA in patients with small body size).	IIa	B
B. Aortic root or tubular ascending aorta aneurysm[d] (irrespective of the severity of aortic regurgitation)		
Aortic valve repair, using the reimplantation or remodelling with aortic annuloplasty technique, is recommended in young patients with aortic root dilation and tricuspid aortic valves,when performed by experienced surgeons.	I	C

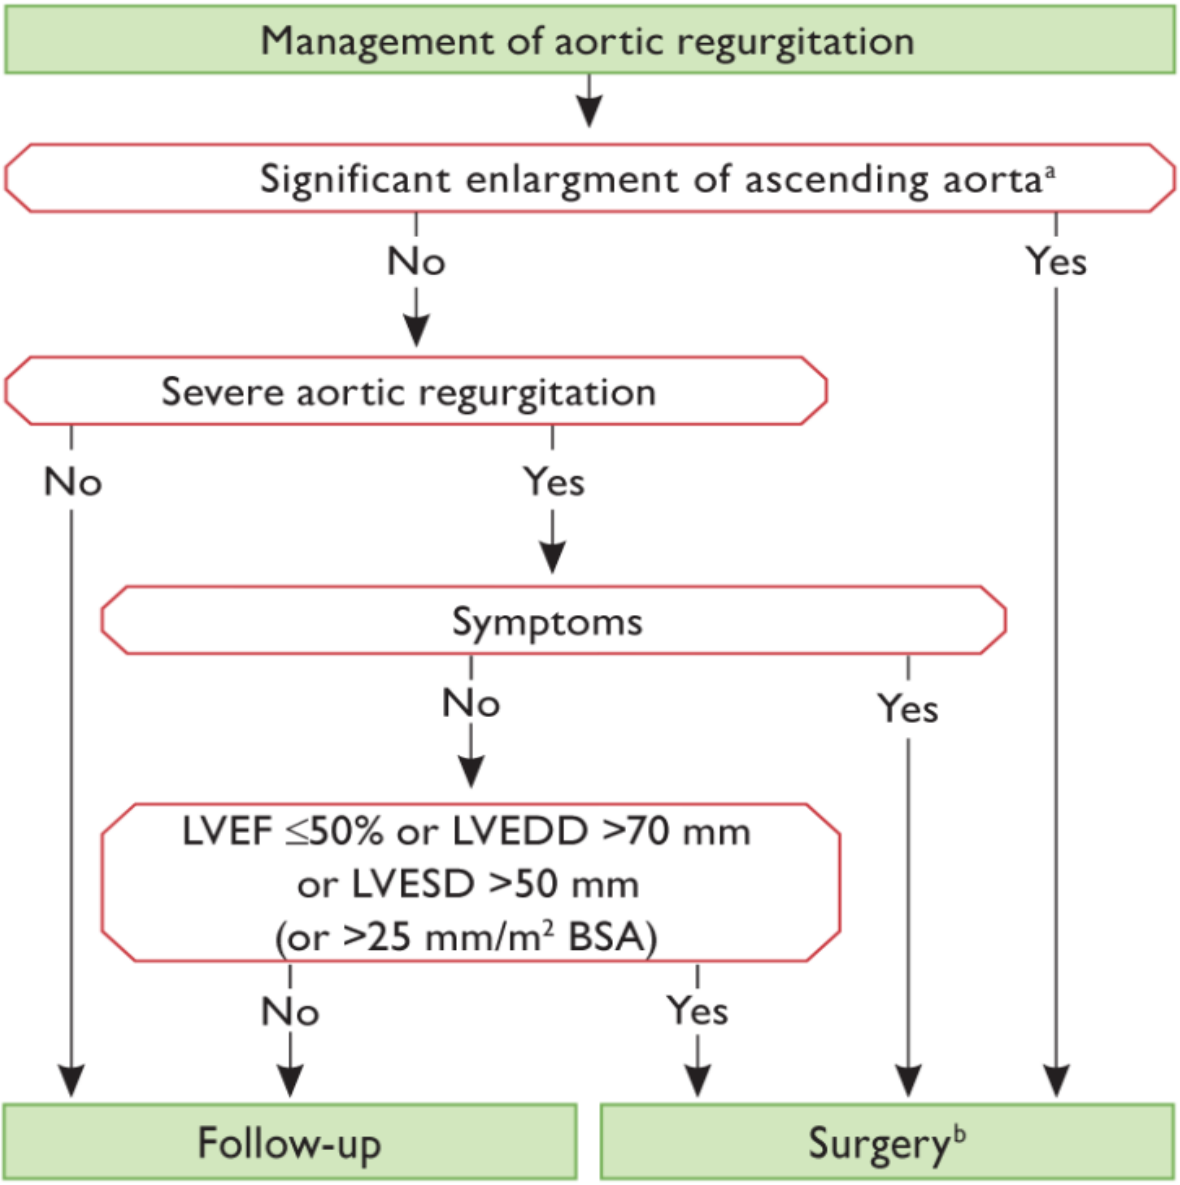
Surgery is indicated in patients with Marfan syndrome, who have aortic root disease with a maximal ascending aortic diameter ≥50 mm.	I	C
Surgery should be considered in patients who have aortic root disease with maximal ascending aortic diameter: • ≥45 mm in the presence of Marfan syndrome and additional risk factors,[e] or patients with a *TGFBR1* or *TGFBR2* mutation (including Loeys-Dietz syndrome).[f] • ≥50 mm in the presence of a bicuspid valve with additional risk factors[e] or coarctation. • ≥55 mm for all other patients.	IIa	C
When surgery is primarily indicated for the aortic valve, replacement of the aortic root or tubular ascending aorta should be considered when ≥45 mm, particularly in the presence of a bicuspid valve.[g]	IIa	C

BSA = body surface area; CABG = coronary artery bypass grafting; CT = computed tomography; ECG = electrocardiogram; LV = left ventricular; LVEDD = left ventricular end-diastolic diameter; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic diameter.

[a] Class of recommendation - [b] Level of evidence - [c] Patients with pliable non-calcified tricuspid or bicuspid valves who have a type I (enlargement of the aortic root with normal cusp motion) or type II (cusp prolapse) mechanism of aortic regurgitation - [d] For clinical decision-making, dimensions of the aorta should be confirmed by ECG-gated CT measurement - [e]Family history of aortic dissection (or personal history of spontaneous vascular dissection), severe aortic regurgitation or mitral regurgitation, desire of pregnancy, systemic hypertension, and/or aortic size increase >3 mm/year (on repeated measurements using the same ECG-gated imaging technique, measured at the same level of the aorta with side-by-side comparison and confirmed by another technique) - [f]A lower threshold of 40 mm may be considered in women with low BSA, in patients with a TGFBR2 mutation, or in patients with severe extra-aortic features - [g] Considering age, BSA, aetiology of valvular disease, presence of a bicuspid aortic valve, and intraoperative shape and thickness of the ascending aorta.

Algorithm Mgmt. of aortic regurgitation

Figure 1 Management of aortic regurgitation



AR = aortic regurgitation;BSA = body surface area;LVEDD = left ventricle end-diastolic diameter; LVEF = left ventricular ejection fraction;LVESD = left ventricle end-systolic diameter.

[a]See table of recommendations on indications for surgery in severe aortic regurgitation and aortic root disease in section 4.2 for definition - [b]Surgery should also be considered if significant changes in LV or aortic size occur during follow-up (see table of recommendations on indications for surgery in severe aortic regurgitation and aortic root disease in section 4.2).

Medical therapy

In patients with Marfan syndrome, beta-blockers and/or losartan may slow aortic root dilatation and reduce the risk of aortic complications, and should be considered before and after surgery. By analogy, while there are no studies that provide evidence, it is common clinical practice to advise beta-blocker or losartan therapy also in patients with bicuspid aortic valve if the aortic root and/ or ascending aorta is dilated.

Serial testing

All asymptomatic patients with severe AR and normal LV function should be seen at least every year. In patients with a first diagnosis, or if LV diameter and/or ejection fraction show significant changes or come close to thresholds for surgery, follow-up should be continued at 3–6 month intervals. In inconclusive cases, BNP may be helpful. Patients with mild-to-moderate AR can be reviewed on a yearly basis and echocardiography performed every 2 years. If the ascending aorta is dilated (>40 mm) it is recommended to perform CT or CMR.

Special patient populations

If AR requiring surgery is associated with severe MR, both should be addressed during the same operation. In patients with moderate AR who undergo coronary artery bypass grafting (CABG) or mitral valve surgery, the decision to treat the aortic valve is controversial as data show that progression of moderate AR is very slow in patients without aortic dilatation. The Heart Team should decide based on the aetiology of AR, other clinical factors, the life expectancy of the patient, and their operative risk.

Aortic stenosis

Overview

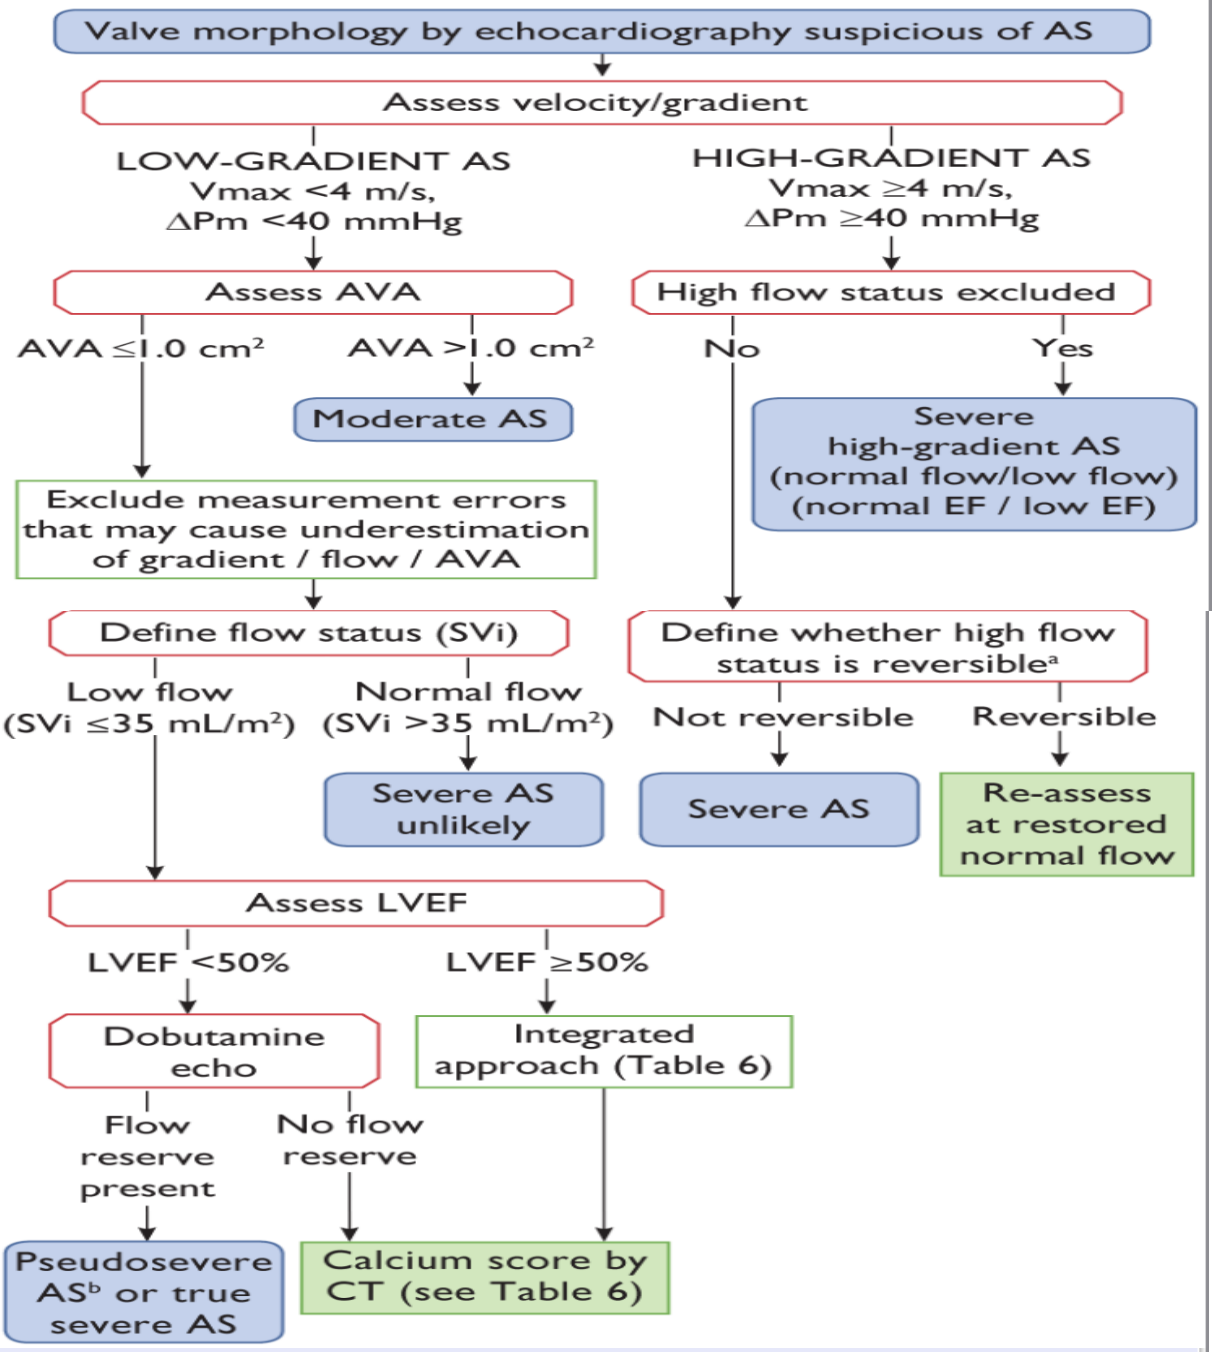
Aortic stenosis (AS) is the most common primary valve disease leading to surgery or catheter intervention in Europe and North America, with a growing prevalence due to the ageing population.

Evaluation

Introduction

Echocardiography is the key diagnostic tool. It confirms the presence of AS, assesses the degree of valve calcification, LV function and wall thickness, detects the presence of other associated valve disease or aortic pathology, and provides prognostic information. Doppler echocardiography is the preferred technique for assessing the severity of AS. Figure 2 and Table 6 provide a practical stepwise approach for the assessment of AS severity. Details can be found in a recent position paper of the European Association of Cardiovascular Imaging (EACVI).

Figure 2 Stepwise integrated approach for the assessment of AS severity (modified from Baumgartner *et al*). High flow may be reversible in settings such as anaemia, hyperthyroidism, arteriovenous shunts. Pseudosevere AS is defined by an increase to an AVA >1.0cm^2 with flow normalization



ΔPm = mean transvalvular pressure gradient; AS = aortic stenosis; AVA = aortic valve area; CT = computed tomography; EF = ejection fraction; LVEF = left ventricular ejection fraction; SVi = stroke volume index; Vmax = peak transvalvular velocity.
[a]High flow may be reversible in settings such as anaemia, hyperthyroidism, arteriovenous shunts.
[b]Pseudosevere AS is defined by an increase to an AVA >1.0 cm2 with flow normalization.

Table 6 Criteria that increase the likelihood of severe aortic stenosis in patients with AVA <1.0 cm² and mean gradient <40 mmHg in the presence of preserved ejection fraction (modified from Baumgartner *et al.*)

Criteria	
Clinical criteria	• Typical symptoms without other explanation • Elderly patient (>70 years)
Qualitative imaging data	• LV hypertrophy (additional history of hypertension to be considered) • Reduced LV longitudinal function without other explanation
Quantitative imaging data	• Mean gradient 30–40 mmHg[a]
	• AVA ≤0.8 cm²
	• Low flow (SVi <35 mL/m²) confirmed by techniques other than standard Doppler technique (LVOT measurement by 3D TOE or MSCT; CMR, invasive data)
	• Calcium score by MSCT[b] Severe aortic stenosis very likely: men≥ 3000; women≥ 1600 Severe aortic stenosis likely: men≥ 2000; women≥ 1200 Severe aortic stenosis unlikely: men <1600; women <800

3D = three-dimensional; AVA = aortic valve area; CMR = cardiovascular magnetic resonance; LV = left ventricular; LVOT = left ventricular outflow tract; MSCT = multislice computed tomography; SVi = stroke volume index; TOE = transoesophageal echocardiography.

[a]Haemodynamics measured when the patient is normotensive.

[b]Values are given in arbitrary units using Agatston method for quantification of valve calcification.

Additional diagnostic aspects, including assessment of prognostic parameters:

Exercise testing is recommended in physically active patients for unmasking symptoms and for risk stratification of asymptomatic patients with severe AS. TOE provides additional evaluation of concomitant mitral valve abnormalities. It has gained importance in the assessment before TAVI and after TAVI or surgical procedures.

MSCT and ***CMR*** provide additional information on the dimensions and geometry of the aortic root and ascending aorta and the extent of calcification. MSCT has become particularly important for the quantification of valve calcification when assessing AS severity in low-gradient AS. CMR may be useful for the detection and quantification of myocardial fibrosis, providing additional prognostic information regardless of the presence of CAD.

Natriuretic peptides have been shown to predict symptom-free survival and outcome in normal and low-flow severe AS, and may be useful in asymptomatic patients to determine optimal timing of intervention.

Retrograde LV catheterization to assess the severity of AS is no longer routinely performed. Its use is restricted to patients with inconclusive non- invasive investigations.

Diagnostic work-up before transcatheter aortic valve implantation: MSCT is the preferred imaging tool to assess anatomy and dimensions of the aortic root, size and shape of the aortic valve annulus, its distance to the coronary ostia, the distribution of calcifications, and the number of aortic valve cusps. It is essential to evaluate the feasibility of the various access routes as it provides information on minimal luminal diameters, atherosclerotic plaque burden, presence of aneurysms or thrombi, vessel tortuosity, and thoracic and LV apex anatomy. CMR–as an alternative technique–is, in this context, inferior to MSCT with regards to assessment of inner vessel dimensions and calcifications. 3D TOE can be used to determine aortic annulus dimensions but remains more operator- and image- quality–dependent than MSCT.

The indications for aortic valve interventions are summarized in the table of indications for intervention in AS and recommendations for the choice of intervention mode and in Table 7, and are illustrated in Figure 3.

Indications for intervention in aortic stenosis and recommendations for the choice of intervention mode

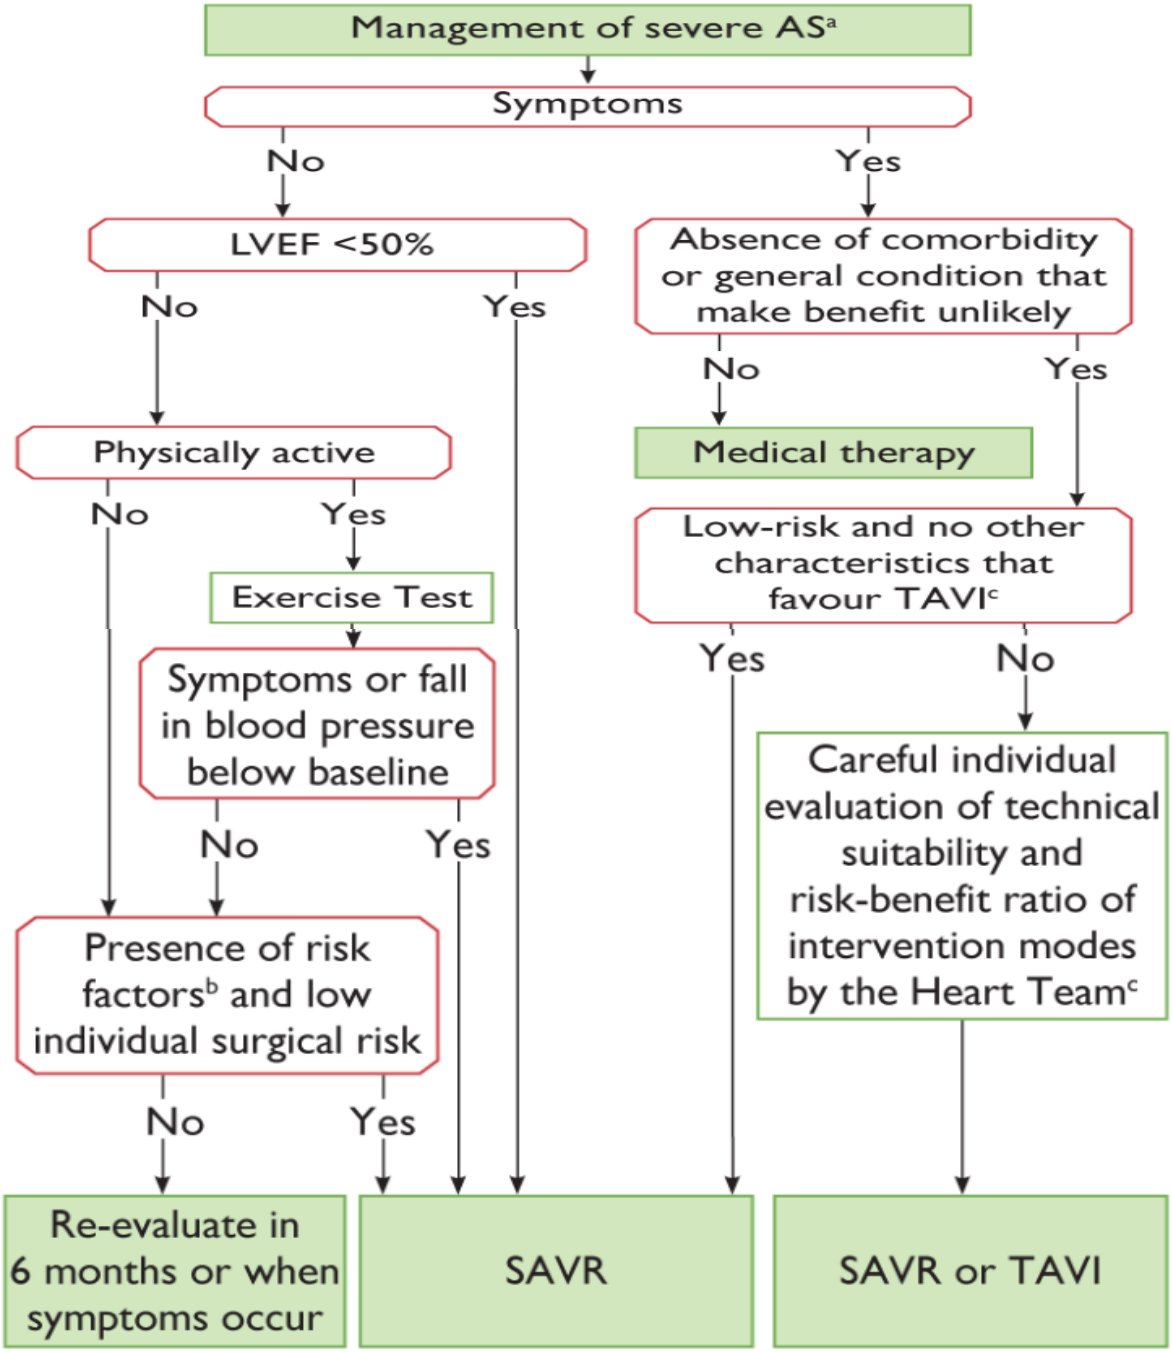
Recommendations	Class[a]	Level[b]
a) Symptomatic aortic stenosis		
Intervention is indicated in symptomatic patients with severe, high-gradient aortic stenosis (mean gradient ≥40 mmHg or peak velocity ≥4.0 m/s).	I	B
Intervention is indicated in symptomatic patients with severe low-flow, low-gradient (<40 mmHg) aortic stenosis with reduced ejection fraction, and evidence of flow (contractile) reserve excluding pseudosevere aortic stenosis.	I	C
Intervention should be considered in symptomatic patients with low-flow, low-gradient (<40 mmHg) aortic stenosis with normal ejection fraction after careful confirmation of severe aortic stenosis[c] (see Figure 2 and Table 6).	IIa	C
Intervention should be considered in symptomatic patients with low- flow, low-gradient aortic stenosis and reduced ejection fraction without flow (contractile) reserve, particularly when CT calcium scoring confirms severe aortic stenosis.	IIa	C
Intervention should not be performed in patients with severe comorbidities when the intervention is unlikely to improve quality of life or survival.	III	C

b) Choice of intervention in symptomatic aortic stenosis		
Aortic valve interventions should only be performed in centres with both departments of cardiology and cardiac surgery on-site, and with structured collaboration between the two, including a Heart Team (heart valve centres).	I	C
The choice for intervention must be based on careful individual evaluation of technical suitability and weighing of risks and benefits of each modality (aspects to be considered are listed in Table 7). In addition, the local expertise and outcomes data for the given intervention must be taken into account.	I	C
SAVR is recommended in patients at low surgical risk (STS or EuroSCORE II <4% or logistic EuroSCORE I <10%[d] and no other risk factors not included in these scores, such as frailty, porcelain aorta, sequelae of chest radiation).	I	B
TAVI is recommended in patients who are not suitable for SAVR as assessed by the Heart Team.	I	B
In patients who are at increased surgical risk (STS or EuroSCORE II ≥4% or logistic EuroSCORE I ≥10%[d] or other risk factors not included in these scores such as frailty, porcelain aorta, sequelae of chest radiation), the decision between SAVR and TAVI should be made by the Heart Team according to the individual patient characteristics (see Table 7), with TAVI being favoured in elderly patients suitable for transfemoral access.	I	B
Balloon aortic valvotomy may be considered as a bridge to SAVR or TAVI in haemodynamically unstable patients or in patients with symptomatic severe aortic stenosis who require urgent major non-cardiac surgery.	IIb	C
Balloon aortic valvotomy may be considered as a diagnostic means in patients with severe aortic stenosis and other potential cause for symptoms (i.e. lung disease) and in patients with severe myocardial dysfunction, pre-renal insufficiency or other organ dysfunction that may be reversible with balloon aortic valvotomy when performed in centres that can escalate to TAVI.	IIb	C
c) Asymptomatic patients with severe aortic stenosis (refers only to patients eligible for surgical valve replacement)		
SAVR is indicated in asymptomatic patients with severe aortic stenosis and systolic LV dysfunction (LVEF <50%) not due to another cause.	I	C
SAVR is indicated in asymptomatic patients with severe aortic stenosis and abnormal exercise test showing symptoms on exercise clearly related to aortic stenosis.	I	C
SAVR should be considered in asymptomatic patients with severe aortic stenosis and abnormal exercise test showing fall in blood pressure below baseline.	IIa	C

SAVR should be considered in asymptomatic patients with normal ejection fraction and none of the above-mentioned exercise test abnormalities if the surgical risk is low and one of the following findings is present: • Very severe aortic stenosis defined by a V_{max} >5.5 m/s • Severe valve calcification and a rate of V_{max} progression ≥ 0.3 m/s/year • Markedly elevated BNP levels (>threefold age- and sex-corrected normal range) confirmed by repeated measurements without other explanations • Severe pulmonary hypertension (systolic pulmonary artery pressure at rest >60 mmHg confirmed by invasive measurement) without other explanation.	IIa	C
d) Concomitant aortic valve surgery at the time of other cardiac/ ascending aorta surgery		
SAVR is indicated in patients with severe aortic stenosis undergoing CABG, or surgery of the ascending aorta or of another valve.	I	C
SAVR should be considered in patients with moderate aortic stenosis[e] undergoing CABG, or surgery of the ascending aorta or of another valve after Heart Team decision.	IIa	C

[a]Class of recommendation - [b] Level of evidence - [c]In patients with a small valve area but low gradient despite preserved LVEF, explanations for this finding other than the presence of severe aortic stenosis are frequent and must be carefully excluded. See Figure 2 and Table 6 - [d]STS score (calculator: http://riskcalc.sts.org/stswebriskcalc/#/calculate); EuroSCORE II (calculator: http://www.euroscore.org/calc.html); logistic EuroSCORE I (calculator: http://www.euroscore.org/calcge.html); scores have major limitations for practical use in this setting by insufficiently considering disease severity and not including major risk factors such as frailty, porcelain aorta, chest radiation etc. EuroSCORE I markedly overestimates 30-day mortality and should therefore be replaced by the better performing EuroSCORE II with this regard; it is nevertheless provided here for comparison as it has been used in many TAVI studies/registries and may still be useful to identify the subgroups of patients for decision between intervention modalities and to predict 1-year mortality - [e]Moderate aortic stenosis is defined as valve area 1.0–1.5 cm^2 or mean aortic gradient 25–40 mmHg in the presence of normal flow conditions. However, clinical judgement is required.

Figure 3 Management of severe aortic stenosis



AS = aortic stenosis; LVEF = left ventricular ejection fraction; SAVR = surgical aortic valve replacement; TAVI = transcatheter aortic valve implantation.

[a]See Figure 2 and Table 6 for the definition of severe AS.

[b]Surgery should be considered (IIa C) if one of the following is present: peak velocity >5.5 m/s; severe valve calcification + peak velocity progression ≥0.3 m/s per year; markedly elevated neurohormones (>threefold age-and sex-corrected normal range) without other explanation; severe pulmonary hypertension (systolic pulmonary artery pressure >60 mmHg

Table 7 Aspects to be considered by the Heart Team for the decision between SAVR and TAVI in patients at increased surgical risk (see Table of Recommendations in section 5.2.)

	Favours TAVI	Favours SAVR
Clinical characteristics		
STS/EuroSCORE II <4% (logistic EuroSCORE I<10%)[a]		+
STS/EuroSCORE II ≥4% (logistic EuroSCORE I ≥10%)[a]	+	
Presence of severe comorbidity (not adequately reflected by scores)	+	
Age <75 years		+

[a]STS score (calculator: http://riskcalc.sts.org/stswebriskcalc/#/calculate); EuroSCORE II (calculator: http://www.euroscore.org/calc.html); logistic EuroSCORE I (calculator: http://www.euroscore.org/calcge.html); scores have major limitations for practical use in this setting by insufficiently considering disease severity and not including major risk factors such as frailty, porcelain aorta, chest radiation etc. EuroSCORE I markedly overestimates 30-day mortality and should therefore be replaced by the better performing EuroSCORE II with this regard; it is nevertheless provided here for comparison as it has been used in many TAVI studies/registries and may still be useful to identify the subgroups of patients for decision between intervention modalities and to predict 1-year mortality.

Medical therapy

No medical therapy for AS can improve outcome compared with the natural history. Randomized trials have consistently shown that statins do not affect the progression of AS. Patients with symptoms of heart failure, who are unsuitable candidates for surgery or TAVI, or who are currently awaiting surgical or catheter intervention, should be medically treated according to the heart failure Guidelines. Co-existing hypertension should be treated. Medical treatment should be carefully titrated to avoid hypotension and patients should be re-evaluated frequently. Maintenance of sinus rhythm is important.

Serial testing

In the asymptomatic patient, the wide variability in the rate of progression of AS stresses the need for patients to be carefully educated about the importance of follow-up and reporting symptoms as soon as they develop. Asymptomatic severe AS should be re-evaluated at least every 6 months for the occurrence of symptoms (change in exercise tolerance, ideally using exercise testing if symptoms are doubtful), and if there is change in echo parameters. Measurement of natriuretic peptides should be considered. In the presence of significant calcification, mild and moderate AS should be re-evaluated yearly. In younger patients with mild AS and no significant calcification, intervals may be extended to 2 to 3 years.

Patients in whom CABG is indicated and who have moderate AS will in general benefit from concomitant SAVR. It has also been suggested that if age is <70 years and, more importantly, an average rate of AS progression of 5 mmHg per year is documented, patients may benefit from valve replacement at the time of coronary surgery once the baseline peak gradient exceeds 30 mmHg. Individual judgement is recommended, taking into consideration BSA, haemodynamic data, leaflet calcification, AS progression rate, patient life expectancy and associated comorbidities, as well as the individual risk of either concomitant valve replacement or late reoperation.

Patients with severe symptomatic AS and diffuse CAD that cannot be revascularized should not be denied SAVR or TAVI.

Combined PCI and TAVI has been shown to be feasible, but requires more data before a firm recommendation can be made. The chronology of interventions should be the subject of individualized discussion based on the patient's clinical condition, extent of CAD, and myocardium at risk.

When MR is associated with severe AS, its severity may be overestimated in the presence of the high ventricular pressures, and careful quantification is required. As long as there are no morphological leaflet abnormalities (flail or prolapse, post-rheumatic changes, or signs of infective endocarditis), mitral annulus dilatation, or marked abnormalities of LV geometry, surgical intervention on the mitral valve is in general not necessary.

Concomitant aneurysm/dilatation of the ascending aorta requires the same treatment as in AR (see Section 4).

For congenital AS, see the ESC Guidelines on Grown-up Congenital Heart Disease.

Mitral regurgitation

Overview

Mitral regurgitation (MR) is the second most frequent indication for valve surgery in Europe. It is essential to distinguish primary from secondary MR, particularly regarding surgical and transcatheter interventional management.

Primary mitral regurgitation

Introduction

In primary MR, one or several components of the mitral valve apparatus are directly affected. The most frequent aetiology is degenerative (prolapse, flail leaflet). Endocarditis as another cause is discussed in specific ESC Guidelines.

Evaluation

Echocardiography is the principal investigation used to assess the severity and mechanism of MR, its consequences for the LV (function and remodelling), left atrium (LA), and pulmonary circulation, as well as the likelihood of repair. For quantification see Table 4. A precise anatomical description of the lesions, using the segmental and functional anatomy according to the Carpentier classification, should be performed to assess the feasibility of repair. TTE also assesses mitral annular dimensions and the presence of calcification. It is diagnostic in most cases, but TOE is recommended, particularly in the presence of suboptimal image quality. Determination of functional capacity and symptoms assessed by cardiopulmonary exercise testing may be useful in asymptomatic patients. Exercise echocardiography is useful to quantify exercise-induced changes in MR, in systolic pulmonary artery pressure, and in LV function. It may be particularly helpful in patients with symptoms and uncertainty about the severity of MR based on measurements at rest.

The use of global longitudinal strain could be of potential interest for the detection of subclinical LV dysfunction but is limited by inconsistent algorithms used by different echo systems.

Neurohormonal activation is observed in MR, with a potential value of elevated BNP levels and a change in BNP as predictors of outcome (particularly of symptom onset). In particular, low plasma BNP has a high negative predictive value and may be helpful in the follow-up of asymptomatic patients.

As echocardiographic measures of pulmonary pressure may show disagreement with invasive measures, the measurement should be invasively confirmed by right- heart catheterization if this is the only indication for surgery.

Indications for intervention

Recommendations

Indications for interventions in severe chronic primary MR are shown in the table of recommendations for indications for intervention in severe primary MR and in Figure 4.

Indications for intervention in severe primary mitral regurgitation		
Recommendations	**Class[a]**	**Level[b]**
Mitral valve repair should be the preferred technique when the results are expected to be durable.	I	C
Surgery is indicated in symptomatic patients with LVEF >30%.	I	B
Surgery is indicated in asymptomatic patients with LV dysfunction (LVESD ≥45 mm[c] and/or LVEF ≤60%).	I	B
Surgery should be considered in asymptomatic patients with preserved LV function (LVESD <45 mm and LVEF >60%) and atrial fibrillation secondary to mitral regurgitation or pulmonary hypertension[d] (systolic pulmonary pressure at rest >50 mmHg).	IIa	B
Surgery should be considered in asymptomatic patients with preserved LVEF (>60%) and LVESD 40–44 mm[c] when a durable repair is likely, surgical risk is low, the repair is performed in heart valve centres, and at least one of the following findings is present: • flail leaflet or • presence of significant LA dilatation (volume index ≥60 mL/m^2 BSA) in sinus rhythm.	IIa	C
Mitral valve repair should be considered in symptomatic patients with severe LV dysfunction (LVEF <30% and/or LVESD >55 mm) refractory to medical therapy when likelihood of successful repair is high and comorbidity low.	IIa	C
Mitral valve replacement may be considered in symptomatic patients with severe LV dysfunction (LVEF <30% and/or LVESD >55 mm) refractory to medical therapy when likelihood of successful repair is low and comorbidity low.	IIb	C
Percutaneous edge-to-edge procedure may be considered in patients with symptomatic severe primary mitral regurgitation who fulfil the echocardiographic criteria of eligibility and are judged inoperable or at high surgical risk by the Heart Team, avoiding futility.	IIb	C

BSA = body surface area; LA = left atrial; LV = left ventricular; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic diameter; SPAP = systolic pulmonary artery pressure.

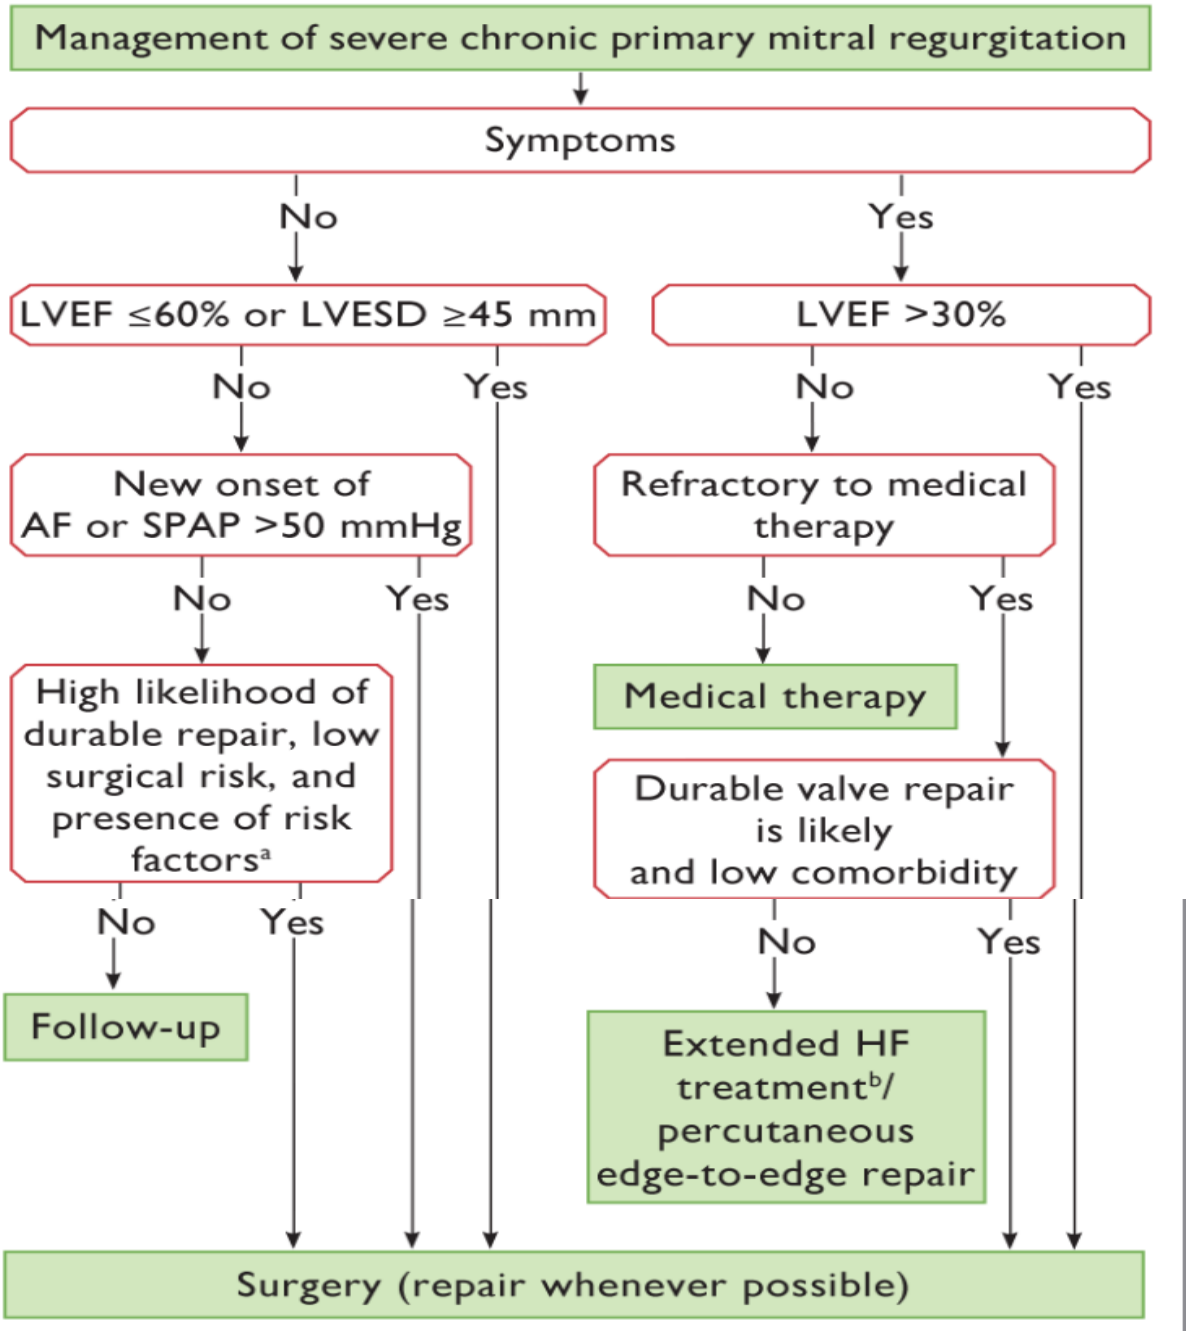
[a]Class of recommendation.

[b]Level of evidence.

[c]Cut-offs refer to averaged sized adults and may require adaption in patients with unusually small or large stature.

[d]If an elevated SPAP is the only indication for surgery, the value should be confirmed by invasive measurement.

Figure 4 Management of severe chronic primary mitral regurgitation



AF = atrial fibrillation; BSA = body surface area; CRT = cardiac resynchronization therapy; HF = heart failure; LA = left atrial; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic diameter; SPAP = systolic pulmonary arterial pressure.

[a]When there is a high likelihood of durable valve repair at a low-risk, valve repair should be considered (IIa C) in patients with LVESD ≥40 mm and one of the following is present: flail leaflet or LA volume ≥60 mL/m² BSA at sinus rhythm - [b]Extended HF management includes the following: CRT; ventricular assist devices; cardiac restraint devices; heart transplantation.

Medical therapy

In chronic MR with good ventricular function, there is no evidence to support the prophylactic use of vasodilators, including ACE-inhibitors. However, ACE-inhibitors should be considered when heart failure has developed in patients who are not suitable for surgery or when symptoms persist after surgery. Beta-blockers and spironolactone (or eplerenone) should also be considered as appropriate.

Serial testing

Asymptomatic patients with severe MR and LVEF >60% should be followed clinically and echocardiographically every 6 months, ideally in the setting of a heart valve centre. Closer follow-up is indicated if no previous evaluation is available and when measured variables show significant dynamic changes or are close to the thresholds. When guideline indications for surgery are reached, early surgery–within 2 months–is associated with better outcomes. Asymptomatic patients with moderate MR and preserved LV function can be followed on a yearly basis and echocardiography should be performed every 1–2 years.

Secondary mitral regurgitation

Introduction

In secondary MR (previously also referred to as "functional MR"), the valve leaflets and chordae are structurally normal and MR results from an imbalance between closing and tethering forces on the valve secondary to alterations in LV geometry. It is most commonly seen in dilated or ischaemic cardiomyopathies. Annular dilatation in patients with chronic atrial fibrillation and LA enlargement can also be an underlying mechanism.

Evaluation

Echocardiography is essential to establish the diagnosis of secondary MR. In secondary MR, lower thresholds have been proposed to define severe MR compared with primary MR (20 mm^2 for effective regurgitant orifice area [EROA] and 30 mL for regurgitant volume) owing to their association with prognosis. However, it is unclear if prognosis is independently affected by MR compared with LV dysfunction. So far, no survival benefit has been confirmed for reduction of secondary MR.

For isolated mitral valve treatment (surgery or percutaneous edge-to-edge repair) in secondary MR, thresholds of severity of MR for intervention still need to be validated in clinical trials. Severity of secondary MR should be reassessed after optimized medical treatment. Severity of tricuspid regurgitation and RV size and function should also be evaluated.

Secondary MR is a dynamic condition; echocardiographic quantification of MR during exercise may provide prognostic information of dynamic characteristics. Myocardial viability testing may be useful in patients with ischaemic secondary MR who are candidates for revascularization.

Indications for MR intervention in severe secondary MR are summarized in the table below.

Indications for mitral valve intervention in chronic secondary mitral regurgitation[a]

Recommendations	Class[b]	Level[c]
Surgery is indicated in patients with severe secondary mitral regurgitation undergoing CABG and LVEF >30%.	I	C
Surgery should be considered in symptomatic patients with severe secondary mitral regurgitation, LVEF <30% but with an option for revascularization, and evidence of myocardial viability.	IIa	C
When revascularization is not indicated, surgery may be considered in patients with severe secondary mitral regurgitation and LVEF >30%, who remain symptomatic despite optimal medical management (including CRT if indicated) and have a low surgical risk.	IIb	C
When revascularization is not indicated and surgical risk is not low, a percutaneous edge-to-edge procedure may be considered in patients with severe secondary mitral regurgitation and LVEF >30%, who remain symptomatic despite optimal medical management (including CRT if indicated) and who have a suitable valve morphology by echocardiography, avoiding futility.	IIb	C
In patients with severe secondary mitral regurgitation and LVEF <30% who remain symptomatic despite optimal medical management (including CRT if indicated) and who have no option for revascularization, the Heart Team may consider percutaneous edge-to-edge procedure or valve surgery after careful evaluation for ventricular assist device or heart transplant according to individual patient characteristics.	IIb	C

CABG = coronary artery bypass grafting; CRT = cardiac resynchronization therapy; LVEF = left ventricular ejection fraction.

[a]See section 6.2.1. for quantification of secondary mitral regurgitation, which must always be performed under optimal treatment - [b]Class of recommendation - [c]Level of evidence.

Medical therapy

Optimal medical therapy in line with the Guidelines for the management of heart failure should be the first step in the management of all patients with secondary MR. Indications for CRT should be evaluated in accordance with related Guidelines. If symptoms persist after optimization of conventional heart failure therapy, options for mitral valve intervention should be evaluated.

Mitral stenosis

Introduction

The incidence of rheumatic mitral stenosis (MS) has greatly decreased in industrialized countries. Degenerative calcific mitral valve disease is now encountered mainly in elderly patients. Percutaneous mitral commissurotomy (PMC) has had a significant impact upon the management of rheumatic MS.

Evaluation

Echocardiography is the preferred method for diagnosing MS, and for assessing its severity and haemodynamic consequences. Valve area using planimetry is the reference measurement of MS severity, whereas mean transvalvular gradient and pulmonary pressures reflect its consequences and have a prognostic value. TTE usually provides sufficient information for routine management. Scoring systems have been developed to help assess suitability for PMC. TOE should be performed to exclude LA thrombus before PMC or after an embolic episode. Echocardiography also plays an important role in monitoring the results of PMC during the procedure. Stress testing is indicated in patients with no symptoms or symptoms equivocal or discordant with the severity of MS. Exercise echocardiography may provide additional objective information by assessing changes in mitral gradient and pulmonary artery pressure.

Indications for intervention are summarized in Figure 5, the according table of indications and Tables 8 and 9.

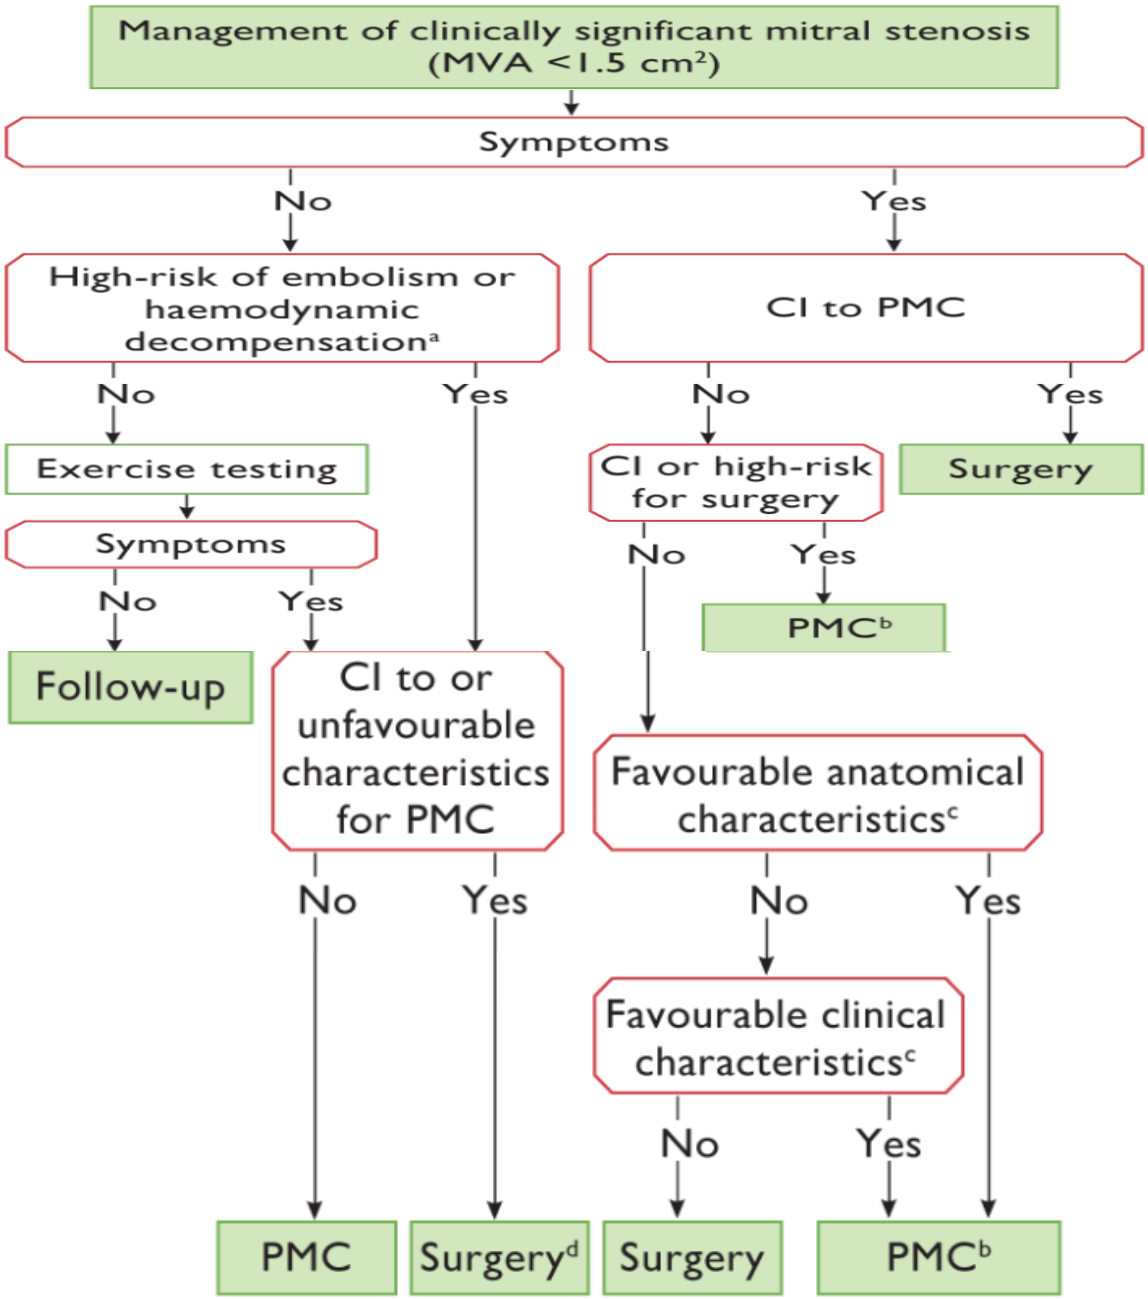
Indications for PMC and mitral valve surgery in clinically significant (moderate or severe) mitral stenosis (valve area ≤1.5 cm²)

Recommendations	Class[a]	Level[b]
PMC is indicated in symptomatic patients without unfavourable characteristics[c] for PMC.	I	B
PMC is indicated in any symptomatic patients with a contra-indication or a high-risk for surgery.	I	C
Mitral valve surgery is indicated in symptomatic patients who are not suitable for PMC.	I	C
PMC should be considered as initial treatment in symptomatic patients with suboptimal anatomy but no unfavourable clinical characteristics for PMC.[c]	IIa	C
PMC should be considered in asymptomatic patients without unfavourable clinical and anatomical characteristicsc for PMC and • high thromboembolic risk (history of systemic embolism, dense spontaneous contrast in the LA, new-onset or paroxysmal atrial fibrillation); and/or • high-risk of haemodynamic decompensation (systolic pulmonary pressure >50 mmHg at rest, need for major non-cardiac surgery,desire for pregnancy).	IIa	C

LA = left atrium; NYHA = New York Heart Association; PMC = percutaneous mitral commissurotomy.

[a]Class of recommendation - [b]Level of evidence - [c]Unfavourable characteristics for PMC can be defined by the presence of several of the following characteristics. Clinical characteristics: old age, history of commissurotomy, NYHA class IV, permanent atrial fibrillation, severe pulmonary hypertension. Anatomical characteristics: echo score >8, Cormier score 3 (calcification of mitral valve of any extent, as assessed by fluoroscopy), very small mitral valve area, severe tricuspid regurgitation. For definition of scores see Table 9.

Figure 5 Management of clinically significant mitral stenosis



CI = contra-indication; MS = mitral stenosis; PMC = percutaneous mitral commissurotomy.
[a]High thromboembolic risk: history of systemic embolism, dense spontaneous contrast in the left atrium, newonset atrial fibrillation. High-risk of haemodynamic decompensation: systolic pulmonary pressure >50 mmHg at rest, need for major non-cardiac surgery, desire for pregnancy - [b]Surgical commissurotomy may be considered by experienced surgical teams or in patients with contra-indications to PMC - [c]See table of recommendations on indications for PMC and mitral valve surgery in clinically significant mitral stenosis in section 7.2 and see echo scores - [d]Surgery if symptoms occur for a low level of exercise and operative risk is low.

Table 8 Contra-indications for percutaneous mitral commissurotomy (PMC)[a]
Contra-indications
Mitral valve area >1.5 cm^{2a}
Left atrial thrombus
More than mild mitral regurgitation
Severe or bi-commissural calcification
Absence of commissural fusion
Severe concomitant aortic valve disease, or severe combined tricuspid stenosis and regurgitation requiring surgery
Concomitant CAD requiring bypass surgery

CAD = coronary artery disease. [a]PMC may be considered in patients with valve area >1.5 cm^2 with symptoms that cannot be explained by another cause and if the anatomy is favourable.

Table 9 Echo scores: Wilkins score, Cormier score, and Echo Score "Revisited" for immediate outcome prediction	
Assessment of mitral valve anatomy according to the Wilkins score	
Grade	**Mobility**
1	Highly mobile valve with only leaflet tips restricted
2	Leaflet mid and base portions have normal mobility
3	Valve continues to move forward in diastole, mainly from the base
4	No or minimal forward movement of the leaflets in diastole
	Thickening
1	Leaflets near normal in thickness (4–5 mm)
2	Mid leaflets normal, considerable thickening of margins (5–8 mm)
3	Thickening extending through the entire leaflet (5–8 mm)
4	Considerable thickening of all leaflet tissue (>8–10 mm)
	Calcification
1	A single area of increased echo brightness
2	Scattered areas of brightness confined to leaflet margins
3	Brightness extending into the mid portions of the leaflets
4	Extensive brightness throughout much of the leaflet tissue

	Subvalvular thickening
1	Minimal thickening just below the mitral leaflets
2	Thickening of chordal structures extending to one third of the chordal length
3	Thickening extended to distal third of the chords
4	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles)
The total score is the sum of the four items and ranges between 4 and 16.	

Assessment of mitral valve anatomy according to the Cormier score	
Echocardiographic group	**Mitral valve anatomy**
Group 1	Pliable non-calcified anterior mitral leaflet and mild subvalvular disease (i.e. thin chordae ≥10 mm long)
Group 2	Pliable non-calcified anterior mitral leaflet and severe subvalvular disease (i.e. thickened chordae <10 mm long)
Group 3	Calcification of mitral valve of any extent, as assessed by fluoroscopy, whatever the state of subvalvular apparatus

Echo Score "Revisited" for immediate outcome prediction	
Echocardiographic variables	**Points for Score (0 to 11)**
Mitral valve area ≤1cm^2	2
Maximum leaflet displacement ≤12mm	3
Commissural area ratio ≥1.25	3
Subvalvular involvement	3

Risk groups for Echo score "Revisited": low (score 0–3); intermediate (score 4–5); high (score 6–11).

Diuretics, beta-blockers, digoxin, or heart-rate regulating calcium channel blockers can transiently improve symptoms. Anticoagulation with a target international normalized ratio (INR) between 2 and 3 is indicated in patients with either new-onset or paroxysmal atrial fibrillation. In patients in sinus rhythm, oral anticoagulation is indicated when there has been a history of systemic embolism, or a thrombus is present in the LA (recommendation Class I, level of evidence C) and should also be considered when TOE shows dense spontaneous echo contrast or an enlarged LA (M-mode diameter >50 mm or LA volume >60 mL/m^2) (recommendation Class IIa, level of evidence C). Patients with moderate to severe MS and persistent atrial fibrillation should be kept on vitamin K antagonist (VKA) treatment and not receive NOACs.

Cardioversion is not indicated before intervention in patients with severe MS, as it does not durably restore sinus rhythm. If atrial fibrillation is of recent onset and the LA only moderately enlarged, cardioversion should be performed soon after successful intervention.

Serial testing

Asymptomatic patients with clinically significant MS who have not undergone intervention should be followed up yearly by means of clinical and echocardiographic examinations and at longer intervals (2 to 3 years) in case of moderate stenosis. Management of patients after successful PMC is similar to that of asymptomatic patients. Follow-up should be more frequent if asymptomatic restenosis occurs. When PMC is not successful, surgery should be considered early unless there are definite contra-indications.

Special patient populations

When restenosis with symptoms occurs after surgical commissurotomy or PMC, reintervention in most cases requires valve replacement, but PMC can be proposed in selected candidates with favourable characteristics if the predominant mechanism is commissural refusion.

In the elderly population with rheumatic MS when surgery is high-risk, PMC is a useful option, even if only palliative. In other elderly patients, surgery is preferable. However, in elderly patients with degenerative MS with severely calcified mitral annulus, surgery is very high-risk. As there is no commissural fusion in these cases, degenerative MS is not amenable to PMC. If degenerative MS is severe, very preliminary experience has suggested that transcatheter valve implantation of a TAVI bioprosthesis in the mitral position is feasible in symptomatic elderly patients who are inoperable if the anatomy is suitable.

In patients with severe tricuspid regurgitation (TR), PMC may be considered in selected patients with sinus rhythm, moderate atrial enlargement, and functional TR secondary to pulmonary hypertension. In other cases, surgery on both valves is preferred.

Tricuspid regurgitation

Introduction

Pathological tricuspid regurgitation (TR) is more often secondary, due to RV dysfunction following pressure and/or volume overload in the presence of structurally normal leaflets. Possible causes of primary TR are infective endocarditis (especially in intravenous drug addicts), rheumatic heart disease, carcinoid syndrome, myxomatous disease, endomyocardial fibrosis, Ebstein's anomaly and congenitally dysplastic valves, drug-induced valve diseases, thoracic trauma, and iatrogenic valve damage.

Evaluation

Echocardiography is the ideal technique to evaluate TR. In primary TR, the aetiology can usually be identified from specific abnormalities of the valve structure. In secondary TR, the degree of dilatation of the annulus, the RV dimension and function, and the degree of tricuspid valve deformation should be measured. Evaluation of TR severity (integration of multiple qualitative and quantitative parameters) and pulmonary systolic pressure should be carried out as currently recommended (Table 4). It has to be noted that the problem of elevated pulmonary vascular resistance may be disguised in the presence of severe TR because its velocity may be lower than expected in the case of pulmonary hypertension.

Evaluations of the RV dimensions and function should be conducted, despite existing limitations of current indices of RV function. The presence of associated lesions (looking carefully at the associated valve lesions, particularly on the left side) and LV function should be assessed. When available, CMR is the preferred method for evaluating RV size and function and represents the gold standard for assessing RV volumes and function.

Cardiac catheterization is not needed to diagnose TR or estimate its severity, but should be obtained in patients in whom isolated tricuspid valve surgery is contemplated for secondary TR to evaluate haemodynamics, in particular pulmonary vascular resistance.

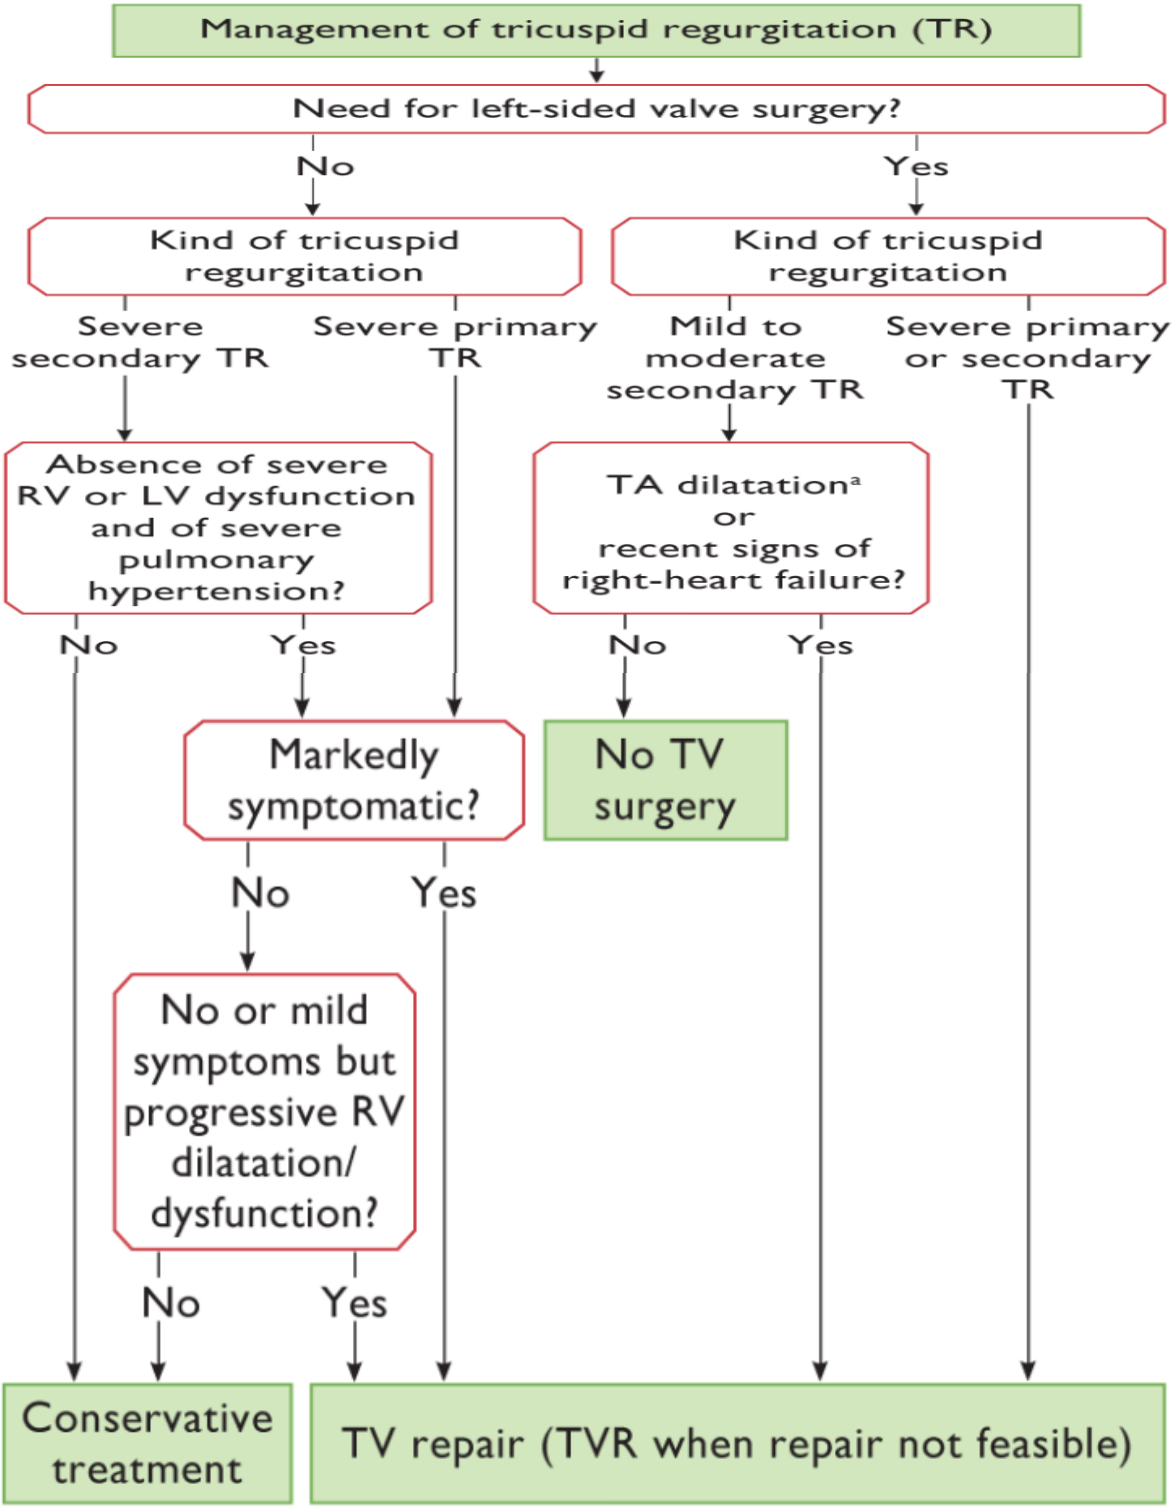
Indications for intervention are summarized in the table below and Figure 6.

Indications for tricuspid valve surgery		
Recommendations on tricuspid stenosis	**Class[a]**	**Level[b]**
Surgery is indicated in symptomatic patients with severe tricuspid stenosis.[c]	I	C
Surgery is indicated in patients with severe tricuspid stenosis undergoing left-sided valve intervention.[d]	I	C
Recommendations on primary tricuspid regurgitation		
Surgery is indicated in patients with severe primary tricuspid regurgitation undergoing left-sided valve surgery.	I	C
Surgery is indicated in symptomatic patients with severe isolated primary tricuspid regurgitation without severe right-ventricular dysfunction.	I	C
Surgery should be considered in patients with moderate primary tricuspid regurgitation undergoing left-sided valve surgery.	IIa	C
Surgery should be considered in asymptomatic or mildly symptomatic patients with severe isolated primary tricuspid regurgitation and progressive right-ventricular dilatation or deterioration of right-ventricular function.	IIa	C
Recommendations on secondary tricuspid regurgitation		
Surgery is indicated in patients with severe secondary tricuspid regurgitation undergoing left-sided valve surgery.	I	C
Surgery should be considered in patients with mild or moderate secondary tricuspid regurgitation with dilated annulus (≥40 mm or >21 mm/m^2 by 2D echocardiography) undergoing left-sided valve surgery.	IIa	C
Surgery may be considered in patients undergoing left-sided valve surgery with mild or moderate secondary tricuspid reguargitation even in the absence of annular dilatation when previous recent right- heart failure has been documented.	IIb	C
After previous left-sided valve surgery and in absence of recurrent left-sided valve dysfunction, surgery should be considered in patients with severe tricuspid regurgitation who are symptomatic or have progressive right-ventricular dilatation/dysfunction, in the absence of severe right or LV dysfunction, and severe pulmonary vascular disease/hypertension.	IIa	C

2D = two-dimensional; LV = left ventricular; PMC = percutaneous mitral commissurotomy.

[a]Class of recommendation - [b]Level of evidence - [c]Percutaneous balloon valvuloplasty can be attempted as a first approach if tricuspid stenosis is isolated - [d]Percutaneous balloon valvuloplasty can be attempted if PMC can be performed on the mitral valve

Figure 6 Indications for surgery in tricuspid regurgitation



LV = left ventricular; RV = right ventricular; TA = tricuspid annulus; TR = tricuspid regurgitation; TV = tricuspid valve; TVR = tricuspid valve replacement. [a]TA ≥40 mm or >21 mm/m^2. See recommendations

Tricuspid stenosis

Introduction

Tricuspid stenosis (TS) is often combined with TR, most frequently of rheumatic origin. It is therefore almost always associated with left-sided valve lesions, particularly MS, that usually dominate the clinical presentation. Other causes are rare: congenital, drug-induced valve diseases, Whipple's disease, endocarditis, or large right atrial tumour.

Evaluation

Echocardiography provides the most useful information. TS is often overlooked and requires careful evaluation. Echocardiographic evaluation of the anatomy of the valve and its subvalvular apparatus is important to assess valve reparability. No generally accepted grading of TS severity exists, but a mean gradient ≥5 mmHg at normal heart rate is considered indicative of clinically significant TS. Catheterization is no longer used for evaluating the severity of TS.

Indications for intervention

The lack of pliable leaflet tissue is the main limitation for valve repair. Even though this is still a matter of debate, biological prostheses for valve replacement are usually preferred over mechanical ones because of the high-risk of thrombosis carried by the latter and the satisfactory long-term durability of the former in the tricuspid position. Percutaneous balloon tricuspid dilatation has been performed in a limited number of cases, either alone or alongside PMC, but frequently induces significant regurgitation. There is a lack of data on long-term results. See table of indications for tricuspid valve surgery (see Section 8.2).

Medical therapy

Diuretics are useful in the presence of heart failure but are of limited long-term efficacy.

Combined & multiple valve diseases

Significant stenosis and regurgitation can be found on the same valve. Disease of multiple valves may be encountered in several conditions, particularly in rheumatic and congenital heart disease but also, less frequently, in degenerative valve disease. There is a lack of data on combined or multiple valve diseases. This does not allow for evidence-based recommendations.

The general principles for the management of combined or multiple valve disease are as follows:

- When either stenosis or regurgitation is predominant, management follows the recommendations concerning the predominant VHD. When the severity of both stenosis and regurgitation is balanced, indications for interventions should be based on symptoms and objective consequences rather than on the indices of severity of stenosis or regurgitation. In this setting, consideration of the pressure gradient that reflects the haemodynamic burden of the valve lesion becomes more important than valve area and measures of the regurgitation for the assessment of disease severity.
- It is necessary to take into account the interaction between the different valve lesions.
- Indications for intervention are based on global assessment of the consequences of the different valve lesions (i.e. symptoms or presence of LV dilatation or dysfunction). Intervention can be considered for non-severe multiple lesions associated with symptoms or leading to LV impairment.
- The decision to intervene on multiple valves should take into account the extra surgical risk of combined procedures.
- The choice of surgical technique should take into account the presence of the other VHD; repair remains the ideal option.

The management of specific associations of VHD is detailed in the individual sections of this document.

The choice between a mechanical and a biological valve in adults is determined mainly by estimating the risk of anticoagulation-related bleeding and thromboembolism with a mechanical valve versus the risk of structural valve deterioration with a bioprosthesis, and by considering the patient's lifestyle and preferences. Rather than setting arbitrary age limits, prosthesis choice should be discussed in detail with the informed patient, cardiologists, and surgeons, taking into account the factors detailed.

Choice of the aortic/mitral prosthesis – in favour of a mechanical prosthesis; the decision is based on the integration of several of the following factors

	Class[b]	Level[c]
A mechanical prosthesis is recommended according to the desire of the informed patient and if there are no contra-indications to long-term anticoagulation.[c]	I	C
A mechanical prosthesis is recommended in patients at risk of accelerated structural valve deterioration.[d]	I	C
A mechanical prosthesis should be considered in patients already on anticoagulation because of a mechanical prosthesis in another valve position.	IIa	C
A mechanical prosthesis should be considered in patients aged <60 years for prostheses in the aortic position and <65 years for prostheses in the mitral position.[e]	IIa	C
A mechanical prosthesis should be considered in patients with a reasonable life expectancy[f], for whom future redo valve surgery would be at high-risk.	IIa	C
A mechanical prosthesis may be considered in patients already on long-term anticoagulation due to high-risk for thromboembolism.[g]	IIb	C

[a]Class of recommendation - [b]Level of evidence - [c]Increased bleeding risk because of comorbidities, compliance concerns, or geographic, lifestyle, or occupational conditions - [d]Young age (<40 years), hyperparathyroidism. [e]In patients aged 60–65 years who should receive an aortic prosthesis, and those between 65–70 years in the case of mitral prosthesis, both valves are acceptable and the choice requires careful analysis of factors other than age. [f]Life expectancy should be estimated >10 years, according to age, sex, comorbidities, and country-specific life expectancy - [g]Risk factors for thromboembolism are atrial fibrillation, previous thromboembolism, hypercoagulable state, severe LV systolic dysfunction.

Choice of the aortic/mitral prosthesis – in favour of a bioprosthesis; the decision is based on the integration of several of the following factors	Class[b]	Level[c]
A bioprosthesis is recommended according to the desire of the informed patient.	I	C
A bioprosthesis is recommended when good-quality anticoagulation is unlikely (compliance problems, not readily available) or contra-indicated because of high bleeding risk (previous major bleed, comorbidities, unwillingness, compliance problems, lifestyle, occupation).	I	C
A bioprosthesis is recommended for reoperation for mechanical valve thrombosis despite good long-term anticoagulant control.	I	C
A bioprosthesis should be considered in patients for whom there is a low likelihood and/or a low operative risk of future redo valve surgery.	IIa	C
A bioprosthesis should be considered in young women contemplating pregnancy.	IIa	C
A bioprosthesis should be considered in patients aged >65 years for a prosthesis in the aortic position, or age >70 years in a mitral position, or those with life expectancy[c] lower than the presumed durability of the bioprosthesis.[d]	IIa	C

[a]Class of recommendation - [b]Level of evidence - [c]Life expectancy should be estimated according to age, sex, comorbidities, and country-specific life expectancy - [d]In patients aged 60–65 years who should receive an aortic prosthesis and those between 65–70 years in the case of mitral prosthesis, both valves are acceptable and the choice requires careful analysis of factors other than age.

Management after valve intervention

General remarks

Thromboembolism and anticoagulant-related bleeding present the majority of complications experienced by prosthetic valve recipients. Endocarditis prophylaxis and management of prosthetic valve endocarditis are detailed in separate ESC Guidelines.

All patients require lifelong follow-up by a cardiologist after valve surgery to detect early deterioration in prosthetic function or ventricular function or progressive disease of another heart valve. Clinical assessment should be performed yearly or as soon as possible if new cardiac symptoms occur. TTE should be performed if any new symptoms occur after valve replacement or if complications are suspected. After transcatheter as well as surgical implantation of a bioprosthetic valve, echocardiography – including the measurement of transprosthetic gradients – should be performed within 30 days (preferably around 30 days for surgery) after valve implantation (i.e. baseline imaging), at 1 year after implantation, and annually thereafter. TOE should be considered if TTE is of poor quality and in all cases of suspected prosthetic dysfunction or endocarditis. Cinefluoroscopy for mechanical valves and MSCT scanning provide useful additional information if valve thrombus or pannus are suspected to impair valve function.

Indications for antithrombotic therapy in patients with a prosthetic heart valve or valve repair		
Mechanical prosthesis	**Class[b]**	**Level[c]**
Oral anticoagulation using a VKA is recommended lifelong for all patients.	I	B
Bridging using therapeutic doses of UFH or LMWH is recommended when VKA treatment should be interrupted.	I	C
The addition of low-dose aspirin (75–100 mg/day) to VKA should be considered after thromboembolism despite an adequate INR.	IIa	C
The addition of low-dose aspirin (75–100 mg/day) to VKA may be considered in the case of concomitant atherosclerotic disease.	IIb	C
INR self-management is recommended provided appropriate training and quality control are performed.	I	B
In patients treated with coronary stent implantation, triple therapy with aspirin (75–100 mg/day), clopidogrel (75 mg/day), and VKA should be considered for 1 month, irrespective of the type of stent used and the clinical presentation (i.e. ACS or stable CAD).	IIa	B
Triple therapy comprising aspirin (75–100 mg/day), clopidogrel (75 mg/ day), and VKA for longer than 1 month and up to 6 months should be considered in patients with high ischaemic risk due to ACS or other anatomical/procedural characteristics that outweighs the bleeding risk.	IIa	B
Dual therapy comprising VKA and clopidogrel (75 mg/day) should be considered as an alternative to 1-month triple antithrombotic therapy in patients in whom the bleeding risk outweighs the ischaemic risk.	IIa	A
In patients who have undergone PCI, discontinuation of antiplatelet treatment should be considered at 12 months.	IIa	B
In patients requiring aspirin and/or clopidogrel in addition to VKA, the dose intensity of VKA should be carefully regulated with a target INR in the lower part of the recommended target range and a time in therapeutic range >65–70%.	IIa	B
The use of NOACs is contra-indicated.	III	B

Bioprostheses	Class[b]	Level[c]
Oral anticoagulation is recommended lifelong for patients with surgical or transcatheter implanted bioprostheses who have other indications for anticoagulation.[c]	I	C
Oral anticoagulation using a VKA should be considered for the first 3 months after surgical implantation of a mitral or tricuspid bioprosthesis.	IIa	C
Oral anticoagulation using a VKA should be considered for the first 3 months after surgical mitral or tricuspid valve repair.	IIa	C
Low-dose aspirin (75−100 mg/day) should be considered for the first 3 months after surgical implantation of an aortic bioprosthesis or valve-sparing aortic surgery.	IIa	C
Dual antiplatelet therapy should be considered for the first 3–6 months after TAVI, followed by lifelong single antiplatelet therapy in patients who do not need oral anticoagulation for other rea-	IIa	C
Single antiplatelet therapy may be considered after TAVI in the case of high bleeding risk.	IIb	C
Oral anticoagulation may be considered for the first 3 months after surgical implantation of an aortic bioprosthesis.	IIb	C

ACS = acute coronary syndrome; CAD = coronary artery disease; INR = international normalized ratio; LMWH = low-molecular-weight heparin; LV = left ventricular; PCI = percutaneous coronary intervention; NOAC = non-vitamin K antagonist oral anticoagulant; TAVI = transcatheter aortic valve implantation; UFH = unfractionated heparin;VKA = vitamin K antagonist.

[a]Class of recommendation - [b]Level of evidence - [c]Atrial fibrillation, venous thromboembolism, hypercoagulable state, or − with a lesser degree of evidence − severely impaired LV dysfunction (ejection fraction <35%).

Table 10 Target INR for mechanical prostheses

Prosthesis thrombogenicity	Patient-related risk factors[a]	
	None	≥1 risk factor
Low[b]	2.5	3.0
Medium[c]	3.0	3.5
High[d]	3.5	4.0

INR = international normalized ratio; LVEF = left ventricular ejection fraction.

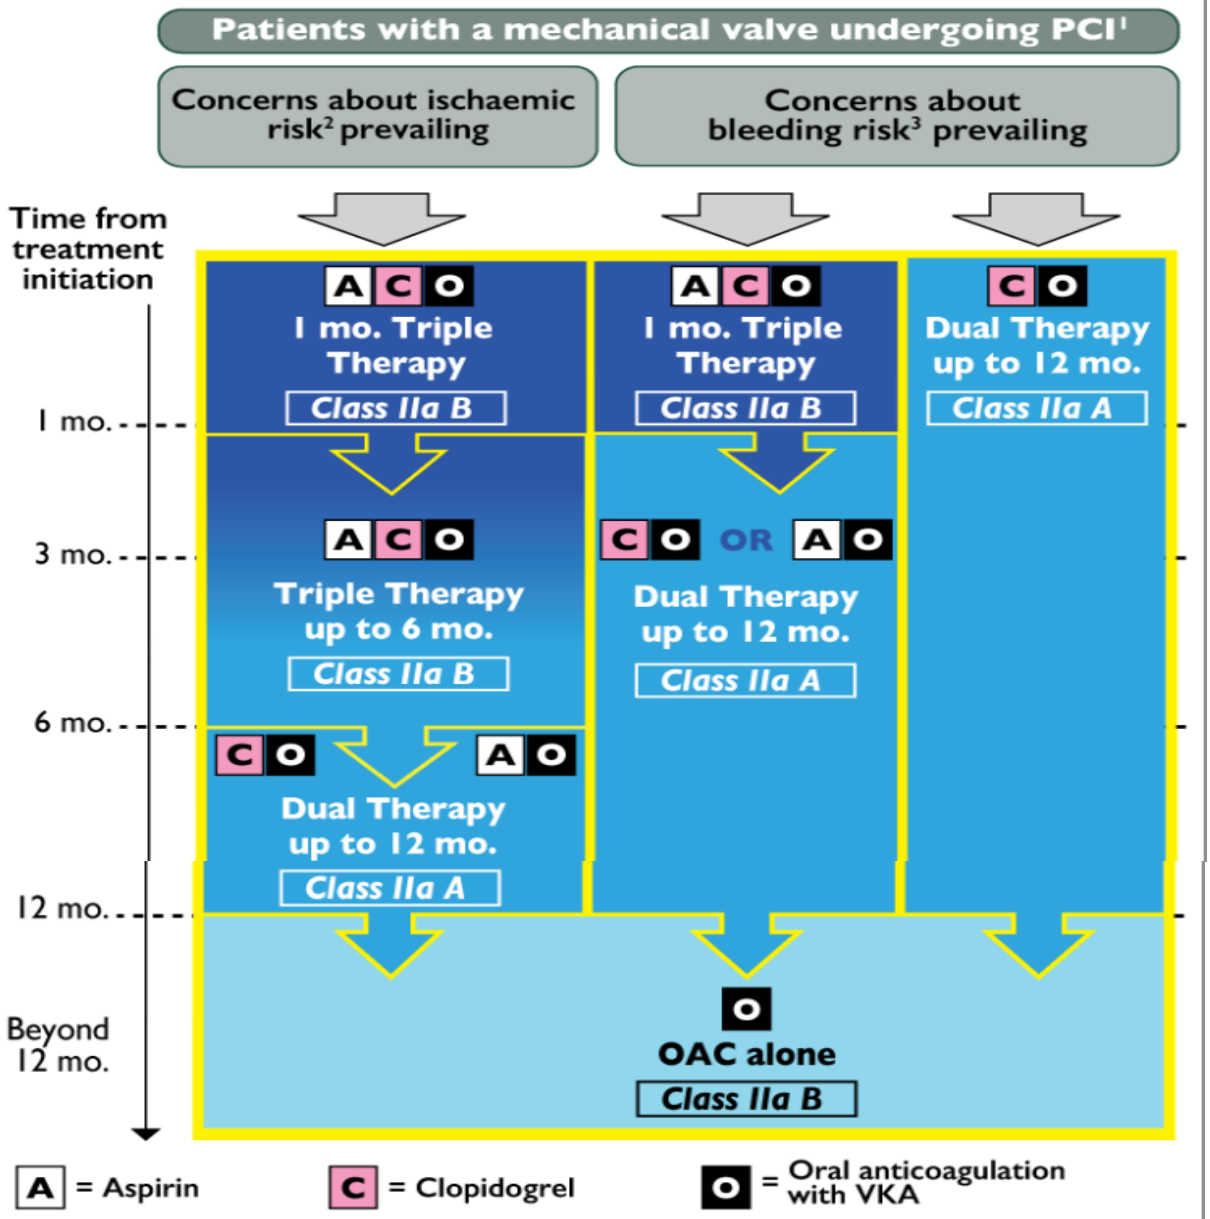
[a]Mitral or tricuspid valve replacement; previous thromboembolism; atrial fibrillation; mitral stenosis of any degree; LVEF <35%.

[b]Carbomedics, Medtronic Hall, ATS, Medtronic Open-Pivot, St Jude Medical, On-X, Sorin Bicarbon.

[c]Other bileaflet valves with insufficient data.

[d]Lillehei-Kaster, Omniscience, Starr-Edwards (ball-cage), Bjork-Shiley and other tilting-disc valves.

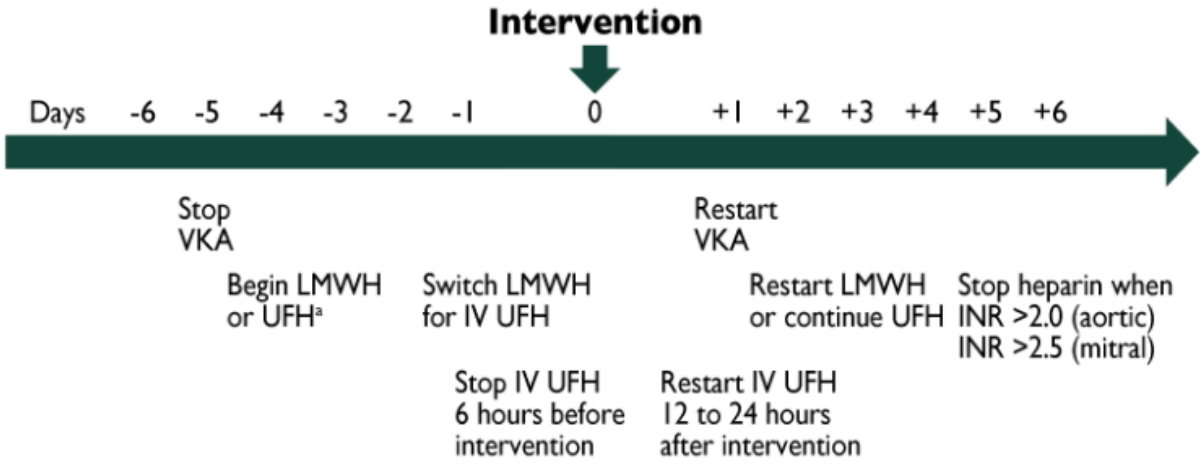
Figure 7 Antithrombotic therapy in patients with mechanical valve prosthesis after undergoing PCI (adapted from the 2017 ESC Focused Update on Dual Antiplatelet Therapy)



A = aspirin; ABC = age, biomarkers, clinical history; ACS = acute coronary syndrome; C = clopidogrel; mo. = month(s); O = oral anticoagulation with a vitamin K antagonist; PCI = percutaneous coronary intervention.
For more details regarding estimation of bleeding risk (HAS-BLED and ABC score) see the 2017 ESC Focused Update on Dual Antiplatelet Therapy (www.escardio.org/guidelines).
[1]: Periprocedural administration of aspirin and clopidogrel during PCI is recommended irrespective of the treatment strategy.
[2]: High ischaemic risk is considered as an acute clinical presentation or anatomical/procedural features which might increase the risk for myocardial infarction.
[3]: Bleeding risk can be estimated by HAS-BLED or ABC score

Anticoagulation during non-cardiac surgery requires careful management based on risk assessment. It is recommended not to interrupt oral anticoagulation for most minor surgical procedures (including dental extraction, cataract removal) and those procedures where bleeding is easily controlled. Major surgical procedures require an INR <1.5. In patients with a mechanical prosthesis, oral anticoagulant therapy should be stopped before surgery and bridging using heparin is recommended. UFH remains the only approved heparin treatment in patients with mechanical prostheses; intravenous administration should be favoured over the subcutaneous route. The use of subcutaneous LMWH, although off-label, is an alternative to UFH for bridging. When LMWHs are used they should be administered twice-a-day using therapeutic doses, adapted to body weight and renal function, and if possible, with monitoring of anti-Xa activity with a target of 0.5–1.0 U/mL. Fondaparinux should not be used for bridging in patients with mechanical prosthesis. Practical modalities of anticoagulation bridging are detailed in Figure 8.

Figure 8 Main bridging steps for an intervention requiring interruption of oral anticoagulation in a patient with a mechanical prosthesis. Timing should be individualized according to patient characteristics, actual INR, and the type of intervention (reproduced with permission from Iung and Rodes-Cabau)



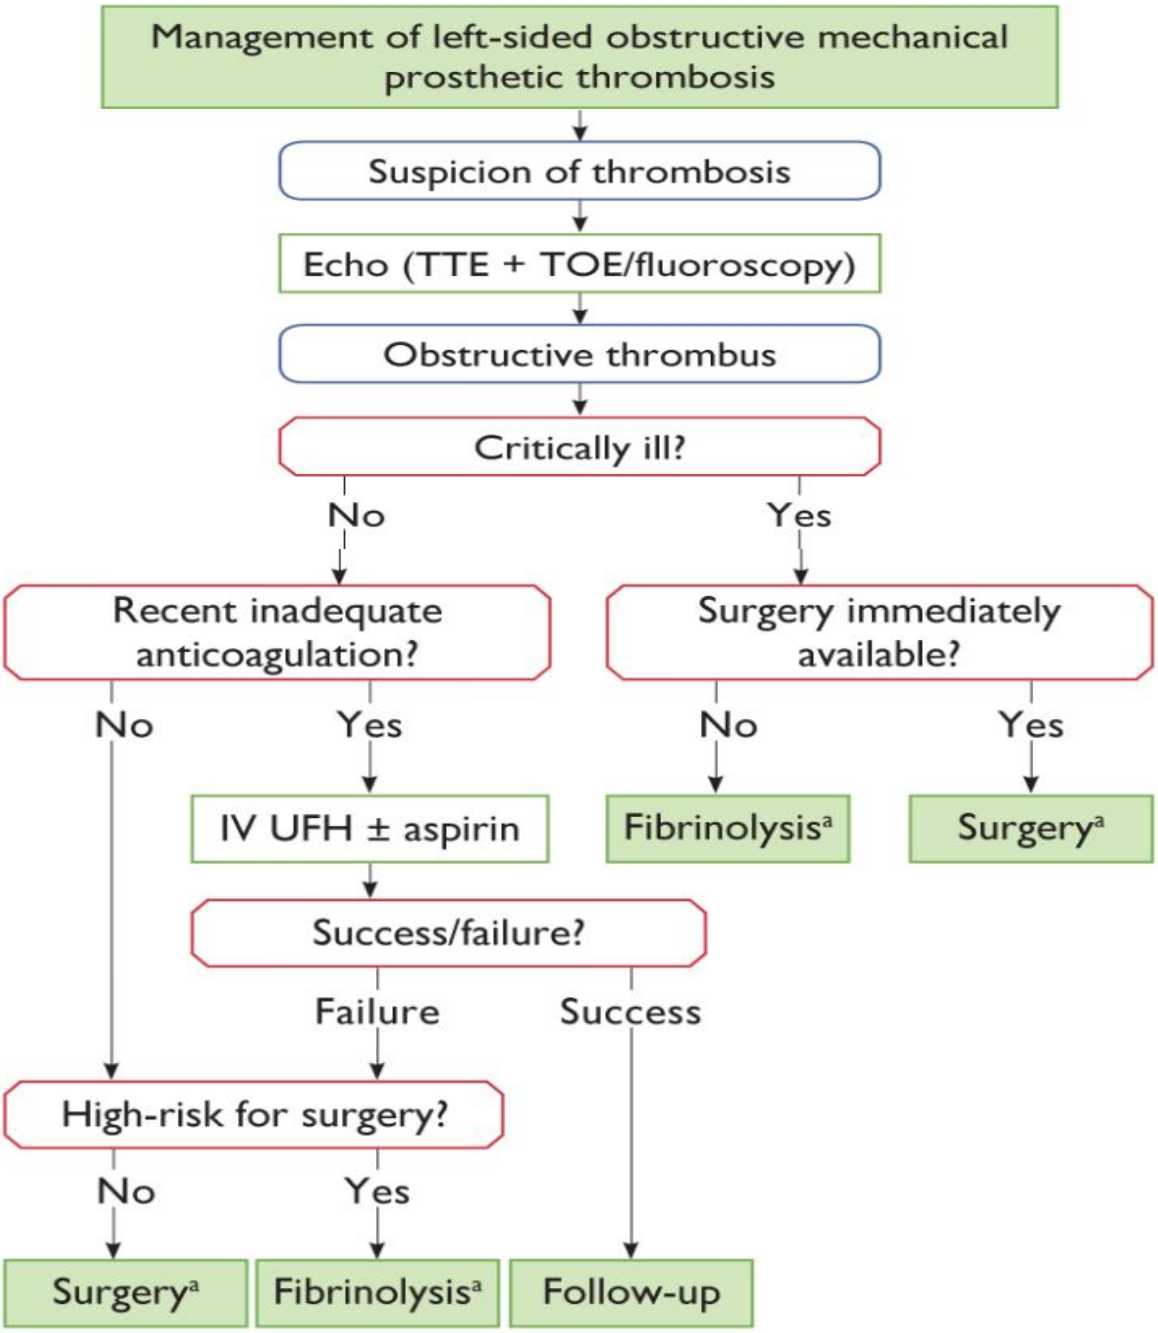
INR = international normalized ratio; IV = intravenous; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin;VKA = vitamin K antagonist.

[a]IV UFH may be favoured in patients at high thrombotic risk.

Management of prosthetic valve dysfunction		
Mechanical prosthetic thrombosis	**Class[b]**	**Level[c]**
Urgent or emergency valve replacement is recommended for obstructive thrombosis in critically ill patients without serious comorbidity.	I	C
Fibrinolysis (using recombinant tissue plasminogen activator 10 mg bolus + 90 mg in 90 minutes with UFH, or streptokinase 1 500 000 U in 60 minutes without UFH) should be considered when surgery is not available or is very high-risk, or for thrombosis of right-sided prostheses.	IIa	C
Surgery should be considered for large (>10 mm) non-obstructive prosthetic thrombus complicated by embolism.	IIa	C
Bioprosthetic thrombosis		
Anticoagulation using a VKA and/or UFH is recommended in bioprosthetic valve thrombosis before considering reintervention.	I	C
Haemolysis and paravalvular leak		
Reoperation is recommended if paravalvular leak is related to endocarditis or causes haemolysis requiring repeated blood transfusions or leading to severe symptoms.	I	C
Transcatheter closure may be considered for paravalvular leaks with clinically significant regurgitation in surgical high-risk patients (Heart Team decision).	IIb	C
Bioprosthetic failure		
Reoperation is recommended in symptomatic patients with a significant increase in transprosthetic gradient (after exclusion of valve thrombosis) or severe regurgitation.	I	C
Reoperation should be considered in asymptomatic patients with significant prosthetic dysfunction, if reoperation is at low-risk.	IIa	C
Transcatheter valve-in-valve implantation in aortic position should be considered by the Heart Team depending on the risk of reoperation and the type and size of prosthesis.	IIa	C

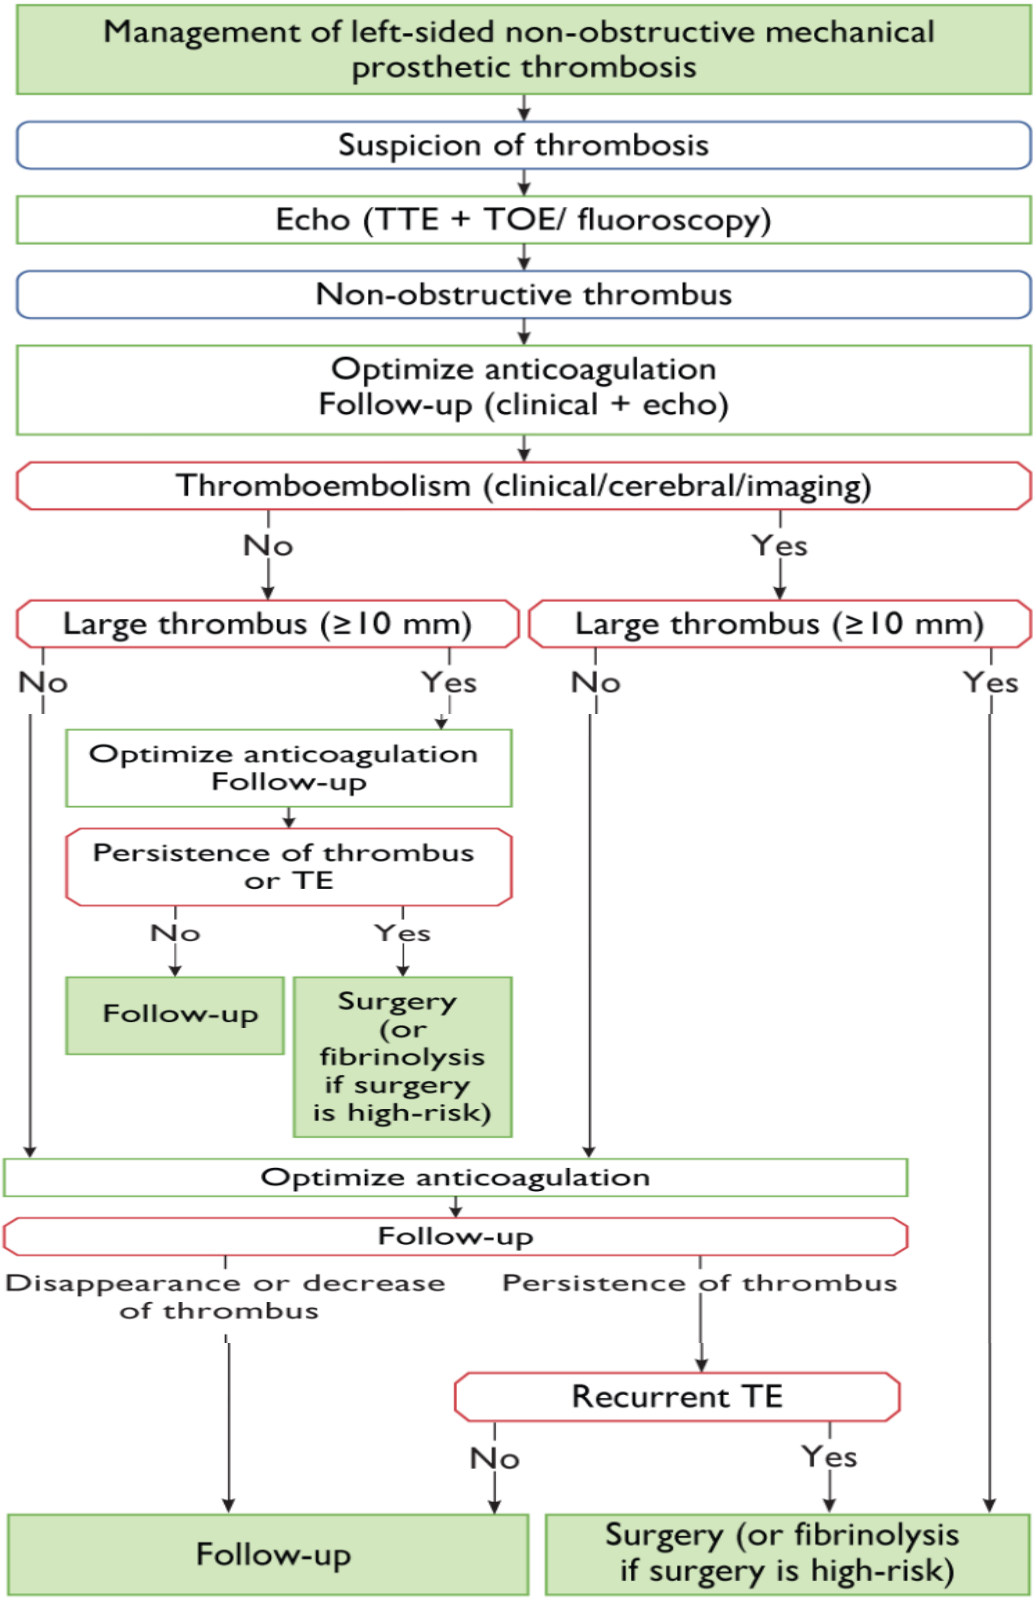
Management of valve thrombosis, hemolysis and paravalvular leak, and bio-prosthetic failure are summarized in the following tables and figures.

Figure 9 Management of left-sided obstructive mechanical prosthetic thrombosis



IV = intravenous; TOE = transoesophageal echocardiography; TTE = transthoracic echocardiography; UFH = unfractionated heparin. [a]Risk and benefits of both treatments should be individualized. The presence of a first-generation prosthesis is an incentive to surgery.

Figure 10 Management of left-sided non-obstructive mechanical prosthetic thrombosis



Management during non-cardiac surgery

Overview

Cardiovascular morbidity and mortality are increased in patients with VHD who undergo non-cardiac surgery. Symptomatic severe aortic stenosis or mitral stenosis may require valve replacement or percutaneous intervention before non- cardiac surgery. A detailed description of these recommendations is available in dedicated Guidelines (www.escardio.org/guideines).

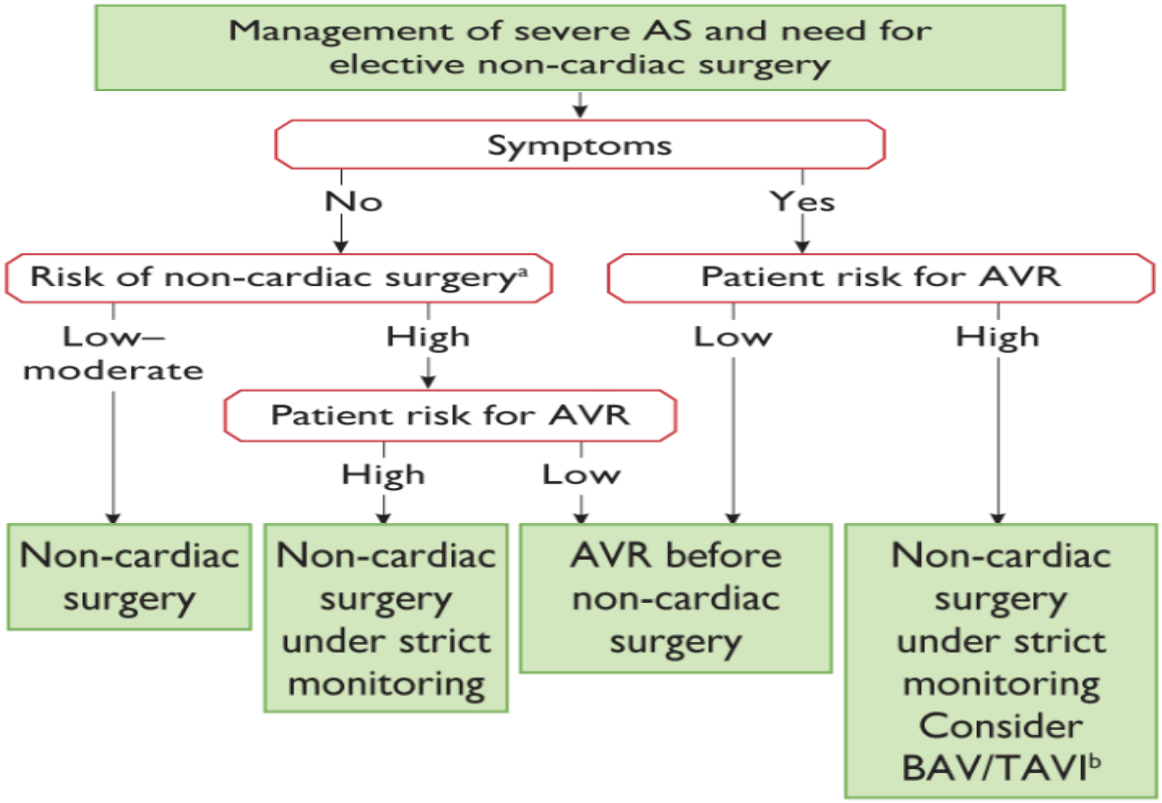
Preoperative evaluation

Echocardiography should be performed in any patient with VHD. Determination of functional capacity is a pivotal step in preoperative risk assessment, measured either by exercise test or ability to perform activities in daily life. The decision for the management should be taken after multidisciplinary discussion involving cardiologists, surgeons, and anaesthesiologists.

Specific valve lesions

In patients with severe aortic stenosis, urgent non-cardiac surgery should be performed under careful haemodynamic monitoring. Recommendations for the management of patients with severe AS who require elective non-cardiac surgery are summarized in Figure 11.

Figure 11 Management of severe aortic stenosis and elective non-cardiac surgery according to patient characteristics and type of surgery



AS = aortic stenosis; AVR = aortic valve replacement; BAV = balloon aortic valvuloplasty; TAVI = transcatheter aortic valve implantation.

[a]Classification into three groups according to the risk of cardiac complications (30-day death and myocardial infarction) for non-cardiac surgery (high-risk >5%; intermediate risk 1–5%; low-risk <1%).[196] - [b]Non-cardiac surgery performed only if strictly needed. The choice between percutaneous aortic valvuloplasty and TAVI should take into account patient life expectancy.

For interactivity see here

Non-cardiac surgery can be performed safely in patients with non-significant mitral stenosis (valve area >1.5 cm^2), and in asymptomatic patients with significant MS and a systolic pulmonary artery pressure <50 mmHg. In symptomatic patients or in patients with systolic pulmonary artery pressure >50 mmHg, correction of mitral stenosis, by means of PMC whenever possible, should be attempted before non-cardiac surgery if it is high-risk.

Non-cardiac surgery can be performed safely in asymptomatic patients with severe mitral regurgitation or aortic regurgitation and preserved LV function. The presence of symptoms or LV dysfunction should lead to consideration of valvular surgery, but this is seldom needed before non-cardiac surgery. If LV dysfunction is severe (ejection fraction <30%), non-cardiac surgery should be performed only if strictly necessary, after optimization of medical therapy for heart failure.

Perioperative monitoring

Heart rate control (particularly in mitral stenosis) and careful fluid management (particularly in aortic stenosis) are needed. TOE monitoring may be considered.

Management during pregnancy

Overview

Detailed Guidelines on the management of cardiovascular disease during pregnancy are available in a specific document (www.escardio.org/guidelines).

The decision for management during pregnancy should be taken after multidisciplinary discussion involving cardiologists, obstetricians, and anaesthesiologists. Valve disease should be evaluated before pregnancy and treated if necessary. Pregnancy should be discouraged in severe mitral stenosis, severe symptomatic AS, and aortic diameter >45 mm in Marfan syndrome or >27.5 mm/m^2 in Turner syndrome.

Caesarean section is recommended for patients with severe mitral or AS, ascending aortic diameter >45 mm, or severe pulmonary hypertension, as well as women on oral anticoagulants in preterm labour.

Native valve disease

Moderate or severe mitral stenosis with valve area <1.5 cm^2 in pregnant women is usually poorly tolerated. PMC should be considered in severely symptomatic patients (NYHA Class III–IV) and/or those with systolic pulmonary artery pressure >50 mmHg despite optimal therapy. PMC should be performed after the 20th week of pregnancy in experienced centres.

Complications of severe AS occur mainly in patients who were symptomatic before pregnancy and among those with impaired LV function. Evaluation with exercise test is recommended before pregnancy.

Chronic mitral regurgitation and aortic regurgitation are well tolerated, even when severe, provided LV systolic function is preserved.

Surgery under cardiopulmonary bypass is associated with a foetal mortality rate of between 15% and 30% and should be restricted to the rare conditions that threaten the mother's life.

Prosthetic valves

Maternal mortality is estimated at between 1% and 4%, and serious events in up to 40% of women with mechanical valves.
Therapeutic anticoagulation is extremely important to avoid complications. In patients requiring ≤5 mg warfarin, oral anticoagulants throughout pregnancy and change to UFH before delivery is favoured. In patients requiring higher doses, switch to LMWH during the first trimester with strict anti-Xa monitoring (therapeutic range 0.8–1.2) and use of oral anticoagulants afterwards is favoured.

2017 ESC Pocket Guidelines

Committee for Practice Guidelines

PAD

2017 ESC Guidelines on the Diagnosis and Treatment of Peripheral Arterial Diseases

ESC
European Society of Cardiology

www.escardio.org/guidelines

Introduction

The term “peripheral arterial diseases” (PADs) encompasses all arterial diseases other than coronary arteries and the aorta. This should be clearly distinguished from the term “peripheral artery disease” often used to name lower extremity artery disease (LEAD). Indeed, other peripheral localizations (Figure 1) are also frequently affected, mainly by atherosclerosis, and complete the family of PADs.

Because of multiple presentations and therapeutic options, a multidisciplinary management of these patients is mostly necessary, and cardiologists should be sensitive in regard to the diagnosis and management of patients with PADs, as many of them are seen and managed for concomitant cardiac conditions. Major efforts are still necessary to sensitize healthcare providers, decision makers and the general population about the need for awareness, screening, prevention and management of the 40 million individuals in our continent affected by PADs.

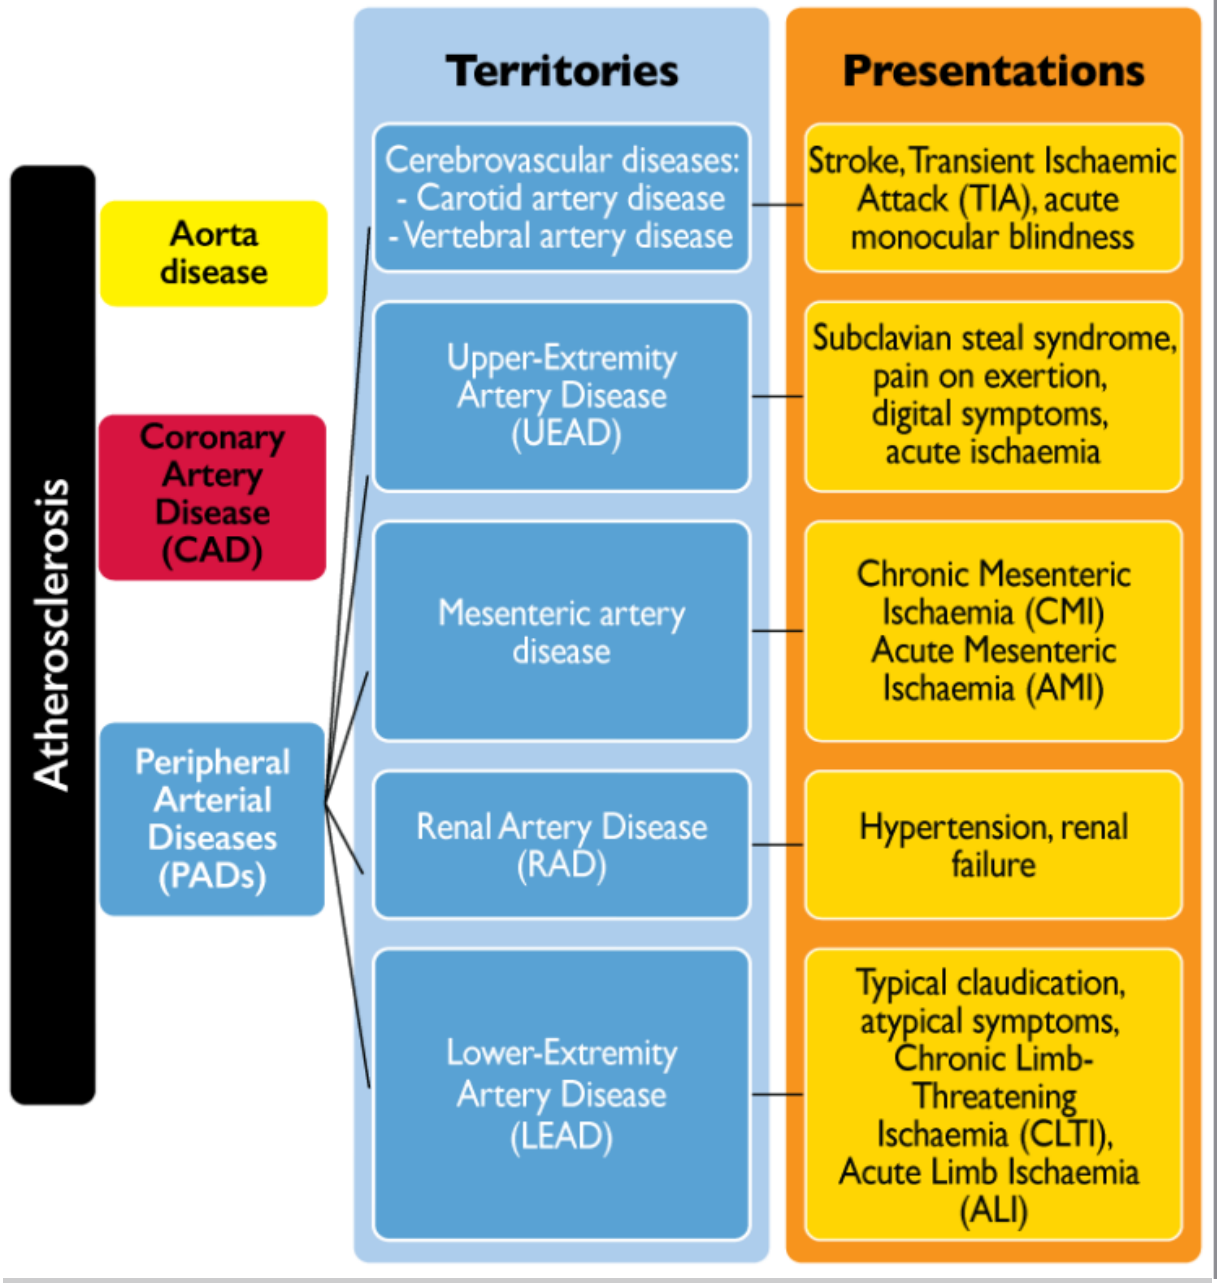
General recommendations on the management of patients with peripheral arterial diseases

Recommendations	Class[a]	Level[b]
In healthcare centres, it is recommended to set up a multidisciplinary Vascular Team to make decisions for the management of patients with PADs.	I	C
It is recommended to implement and support initiatives to improve medical and public awareness of PADs, especially cerebrovascular and lower extremity artery diseases.	I	C

Epidemiology and risk factors

The risk of different localizations of PADs increases with age and with exposure to major CV risk factors: smoking, hypertension, dyslipidaemia and diabetes. The strength of association between each risk factor and each vascular territory is variable. When a vascular territory is affected by atherosclerosis, not only is the corresponding organ endangered (e.g. the brain for carotid artery disease) but also the total risk of any cardiovascular event is increased (e.g. coronary events).

Figure 1 Presentations of Peripheral Arterial Diseases (PADs)



Overview

Thorough clinical history and physical examination are key steps in PADs management (Tables 1 & 2).

Laboratory testing (Table 3) is a key component especially for assessing the risk factors and end organ damages.

The Ankle-Brachial Index (ABI) has a specific particularity since it can not only diagnose LEAD but can be used as marker of atherosclerosis and risk of mortality and CV events (Table 4).

Table 1 Main points of medical history for assessment of peripheral arterial diseases

Family history of CVD (coronary artery disease, cerebrovascular disease, aortic aneurysm, LEAD), and premature CVD (fatal or non-fatal CVD event or/and established diagnosis of CVD in first degree male relatives before 55 years or female relatives before 65 years).
Personal history of: • Hypertension • Diabetes • Dyslipidaemia • Smoking (present and/or past), passive smoking exposure • Prior CVD • Chronic kidney disease • Sedentary life • Dietary habits • History of cancer radiation therapy • Psycho-social factors
Transient or permanent neurological symptoms.
Arm exertion pain, particularly if associated with dizziness or vertigo.
Symptoms suggesting angina, dyspnoea.
Abdominal pain, particularly if related to eating and associated with weight loss.
Walking impairment/claudication: • type: fatigue, aching, cramping, discomfort, burning • location: buttock, thigh, calf, or foot • timing: triggered by exercise, uphill rather than downhill, quickly relieved with rest; chronic • distance
Lower limb pain (including foot) at rest, and evolution at upright or recumbent position.
Poorly healing wounds of the extremities.
Physical activity assessment: • Functional capacity and causes of impairment.
Erectile dysfunction.

CVD = cardiovascular disease; LEAD = lower extremity artery disease.

Table 2 Physical examination for assessment of peripheral arterial diseases

Auscultation and palpation of cervical and supraclavicular areas.
Careful inspection of upper extremities, including hands (i.e. colour, skin integrity).
Palpation of upper extremity pulses.
Blood pressure measurement of both arms and notation of inter-arm difference.
Auscultation at different levels including the flanks, peri-umbilical region, and groin.
Abdominal palpation, palpation of femoral, popliteal, dorsalis pedis, and posterior tibial artery pulses, temperature gradient assessment.
Careful inspection of lower limbs, including feet (i.e. colour, presence of any cutaneous lesion). Findings suggestive of lower extremity arterial disease, including calf hair loss and muscle atrophy, should be noted.
Peripheral neuropathy assessment in case of diabetes or LEAD: sensory loss (monofilament testing), ability to detect pain and light touch (sharp examination pin, cotton wool), vibration impairment (128 Hz tuning fork); deep tendon reflexes examination; sweating.

Table 3 Laboratory testing in patients with peripheral arterial diseases

Routine tests
Fasting plasma glucose.
Fasting serum lipid profile: • total cholesterol • triglycerides • high-density lipoprotein cholesterol • low-density lipoprotein cholesterol
Serum creatinine and creatinine clearance.
Urine analysis: urinary protein by dipstick test, microalbuminuria.
• Blood count • Uric acid
Additional tests, based on findings from clinical history, physical examination and routine tests
Either glycated haemoglobin if fasting plasma glucose >5.6 mmol/L (101 mg/dL) or impaired glucose tolerance test when there is doubt.
Lipoprotein(a) if there is a family history of premature cardiovascular disease.
Quantitative proteinuria if positive dipstick test.

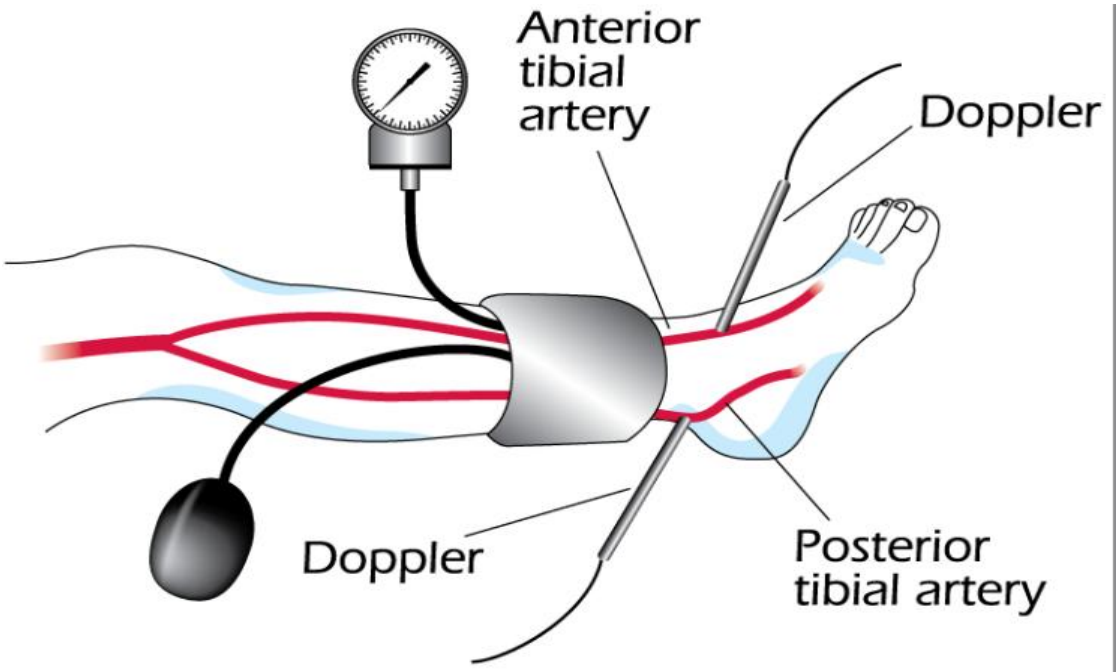
Table 4 The Ankle-Brachial Index

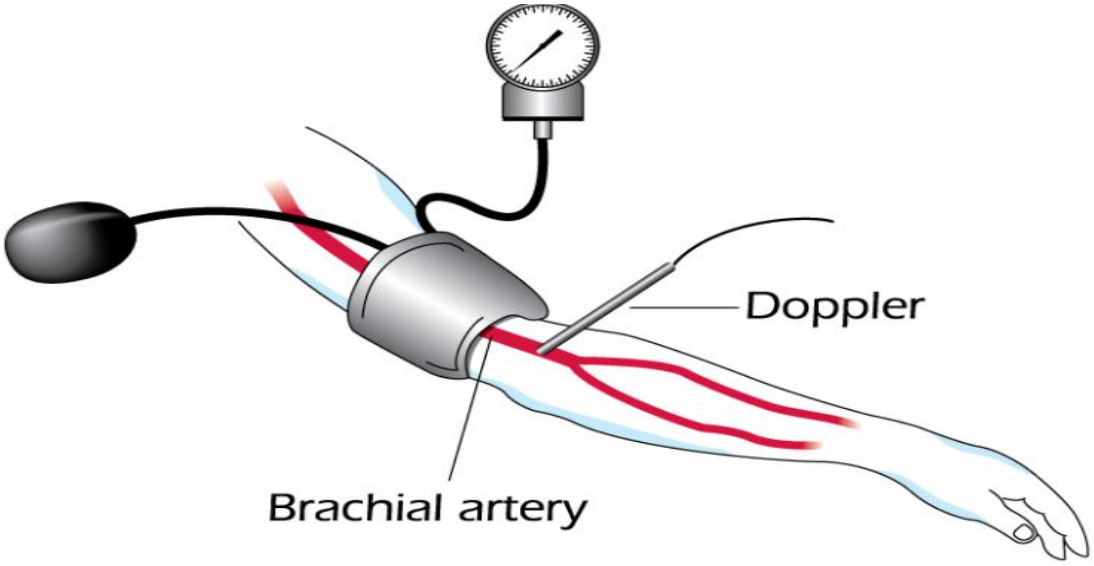
1. Who should have an ABI measurement in clinical practice?

- **Patients with clinical suspicion for LEAD:**
  - Lower extremities pulse abolition and/or arterial bruit
  - Typical intermittent claudication or symptoms suggestive for LEAD
  - Non-healing lower extremity wound
- **Patients at risk for LEAD because of the following clinical conditions:**
  - Atherosclerotic diseases: CAD, any PADs
  - Other conditions: AAA, CKD, heart failure
- **Asymptomatic individuals clinically-free but at-risk for LEAD:**
  - Men and women aged >65 years
  - Men and women aged <65 years classified at high CV risk according the ESC Guidelines[a]
  - Men and women aged >50 years with family history for LEAD

2. How to measure the ABI?

In supine position, with cuff placed just above the ankle, avoiding wounded zones. After a 5–10 minute rest, the SBP is measured by a Doppler probe (5–10 MHz) on the posterior and the anterior tibial (or dorsal pedis) arteries of each foot and on the brachial artery of each arm. Automated BP cuffs are mostly not valid for ankle pressure and may display overestimated results in case of low ankle pressure. The ABI of each leg is calculated by dividing the highest ankle SBP by the highest arm SBP.





3. How to interpret the ABI?

- For diagnosis of LEAD interpret each leg separately (one ABI per leg).
- For the CV risk stratification: take the lowest ABI between the two legs.
- Interpretation:

[a]Subjects with: markedly elevated single risk factors; diabetes mellitus (except for young people with type 1 diabetes without other major risk factors); a calculated SCORE ≥5% and <10%.

The management of patients with PADs includes both interventions to address specific arterial symptoms and general CV risk prevention. Best medical therapy includes CV risk factor management with non-pharmacological measures (i.e. smoking cessation, healthy diet, weight loss and regular physical exercise) and optimal pharmacological therapy.

Recommendations in patients with peripheral arterial diseases: best medical therapy

Recommendations	Class[a]	Level[b]
Smoking cessation is recommended in all patients with PADs.	I	B
Healthy diet and physical activity are recommended for all patients with PADs.	I	C
Statins are recommended in all patients with PADs.	I	A
In patients with PADs, it is recommended to reduce LDL-C to <1.8 mmol/L (70 mg/dL) or decrease it by ≥50% if baseline values are 1.8–3.5 mmol/L (70–135 mg/dL).	I	C
In diabetic patients with PADs, strict glycaemic control is recommended.	I	C
Antiplatelet therapy is recommended in patients with symptomatic PADs.	I	C[d]
In patients with PADs and hypertension, it is recommended to control blood pressure at <140/90 mmHg.	I	A
ACEIs or ARBs should be considered as first line therapy in patients with PADs and hypertension.[c]	IIa	B

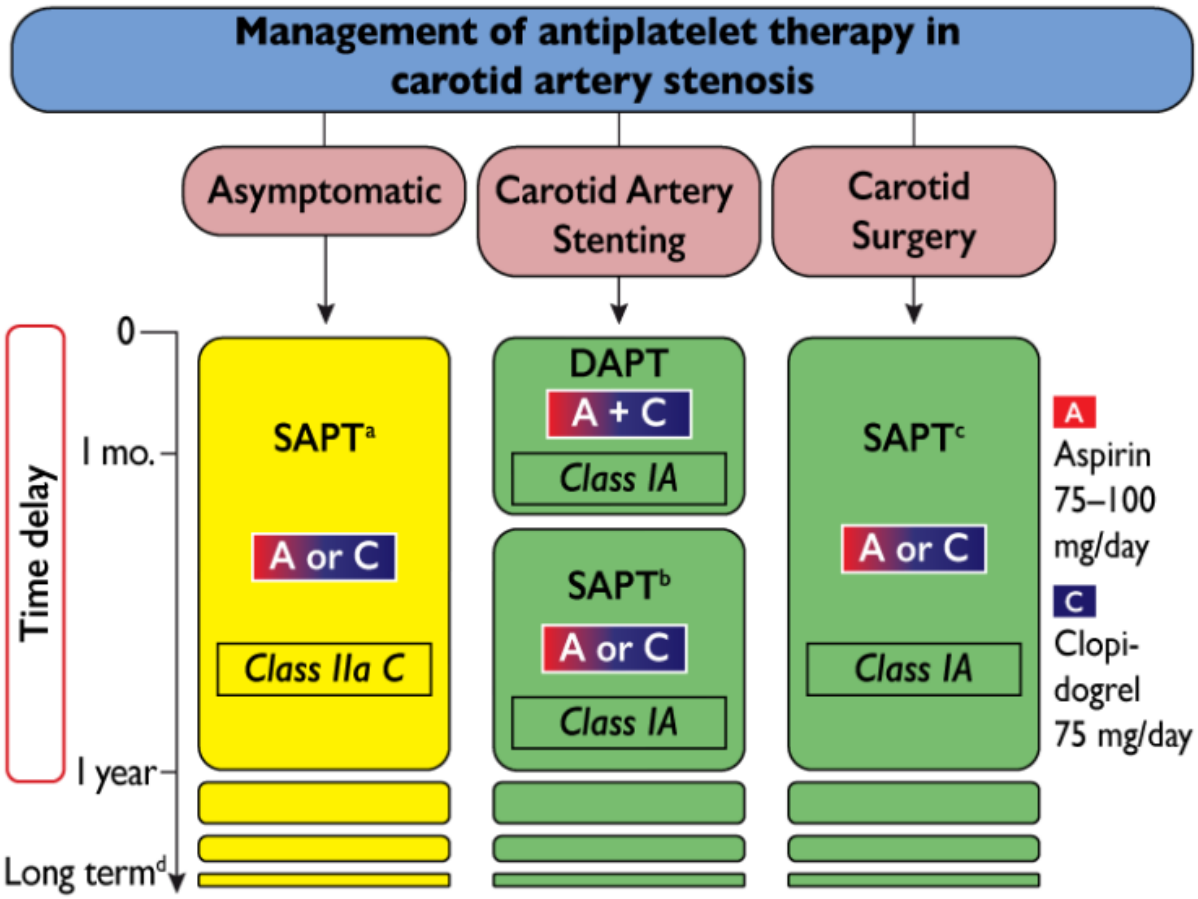
ACEIs = angiotensin-converting enzyme inhibitors; ARBs = angiotensin-receptor blockers; BP = blood pressure; HbA1c = glycated haemoglobin; LDL-C = low-density lipoprotein cholesterol; LEAD = lower extremity artery disease; PADs = peripheral arterial diseases.

[c]Calcium channel blockers should be proposed in black individuals.

[d]Evidence is not available for all sites.When evidence is available, recommendations specific for the vascular site are presented in the corresponding sections.

This chapter addresses specifically the antithrombotic therapy, as part of best medical therapy, in most frequent cases. Other cases with PADs (e.g. renal artery disease) without any specific indication for oral anticoagulation (e.g. atrial fibrillation) require long-term antiplatelet therapy.

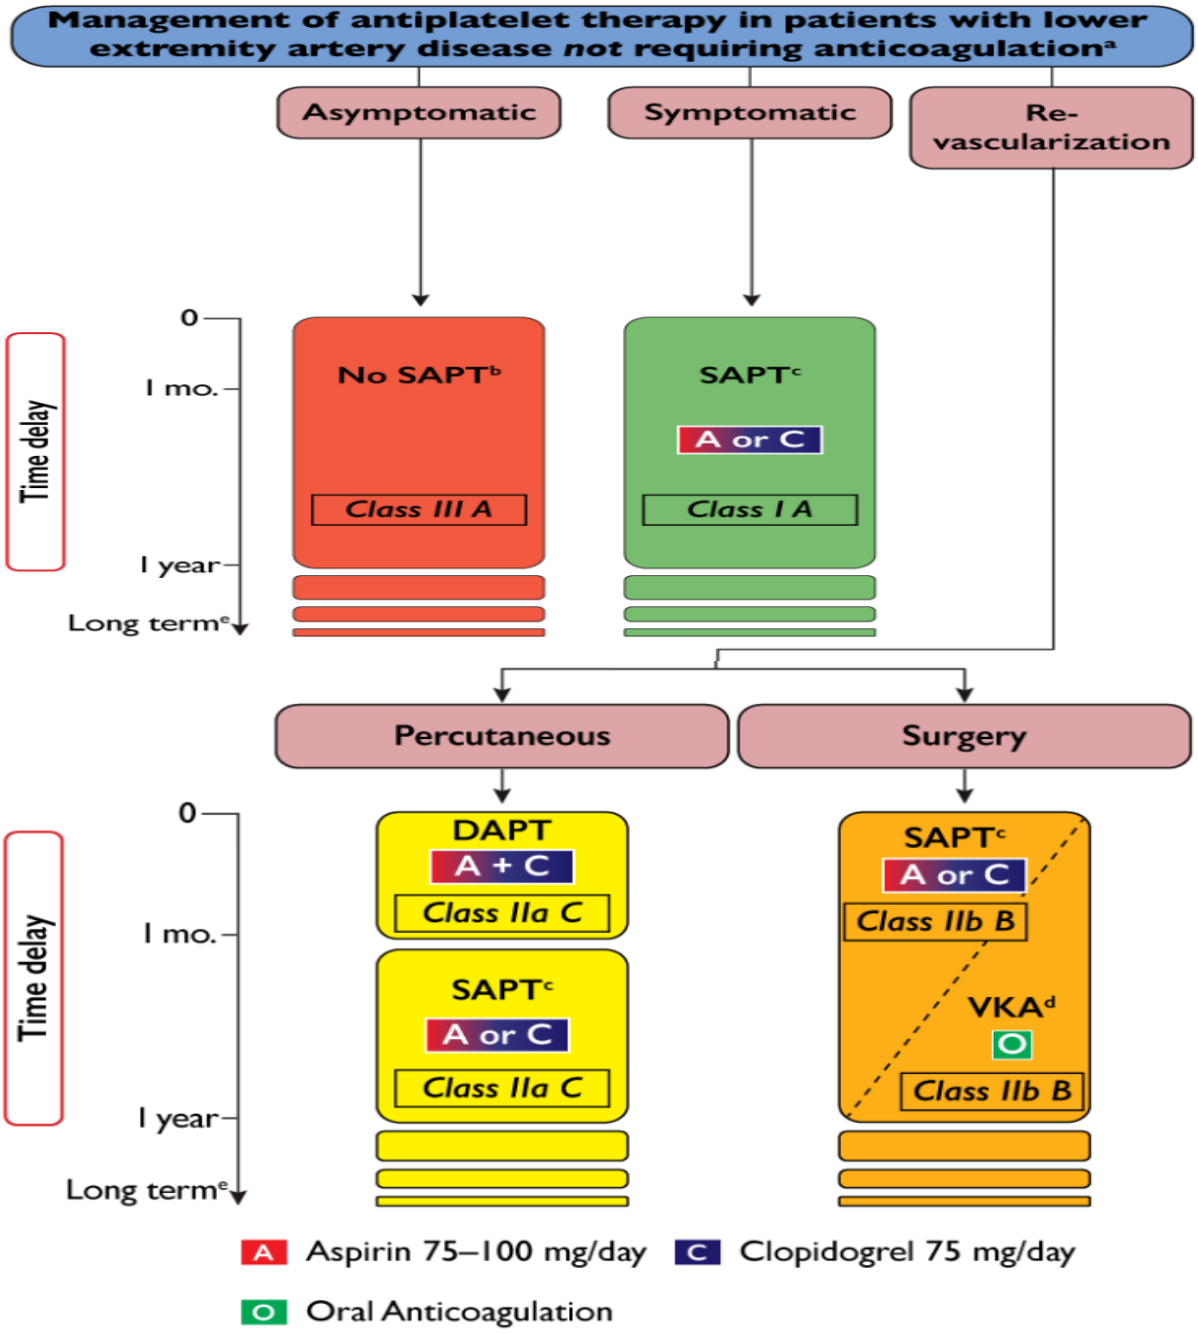
Figure 2 Management of antithrombotic treatment in patients with carotid artery stenosis



DAPT = dual antiplatelet therapy, a daily combination of aspirin (75–100 mg) and clopidogrel (75 mg); CAS = carotid artery stenting; SAPT = single antiplatelet therapy; TIA = transient ischaemic attack.

[a]At the exception of patient at very high bleeding risk - [b]DAPT may be used if another indication supersedes that of carotid artery stenting such as acute coronary syndrome or percutaneous coronary intervention of less than 1 year - [c] In case of recent minor stroke or TIA.A loading dose of aspirin (300 mg) and/or clopidogrel (300/600 mg) is recommended at the acute phase of stroke/TIA or during CAS - [d]Stands for as long as it is well tolerated.

Figure 3 Antiplatelet therapy in patients with lower extremity artery disease



DAPT = dual antiplatelet therapy; SAPT = single antiplatelet therapy;VKA = vitamin K antagonist.

[a]e.g. concomitant AF or mechanical valve prosthesis.

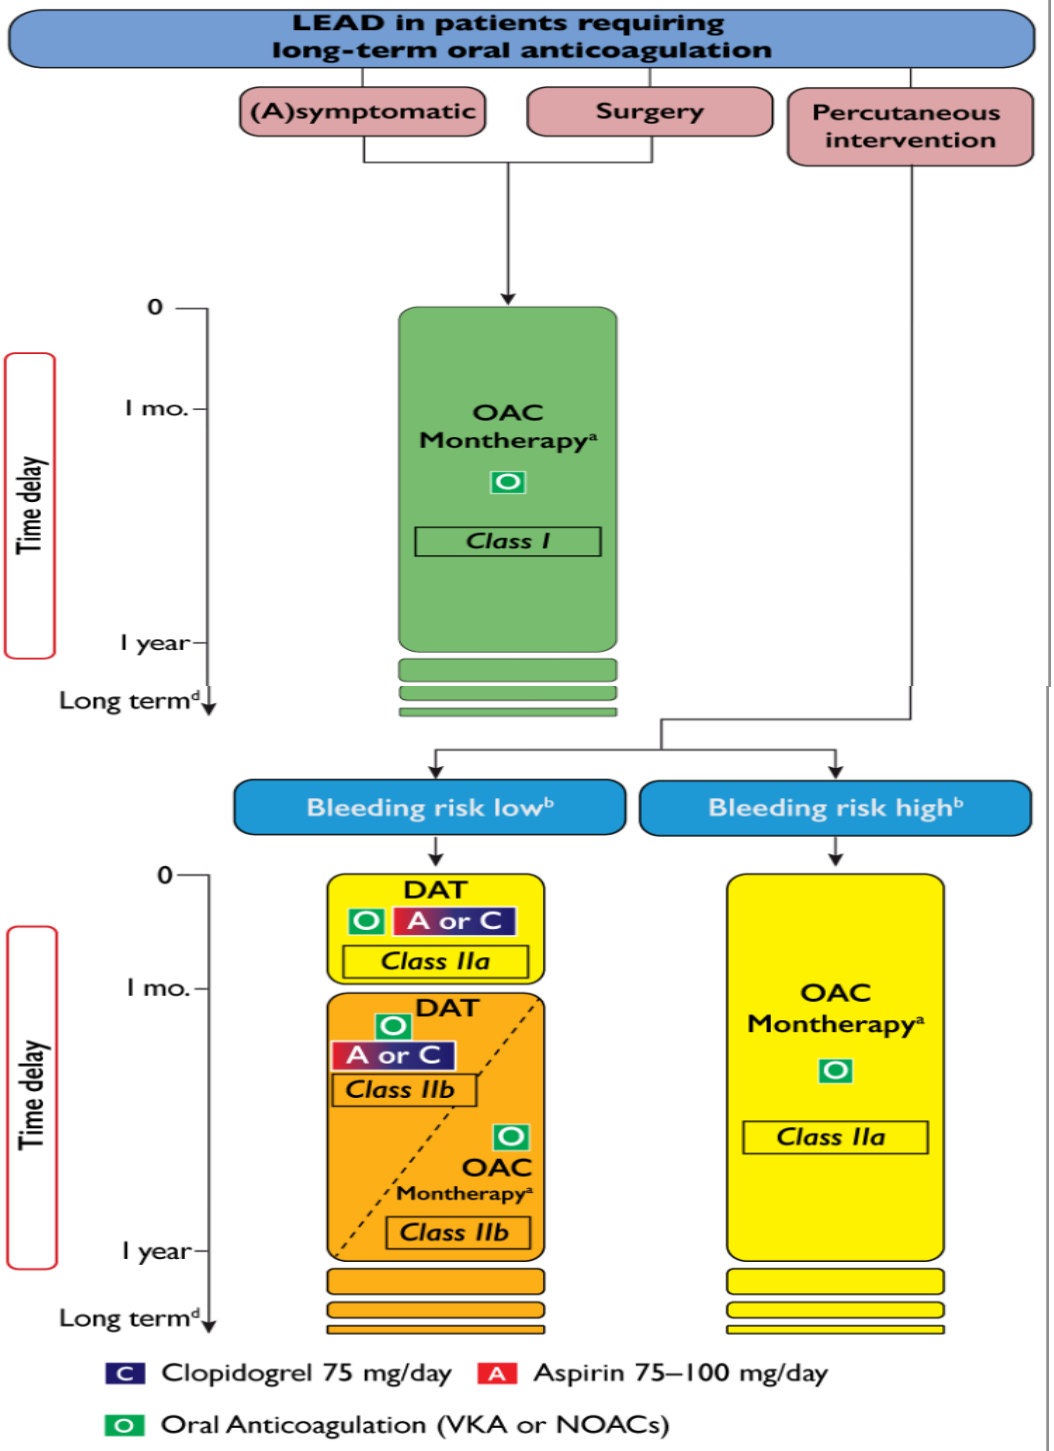
[b]SAPT should be considered if there is another concomitant atherosclerotic disease (e.g. coronary artery disease).

[c]DAPT may be considered in patients with recent acute coronary syndrome and/or percutaneous coronary intervention (<1 year), stenting of the last patent coronary artery, multiple coronary vessel disease in diabetic patients with incomplete revascularization.

[d]Evidence is weak and bleeding doubles as compared to SAPT.

[e]Stands for as long as it is well tolerated.

Figure 4 Antithrombotic therapy in patients with LEAD requiring oral anticoagulation



ACS = acute coronary syndrome; CAD = coronary artery disease; CLTI = chronic limb-threatening ischaemia; DAT = dual antithrombotic therapy;LEAD = lower extremity artery disease; OAC = oral anticoagulation.

[a]DAT may be considered in high ischaemic rick patients defined as prior stent thrombosis, acute limb ischaemia on OAC and concomitant CAD (recent ACS, stenting of the last patent coronary artery, multiple coronary vessel disease in diabetic patients with incomplete revascularization).

[b]Compared to the risk for stroke/CLTI due to stent/graft occlusion.

[c]Stands for as long as it is well tolerated.

Recommendations on antithrombotic therapy in patients with peripheral artery diseases

Recommendations	Class[a]	Level[b]
Carotid artery disease		
In patients with symptomatic carotid stenosis, long-term SAPT is recommended.	I	A
DAPT with aspirin and clopidogrel is recommended for at least one month after CAS.	I	B
In patients with asymptomatic >50% carotid artery stenosis, long-term antiplatelet therapy (commonly low dose aspirin) should be considered when the bleeding risk is low.[c]	IIa	C
Lower extremity artery disease		
Long-term SATP is recommended in symptomatic patients.	I	A
Long-term SATP is recommended in all patients who have undergone revascularization.	I	C
SATP is recommended after infra-inguinal bypass surgery.	I	A
In patients requiring antiplatelet therapy, clopidogrel may be preferred over aspirin.	IIb	B
Vitamin K antagonists may be considered after autologous vein infra- inguinal bypass.	IIb	B
DAPT with aspirin and clopidogrel for at least one month should be considered after infra-inguinal stent implantation.	IIa	C
DAPT with aspirin and clopidogrel may be considered in below-knee bypass with prosthetic graft.	IIb	B
Because of a lack of proved benefit, antiplatelet therapy is not routinely indicated in patients with isolated[d] asymptomatic LEAD.	III	A

Antithrombotic therapy for PADs patients requiring oral anticoagulant		
In patients with PADs and AF, oral anticoagulation:		
• is recommended when CHA_2DS_2-VASc score ≥2	I	A
• should be considered in all other patients	IIa	B
In patients with PADs who have an indication for OAC (e.g.AF or mechanical prosthetic valve), oral anticoagulants alone should be considered.	IIa	B
After endovascular revascularization, aspirin or clopidogrel should be considered in addition to OAC for at least I month if the bleeding risk is low compared to the risk of stent/graft occlusion.	IIa	C
After endovascular revascularization, OAC alone should be considered if the bleeding risk is high compared to the risk of stent/graft occlusion.	IIa	C
OAC and SAPT may be considered beyond one month in high ischaemic risk patients or when there is another firm indication for long-term SAPT.	IIb	C

AF = atrial fibrillation; CAS = carotid artery stenting; DAPT = dual antiplatelet; LEAD = lower extremity artery disease; OAC = oral anticoagulation; PADs = peripheral arterial diseases; SAPT = single antiplatelet therapy.

CHA_2DS_2-VASc score is calculated as follows: Congestive heart failure history (1 point), Hypertension (1 point),Age >75 years (2 points), Diabetes mellitus (1 point), Stroke or TIA or arterial thromboembolic history (1 point),Vascular disease history (1 point), Age between 65 and 74 years (1 point), Sex category (1 point if female).

[a]Class of recommendation.

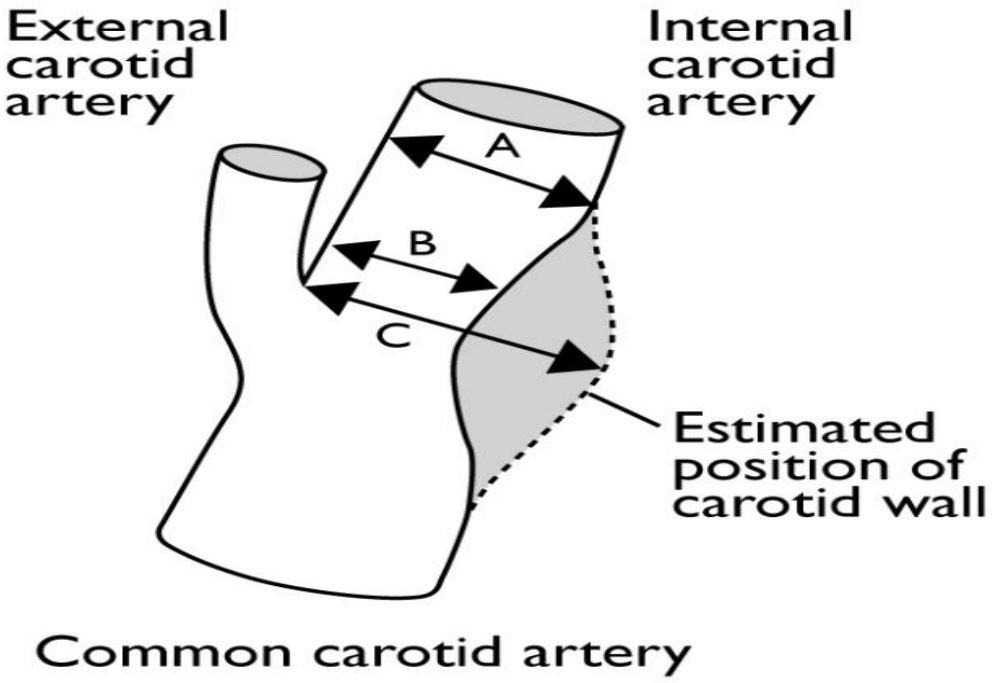
[b]Level of evidence.

[c]With the exception of patients with an indication for long-term oral anticoagulation.

[d]Without any other clinical cardiovascular condition requiring antiplatelet therapy (e.g. coronary artery disease or other multi-site artery diseases).

The management of carotid artery disease mostly depend on the symptomatic/asymptomatic characteristic, as well as the stenosis degree (Figure 4 and 5). Other characteristics can stratify the risk for patient with asymptomatic stenosis (Table 3).

Figure 5 Angiographic carotid stenosis according to different methods.



NASCET $\frac{A-B}{A}$	ECST $\frac{C-B}{C}$
NASCET	**ECST**

90	97

Approximate equivalent degrees of internal carotid artery stenosis used in NASCET and ESCT according to recent comparisons

ECST = European Carotid Surgery Trial; NASCET = North American Symptomatic Carotid Endarterectomy Trial

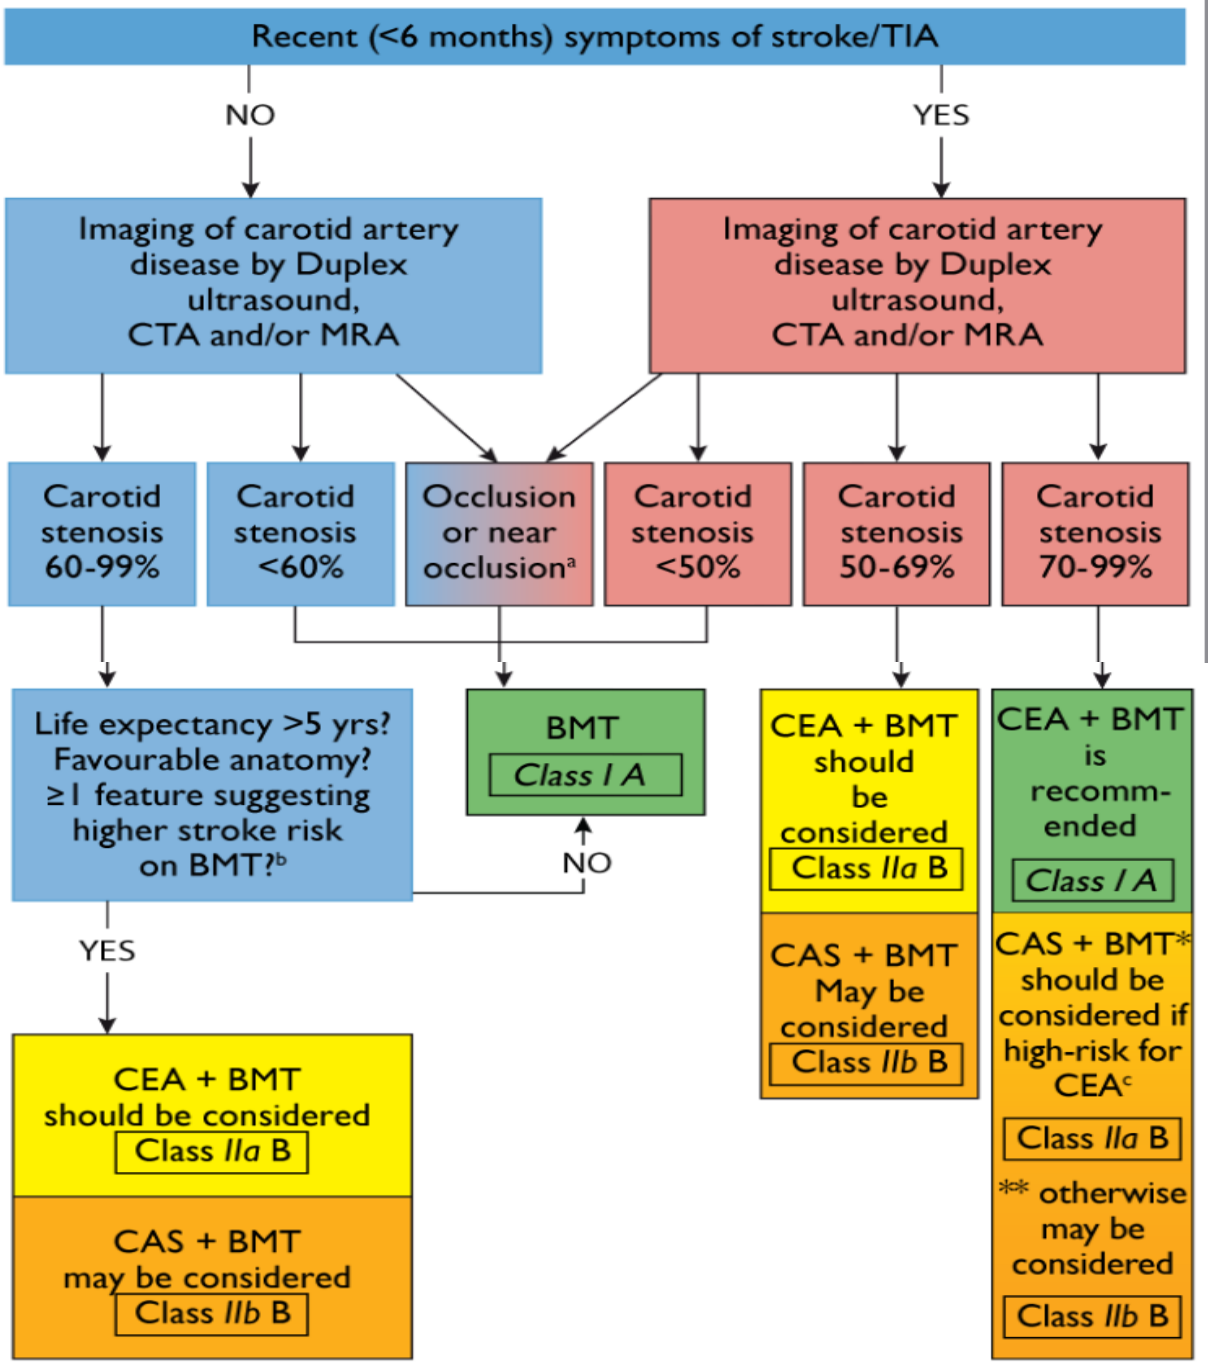
Recommendations for imaging of extracranial carotid arteries		
Recommendations	**Class[a]**	**Level[b]**
DUS (as first-line), CTA and/or MRA are recommended for evaluating the extent and severity of extracranial carotid stenoses.	I	B
When CAS is being considered, it is recommended that any DUS study be followed either by MRA or CTA to evaluate the aortic arch, as well as the extra- and intracranial circulation.	I	B
When CEA is considered, it is recommended that the DUS stenosis estimation be corroborated either by MRA or CTA (or by a repeat DUS study performed in an expert vascular laboratory).	I	B

CAS = carotid artery stenting; CEA = carotid endarterectomy; CTA = computed tomography angiography; DUS = duplex ultrasound; MRA = magnetic resonance an-

Recommendations for management of asymptomatic carotid artery disease		
Recommendations	**Class[a]**	**Level[b]**
In "average surgical risk" patients with an asymptomatic 60–99% stenosis, CEA should be considered in the presence of clinical and/or more imaging characteristics[c] that may be associated with an increased risk of late ipsilateral stroke, provided documented perioperative stroke/death rates are <3% and the patient's life expectancy is >5 years.	IIa	B
In asymptomatic patients who have been deemed "high-risk for CEA"[d] and who have an asymptomatic 60–99% stenosis in the presence of clinical and/or imaging characteristics[c] that may be associated with an increased risk of late ipsilateral stroke, CAS should be considered, provided documented perioperative stroke/death rates are <3% and the patient's life expectancy is >5 years.	IIa	B
In "average surgical risk" patients with an asymptomatic 60–99% stenosis in the presence of clinical and/or imaging characteristics[d] that may be associated with an increased risk of late ipsilateral stroke, CAS may be an alternative to CEA provided documented perioperative stroke/death rates are <3% and the patient's life expectancy is >5 years.	IIb	B

BP = blood pressure; CAS = carotid artery stenting; CEA = carotid endarterectomy. [a]Class of recommendation - [b]Level of evidence. - [c]See Table 5 - [d]Age > 80 years, clinically significant cardiac disease, severe pulmonary disease, contralateral internal carotid artery occlusion, contralateral recurrent laryngeal nerve palsy, previous radical neck surgery or radiotherapy and recurrent stenosis after CEA.

Figure 6 Management of extracranial carotid artery disease



BMT = best medical therapy; CAS = carotid artery stenting; CEA = carotid endarterectomy; CTA = computed tomography angiography; MRA = magnetic resonance angiography;TIA = transient ischaemic attack.

[a]With post-stenotic internal carotid artery narrowed to the point of near occlusion -
[b]See Table 5.

[c]Age >80 years, clinically significant cardiac disease, severe pulmonary disease, contralateral internal carotid artery occlusion, contralateral recurrent laryngeal nerve palsy, previous radical neck surgery or radiotherapy and recurrent stenosis after CEA.

Table 5 Features associated with increased risk of stroke in patients with asymptomatic carotid stenosis treated medically (for details see Web Table 5, see Web Addenda online*)	
Clinical[a]	• Contralateral TIA/stroke
Cerebral imaging	• Ipsilateral silent infarction
Ultrasound imaging	• Stenosis progression (> 20%) • Spontaneous embolization on transcranial Doppler (HITS) • Impaired cerebral vascular reserve • Large plaques[b] • Echolucent plaques • Increased juxta-luminal black (hypoechogenic) area
MRA	• Intraplaque haemorrhage • Lipid-rich necrotic core

HITS = high intensity transient signal; MRA = magnetic resonance angiography; TIA = transient ischaemic attack.
[a]Age is not a predictor of poorer outcome -[b]More than 40 mm^2 on digital analysis.

Recommendations on revascularization in patients with symptomatic carotid disease[c]		
Recommendations	**Class[a]**	**Level[b]**
CEA is recommended in symptomatic patients with 70–99% carotid stenoses, provided the documented procedural death/stroke rate is <6%.	I	A
CEA should be considered in symptomatic patients with 50–69% carotid stenoses, provided the documented procedural death/stroke rate is <6%.	IIa	A
In recently symptomatic patients with a 50–99% stenosis who present with adverse anatomical features or medical comorbidities that are considered to make them "high-risk for CEA", CAS should be considered, provided the documented procedural death/stroke rate is <6%.	IIa	B
When revascularization is indicated in "average surgical risk" patients with symptomatic carotid disease, CAS may be considered as an alternative to surgery, provided the documented procedural death/ stroke rate is <6%.	IIb	B
When decided, it is recommended to perform revascularization of symptomatic 50–99% carotid stenoses as soon as possible, preferably within 14 days of symptom onset.	I	A
Revascularization is not recommended in patients with a <50% carotid stenosis.	III	A

[a]Class of recommendation - [b]Level of evidence - [c]Stroke or TIA occuring within the 6 months.

Recommendation on the use of embolic protection device during carotid stenting		
Recommendations	**Class[a]**	**Level[b]**
The use of embolic protection devices should be considered in patients undergoing carotid artery stenting.	IIa	C

Recommendations for management of vertebral artery stenoses		
Recommendations	**Class[a]**	**Level[b]**
In patients with symptomatic extracranial vertebral artery stenoses, revascularization may be considered for lesions ≥50% in patients with recurrent ischaemic events, despite optimal medical management.	IIb	B
Revascularization of asymptomatic vertebral artery stenosis is not indicated, irrespective of the degree of severity.	III	C

Upper extremity artery disease (UEAD) due to atherosclerosis is mostly situated at the brachio-cephalic trunk, the subclavian and axillary arteries. Other aetiologies should be considered (Table 6). When suspected, it can be assessed by DUS, CTA or MRA.

Table 6 Differential diagnosis in upper limbs artery disease

Causes	Subclavian	Axillary	Brachial	Forearm	Hand
Atherosclerosis	•				
Thoracic outlet syndrome	•				
Giant cell arteritis	•				
Takayasu arteritis	•	•			
Radiation artery fibrosis	•	•			
Embolic		•	•	•	•
Fibromuscular dysplasia		•			•
Buerger's disease				•	•
Ergotism				•	•
Connective tissue disease				•	•
Cytotoxic drugs					•
Arterial drug injection					•
Diabetes mellitus					•
Myeloproliferative disorders					•
Hypercoagulative status					•

Cryoglobulins					•
Repetitive trauma					•
Vinyl chloride exposure					•
Iatrogenic lesions	•	•	•	•	•

Recommendations on the management of subclavian artery stenosis		
Recommendations	**Class[a]**	**Level[b]**
In symptomatic patients with subclavian artery stenosis/occlusion revascularization should be considered.	**IIa**	C
In symptomatic patients with a stenotic/occluded subclavian artery, both revascularization options (stenting or surgery) should be considered and discussed case by case according to the lesion characteristics and patient's risk.	**IIa**	C
In asymptomatic subclavian artery stenosis, revascularization:		
• should be considered in the case of proximal stenosis in patients undergoing CABG using the ipsilateral internal mammary artery.	**IIa**	C
• should be considered in the case of proximal stenosis in patients who already have the ipsilateral internal mammary artery grafted to coronary arteries with evidence of myocardial ischaemia.	**IIa**	C
• should be considered in the case of subclavian artery stenosis and ipsilateral arteriovenous fistula for dialysis.	**IIa**	C
• may be considered in the case of bilateral		

Mesenteric artery disease is underdiagnosed and highly lethal. The prerequisite of diagnosis is clinical suspicion, followed by imaging.

Acute mesenteric ischaemia is more often related to embolism than to thrombotic occlusion. Outcome is very time-sensitive, and dependent on clinical suspicion.

Recommendations on the management of acute mesenteric ischaemia

Recommendations	Class[a]	Level[b]
Diagnosis		
In patients with suspected acute mesenteric ischaemia, urgent CTA is recommended.	I	C
In patients with suspicion of acute mesenteric ischaemia,the measurement of D-dimer should be considered to rule out the diagnosis.	IIa	B
Treatment		
In patients with acute thrombotic occlusion of the superior mesenteric artery, endovascular therapy should be considered as first line therapy for revascularization.	IIa	B
In patients with acute embolic occlusion of the superior mesenteric artery, both endovascular and open surgery therapy should be considered.	IIa	B

The classical symptoms of CMI are postprandial abdominal pain, weight loss, diarrhoea or constipation, and food aversion.

Recommendations for management of chronic mesenteric artery disease

Recommendations	Class[a]	Level[b]
Diagnosis		
In patients with suspected CMI, DUS is recommended as the first line examination.	I	C
In patients with suspected CMI, occlusive disease of a single mesenteric artery makes the diagnosis unlikely, and a careful search for alternative causes should be considered.	IIa	C
Treatment		
In patients with symptomatic multivessel CMI, revascularization is recommended.	I	C
In patients with symptomatic multivessel CMI, it is not recommended to delay revascularization in order to improve the nutritional status.	III	C

CMI = chronic mesenteric ischaemia; DUS = duplex ultrasound.

Atherosclerotic renal artery disease (RAD) is the most common cause of "renovascular hypertension". The clinical situations raising suspicion for RAD are enlisted in Table 7.

Table 7 Clinical situations raising suspicion for renal artery disease

Onset of hypertension before the age of 30 years.
Onset of severe hypertension after the age of 55 years, when associated with CKD or heart failure.
Hypertension and abdominal bruit.
Rapid and persistent worsening of previously controlled hypertension.
Resistant hypertension (i.e. other secondary form unlikely and target not achieved despite four drug classes including a diuretic and a mineralocorticoid-receptor antagonist in appropriate doses).
Hypertensive crisis (i.e. acute renal failure, acute heart failure, hypertensive encephalopathy, or grade 3–4 retinopathy).
New azotaemia or worsening of renal function after treatment with RAAS blockers.
Unexplained atrophic kidney or discrepancy in kidney size, or unexplained renal failure.
Flash pulmonary oedema.

CKD = chronic kidney disease; RAAS = renin-angiotensin-aldosterone system.

Recommendations for diagnostic strategies for renal artery disease

Recommendations	Class[a]	Level[b]
DUS (as first-line), CTA[c] and MRA[d] are recommended imaging modalities to establish a diagnosis of RAD.	I	B
DSA may be considered to confirm a diagnosis of RAD when clinical suspicion is high and the results of non-invasive examinations are inconclusive.	IIb	C
Renal scintigraphy, plasma renin measurements before and after ACEI provocation, and vein renin measurements are not recommended for screening of atherosclerotic RAD.	III	C

ACEI = angiotensin-converting enzyme inhibitor; CTA = computed tomography angiography; DSA = digital subtraction angiography; DUS = duplex ultrasound; eGFR = estimated glomerular filtration rate; MRA = magnetic resonance angiography; RAD = renal artery disease.

[a]Class of recommendation - [b]Level of evidence - [c]When eGFR is ≥60 mL/min - [d]When eGFR is ≥30 mL/min.

Recommendations for treatment strategies for renal artery disease		
Recommendations	**Class[a]**	**Level[b]**
Medical therapy		
ACEIs/ARBs are recommended for treatment of hypertension associated with unilateral RAS.	I	B
Calcium channel blockers,beta-blockers and diuretics are recommended for treatment of hypertension associated with renal artery disease.	I	C
ACEIs/ARBs may be considered in bilateral severe RAS and in the case of stenosis in a single functioning kidney, if well-tolerated and under close monitoring.	IIb	B
Revascularization		
Routine revascularization is not recommended in RAS secondary to atherosclerosis.	III	A
In cases of hypertension and/or signs of renal impairment related to renal arterial fibromuscular dysplasia, balloon angioplasty with bailout stenting should be considered.	IIa	B
Balloon angioplasty, with or without stenting, may be considered in selected patients with RAS and unexplained recurrent congestive heart failure or sudden pulmonary oedema.	IIb	C
In the case of an indication for revascularization,surgical revascularization should be considered for patients with complex anatomy of the renal arteries, after a failed endovascular procedure, or during open aortic surgery.	IIa	B

ACEI(s) = angiotensin-converting enzyme inhibitor(s); ARB(s) = angiotensin-receptor blocker(s); RAS = renal artery stenosis.

Clinical presentation

Most patients with LEAD are asymptomatic. Walking capacity must be assessed to detect clinically "masked LEAD". Atypical symptoms are frequent. Even asymptomatic patients with LEAD are at high-risk of CV events and must benefit from most CV preventive strategies.

Table 8 Clinical stages of lower extremity artery disease

Fontaine classification		
Stage		Symptoms
I		Asymptomatic
II	IIa	Non-disabling intermittent claudication
	IIb	Disabling intermittent claudication
III		Ischaemic rest pain
IV		Ulceration or gangrene

Rutherford classification		
Grade	Category	Symptoms
0	0	Asymptomatic
I	1	Mild claudication
I	2	Moderate claudication
I	3	Severe claudication
II	4	Ischaemic rest pain
III	5	Minor tissue loss
III	6	Major tissue loss

Diagnostic tests

Recommendations for ankle-brachial index measurement

Recommendations	**Class[a]**	**Level[b]**
Measurement of the ABI is indicated as a first-line non-invasive test for screening and diagnosis of LEAD.	I	C
In the case of incompressible ankle arteries or ABI >1.40, alternative methods such as the toe-brachial index, Doppler waveform analysis or pulse volume recording are indicated.	I	C

ABI = ankle-brachial index; LEAD = lower extremity artery disease.
[a]Class of recommendation - [b]Level of evidence.

Recommendations on imaging in patients with lower extremity artery disease		
Recommendations	**Class[a]**	**Level[b]**
DUS is indicated as first-line imaging method to confirm LEAD lesions.	I	C
DUS and/or CTA and/or MRA are indicated for anatomical characterization of LEAD lesions and guidance for optimal revascularization strategy.	I	C
Data from an anatomical imaging test should always be analyzed in conjunction with symptoms and haemodynamic tests prior to treatment decision.	I	C
DUS screening for AAA should be considered.	IIa	C

AAA = abdominal aorta aneurysm; CTA = computed tomography angiography; DUS = duplex ultrasound; LEAD = lower extremity artery disease; MRA = magnetic resonance angiography.

Recommendations on revascularization of aorto-iliac occlusive lesions[c]		
Recommendations	**Class[a]**	**Level[b]**
An endovascular-first strategy is recommended for short (i.e. <5 cm) occlusive lesions.	I	C
In patients fit for surgery, aorto-(bi)femoral bypass should be considered in aorto-iliac occlusion(s).	IIa	B
An endovascular-first strategy should be considered in long and/or bilateral lesions in patients with severe comorbidities.	IIa	B
An endovascular-first strategy may be considered for aorto-iliac occlusive lesions, if done by an experienced team and if it does not compromise subsequent surgical options.	IIb	B
Primary stent implantation, rather than provisional stenting, should be considered.	IIa	B
Open surgery should be considered in fit patients with an aortic occlusion extending up to the renal arteries.	IIa	C
In the case of ilio-femoral occlusive lesions, a hybrid procedure combining iliac stenting and femoral endarterectomy or bypass should be considered.	IIa	C
Extra-anatomical bypass may be indicated only for patients with no other alternatives for revascularization.	IIb	C

[a]Class of recommendation - [b]Level of evidence - [c]These recommendations apply both for patients with intermittent claudication and severe chronic limb ischaemia.

Recommendations on revascularization of femoro-popliteal occlusive lesions[c]

Recommendations	Class[a]	Level[b]
An endovascular-first strategy is recommended in short (i.e. <25 cm) lesions.	I	C
Primary stent implantation should be considered in short (i.e. <25 cm) lesions.	IIa	A
Drug-eluting balloons may be considered in short (i.e. <25 cm) lesions.	IIb	A
Drug-eluting stents may be considered for short (i.e. <25 cm) lesions.	IIb	B
Drug-eluting balloons may be considered for the treatment of in-stent restenosis.	IIb	B
In patients who are not at high-risk for surgery, bypass surgery is indicated for long (i.e. ≥25 cm) superficial femoral artery lesions when an autologous vein is available and life expectancy is >2 years.	I	B
The autologous saphenous vein is the conduit of choice for femoro- popliteal bypass.	I	A
When above-knee bypass is indicated, in the absence of any autologous saphenous vein, the use of a prosthetic conduit should be considered	IIa	A
In patients unfit for surgery, endovascular therapy may be considered in long (i.e. ≥25 cm) femoro-popliteal lesions.	IIb	C

[a]Class of recommendation - [b]Level of evidence - [c]These recommendations apply both for patients with intermittent claudication and chronic limb-threatening ischaemia.

Recommendations on revascularization of infra-popliteal occlusive lesions

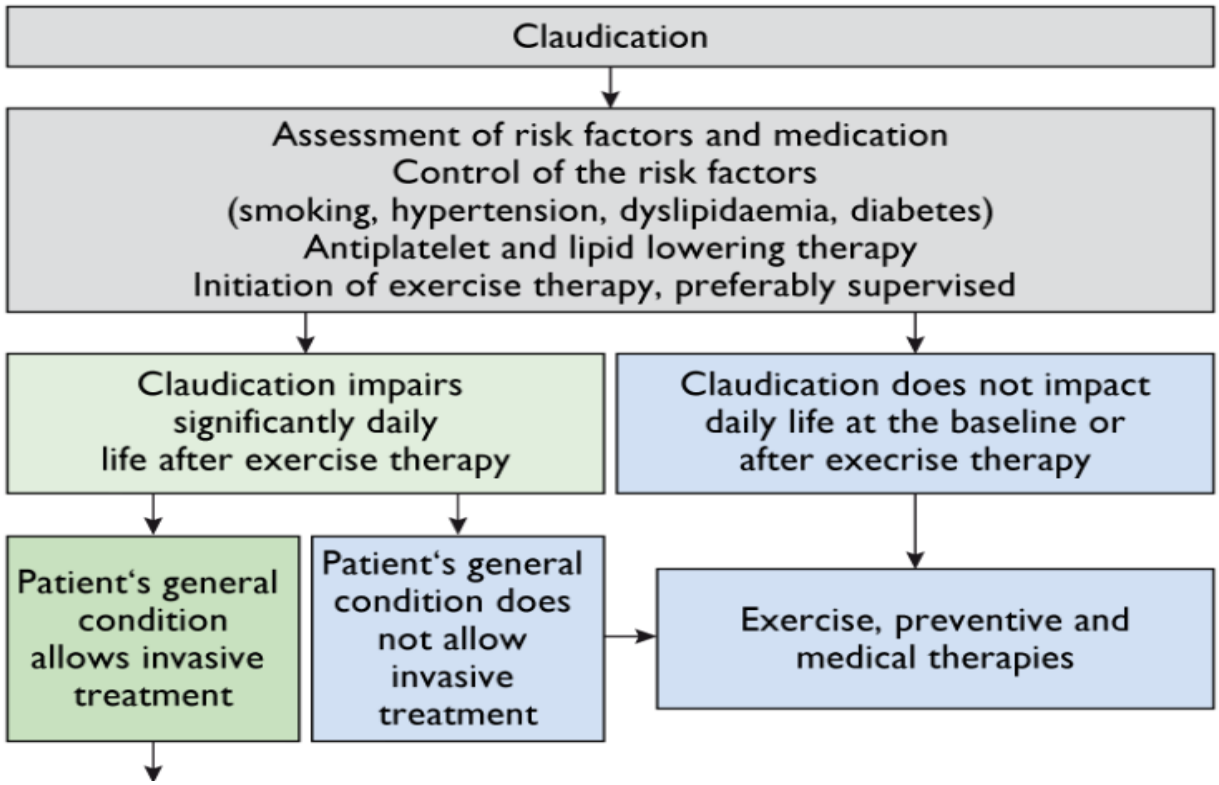
Recommendations	Class[a]	Level[b]
In the case of CLTI, infra-popliteal revascularization is indicated for limb salvage.	I	C
For revascularization of infra-popliteal arteries:		
• bypass using the great saphenous vein is indicated	I	A
• endovascular therapy should be considered.	IIa	B

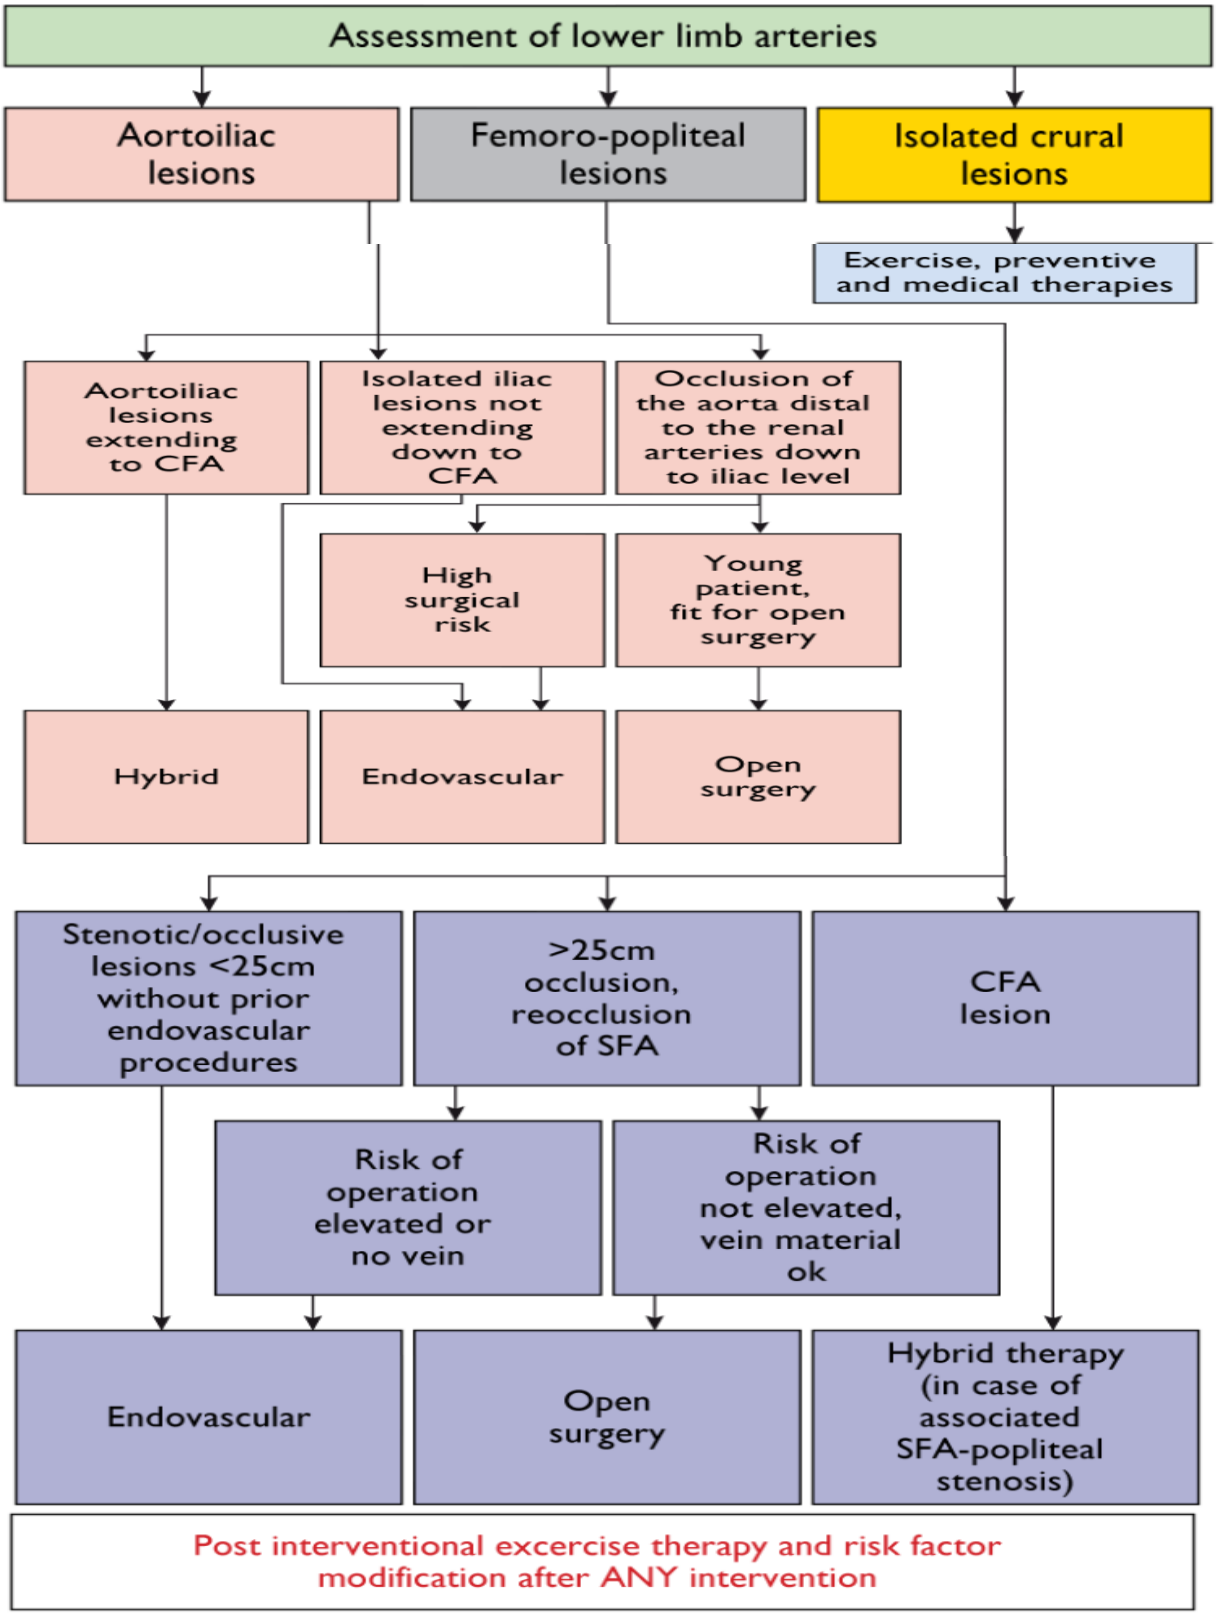
CLTI = chronic limb-threatening ischaemia. [a]Class of recommendation - [b]Level of evidence.

Recommendations for the management of patients with intermittent claudication

Recommendations	Class[a]	Level[b]
On top of general prevention, statins are indicated to improve walking distance.	I	A
In patients with intermittent claudication:		
• supervised exercise training is recommended.	I	A
• non-supervised exercise training is recommended when supervised exercise training is not feasible or available.	I	C
When daily life activities are compromised despite exercise therapy, revascularization should be considered.	IIa	C
When daily life activity is severely compromised, first line revascularization should be considered, in association with exercise therapy.	IIa	B

Figure 7 Management of patients with intermittent claudication[a]





CFA = common femoral artery; SFA = superficial femoral artery.
[a]Related to atherosclerotic lower extremity artery disease (LEAD).

CLTI specifies clinical patterns with vulnerable limb viability, related to ischaemia, wounds, and infection (Table 9 & Figure 8). Risk stratification and early recognition of tissue loss and/or infection and referral to the vascular specialist is mandatory for limb salvage by a multidisciplinary approach. Revascularization is indicated whenever feasible.

Table 9 Assessment of the risk of amputation: the WIFI classification

Score	Description		
W (Wound)			
0	No ulcer (ischaemic rest pain)		
1	Small, shallow ulcer on distal leg or foot without gangrene		
2	Deeper ulcer with exposed bone, joint or tendon ± gangrenous changes limited to toes		
3	Extensive deep ulcer, full thickness heel ulcer ± calcaneal involvement ± extensive gangrene		
I (Ischaemia)			
	ABI	Ankle pressure (mmHg)	Toe pressure or $TcPO_2$
0	≥0.80	>100	≥60
1	0.60–0.79	70–100	40–59
2	0.40–0.59	50–70	30–39
3	<0.40	<50	<30
fI (foot Infection)			
0	No symptoms/signs of infection		
1	Local infection involving only skin and subcutaneous tissue		
2	Local infection involving deeper than skin/subcutaneous tissue		
3	Systemic inflammatory response syndrome		

Example: A 65-year-old male diabetic patient with gangrene of the big toe and a <2 cm rim of cellulitis at the base of the toe, without any clinical/biological sign of general infection/inflammation, whose toe pressure is at 30 mmHg would be classified as Wound 2, Ischaemia 2, foot Infection 1 (WIfI 2-2-1).
The clinical stage would be 4 (high-risk of amputation). The benefit of revascularization (if feasible) is high, also depending on infection control.
[a]Adapted from Mills JL et al. J Vasc Surg 2014;59(1):220–234.

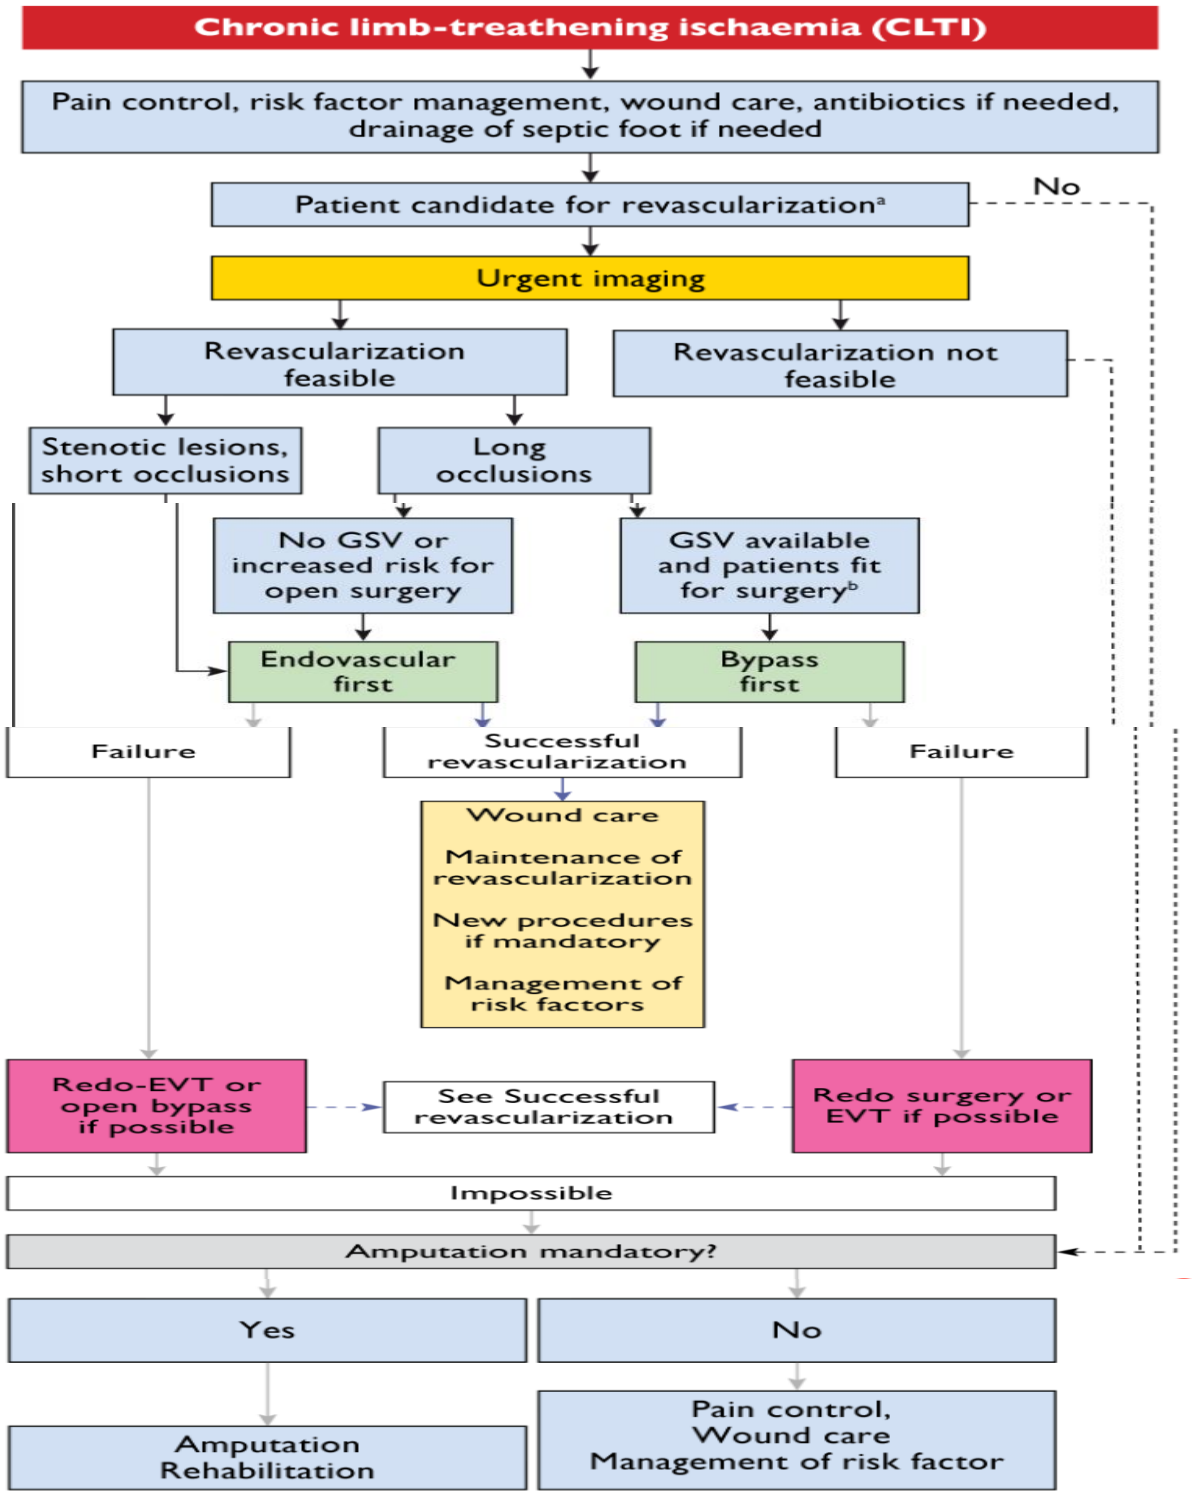
ABI = ankle-brachial index;TcPO2 = transcutaneous oxygen pressure.

Figure 8 Estimation of the amputation risk according to the WIfI classification (see also Table 7)[a]

Estimate risk of amputation at I year for each combination				
	Ischaemia-0			
W-0	VL	VL	L	M
W-1	VL	VL	L	M
W-2	L	L	M	H
W-3	M	M	H	H
	fI-0	fI-1	fI-2	fI-3
	Ischaemia-1			
W-0	VL	L	M	H
W-1	VL	L	M	H
W-2	M	M	H	H
W-3	H	H	H	H
	fI-0	fI-1	fI-2	fI-3
	Ischaemia-2			
W-0	L	L	M	M
W-1	L	M	H	H
W-2	M	H	H	H
W-3	H	H	H	H
	fI-0	fI-1	fI-2	fI-3
	Ischaemia-3			
W-3	L	M	M	H
W-3	M	M	H	H
W-3	H	H	H	H
W-3	H	H	H	H
	fI-0	fI-1	fI-2	fI-3

fI = foot infection; H = high-risk; L = low-risk; M = moderate risk;VL = very low risk;W = wound.

Figure 9 Management of patients with chronic limb-threatening ischaemia



EVT= endovascular therapy;
GSV = great saphenous vein.
[a]In bedridden, demented and/or frail patients, primary amputation should be considered.
[b]In the absence of contra-indication for surgery and in the presence of adequate target for anastomosis/runoff.

Recommendations on the management of chronic limb-threatening ischaemia		
Recommendations	**Class[a]**	**Level[b]**
Early recognition of tissue loss and/or infection and referral to the vascular team is mandatory to improve limb salvage.	I	C
In patients with CLTI, assessment of the risk of amputation is indicated.	I	C
In patients with CLTI and diabetes, optimal glycaemic control is recommended.	I	C
For limb salvage, revascularization is indicated whenever feasible.	I	B
In CLTI patients with below-the-knee lesions, angiography including foot runoff should be considered prior to revascularization.	IIa	C
In patients with CLTI, stem cell/gene therapy is not indicated.	III	B

CLTI = chroniclimb threatening ischaemia·

Acute limb ischaemia

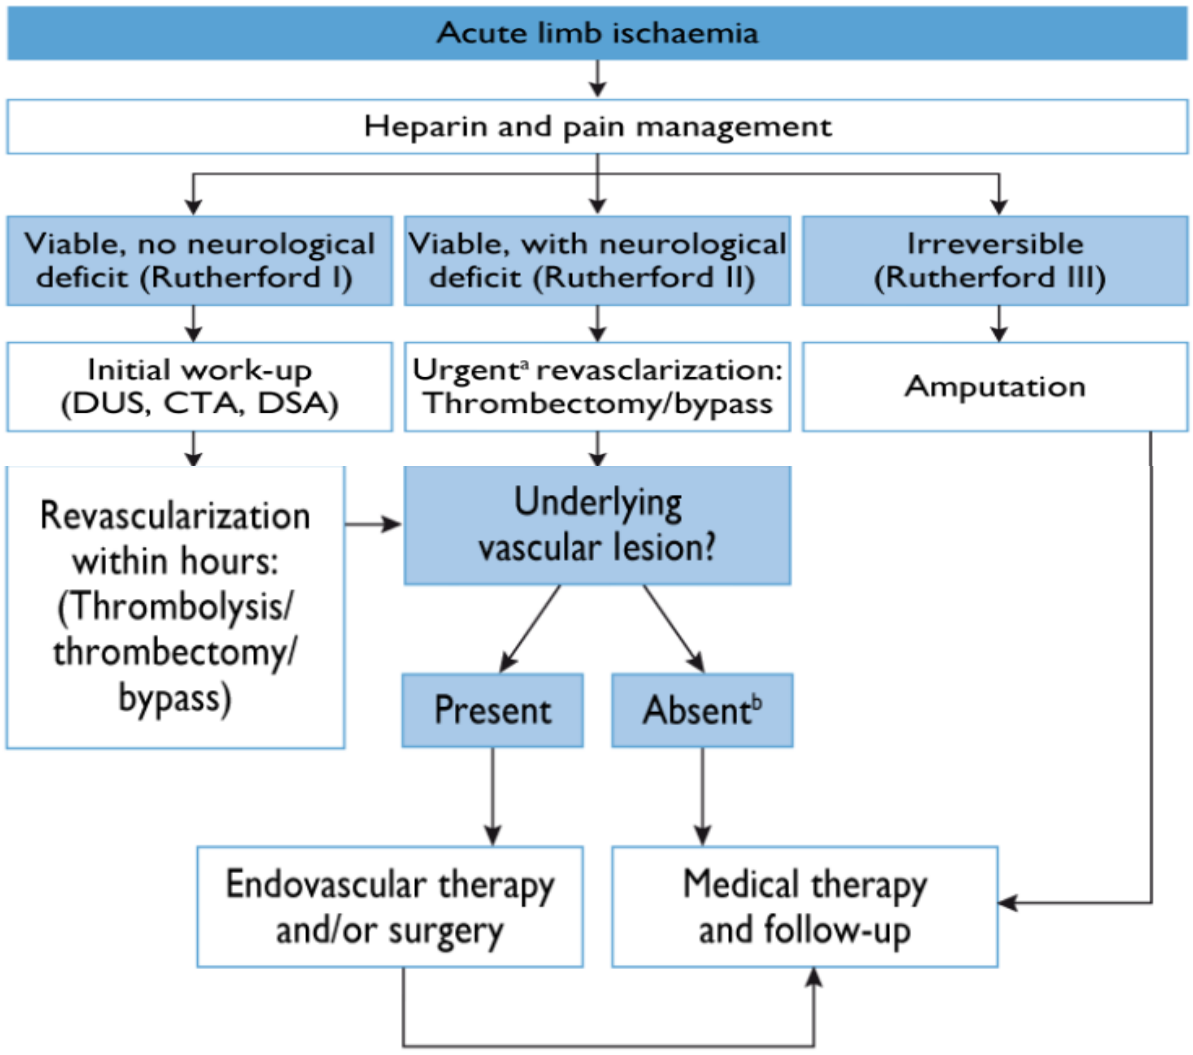
Acute limb ischaemia with neurological deficit mandates urgent revascularization.

Table 10 Clinical categories of acute limb ischaemia	
Grade I	
Category	Viable
Sensory loss	None
Motor deficit	None
Prognosis	No immediate threat
Grade IIA	
Category	Marginally threatened
Sensory loss	None or minimal (toes)
Motor deficit	None
Prognosis	Salvageable if promptly treated
Grade IIB	
Category	Immediately threatened
Sensory loss	More than toes
Motor deficit	Mild/moderate
Prognosis	Salvageable if promptly revascularized
Grade III	
Category	Irreversible
Sensory loss	Profound, anaesthetic
Motor deficit	Profound, paralysis (rigor)
Prognosis	Major tissue loss, permanent nerve damage inevitable

Recommendations for the management of patients presenting with acute limb ischaemia		
Recommendations	**Class[a]**	**Level[b]**
In the case of neurological deficit, urgent revascularization is indicated.[c]	I	C
In the absence of neurological deficit, revascularization is indicated within hours after initial imaging in a case to case decision.	I	C
Heparin and analgesics are indicated as soon as possible.	I	C

[a]Class of recommendation - [b]Level of evidence - [c]In this case imaging should not delay intervention.

Figure 10 Management of acute limb ischaemia

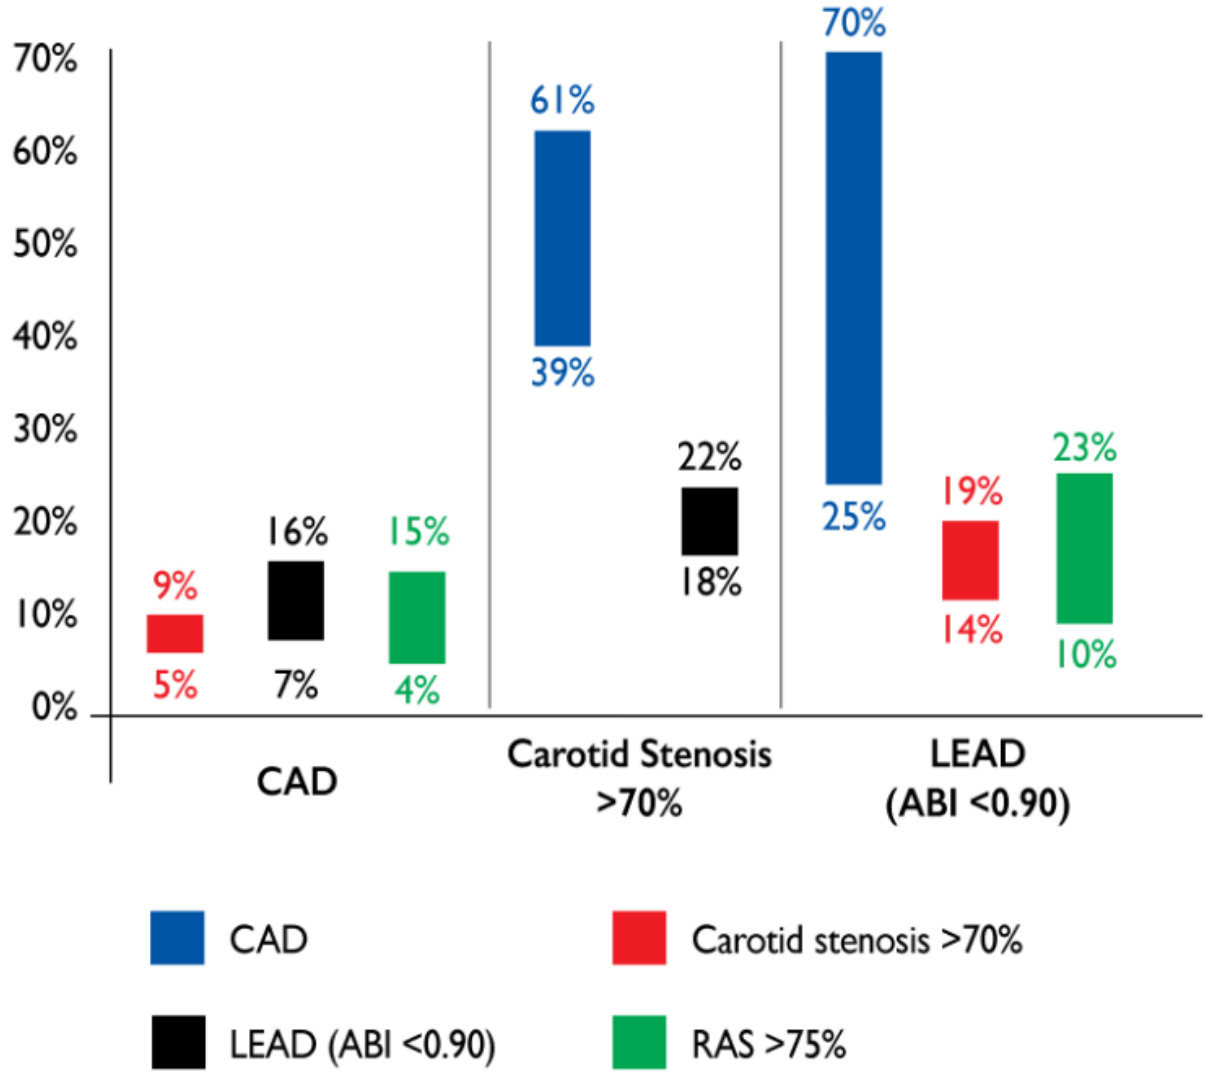


CTA = computed tomography angiography; DSA = digital subtraction ultrasound; DUS = duplex ultrasound.

[a]Imaging should not delay revascularization - [b] Specific etiological work-up is necessary (cardiac, aorta).

Multisite artery disease (MSAD) is defined by the simultaneous presence of clinically relevant atherosclerotic lesions in at least two major vascular territories ranging from 10–15% in patients with CAD to 60–70% in patients with severe carotid stenosis or LEAD (Figure 12).

Figure 11 Reported rate ranges of other localizations of atherosclerosis in patients with a specific arterial disease



The graph reports the rates of concomitant arterial diseases in patients presenting an arterial disease in one territory (e.g. in patients with CAD, 5–9% of cases have concomitant carotid stenosis >70%).

ABI = ankle-brachial index; CAD = coronary artery disease; LEAD = lower extremity artery disease; RAS = renal artery stenosis.

MSAD is invariably associated with worse clinical outcomes; however, systematic screening for asymptomatic disease in additional vascular sites has not been proven to improve prognosis and is yet not indicated. In patients with any presentation of PADs, clinical assessment of symptoms and physical signs of other localizations and/or CAD is necessary, and in case of clinical suspicion, further tests may be planned. Screening for asymptomatic lesions may be interesting in some cases (Table 11). This is the case for patients undergoing CABG, where ABI measurement may be considered especially when saphenous vein harvesting is planned, and carotid screening should be considered in a subset of patients at high risk of carotid artery disease.

Table 11 Indication for screening of associated atherosclerotic disease in additional vascular territories

Landing disease \ Screened disease	CAD	LEAD	Carotid	Renal
CAD				
Scheduled for CABG		IIa[a]	IIb[c] / I[b]	U
Not scheduled for CABG		IIb	NR	U
LEAD				
Scheduled for CABG	I[d]		NR	U
Not scheduled for CABG	NR		NR	U
Carotid stenosis				
Scheduled for CEA/CAS	IIb	NR		U
Not scheduled for CEA/CAS	NR	NR		U

CABG = coronary artery bypass grafting; CAD = coronary artery disease; CAS = coronary endarterectomy; CKD = chronic kidney disease; ECG = electrocardiogram; LEAD = lower extremity artery disease; NR = no recommendation (not enough evidence to support systematic screening); TIA = transient ischaemic attack; U = uncertain.

[a]Especially when venous harvesting is planned for bypass - [b]In patients with symptomatic cerebrovascular disease.

[c]In patients with asymptomatic carotid disease and: age ≥ 70 years, multivessel CAD, associated LEAD or carotid bruit. [d]Screening with ECG is recommended in all patients and with imaging stress testing in patients with poor functional capacity and more than two of the following: history of CAD, heart failure, stroke or TIA, CKD, diabetes mellitus requiring insulin therapy.

Recommendations on screening for carotid disease in patients undergoing coronary artery bypass grafting

Recommendations	Class[a]	Level[b]
In patients undergoing CABG, DUS is recommended in patients with a recent (<6 months) history of TIA/stroke.	I	B
In patients with no recent (< 6 months) history of TIA/stroke, DUS may be considered in the following cases: age ≥70 years, multivessel coronary artery disease, concomitant LEAD, or carotid bruit.	IIb	B
Screening for carotid stenosis is not indicated in patients requiring urgent CABG with no recent stroke/TIA.	III	C

CABG = coronary artery bypass grafting; DUS = duplex ultrasound; LEAD = lower extremity artery disease; TIA = transient ischaemic attack.
[a]Class of recommendation - [b]Level of evidence.

Recommendations on the management of carotid stenosis in patients undergoing coronary artery bypass grafting

Recommendations	Class[a]	Level[b]
It is recommended that the indication (and if so the method and timing) for carotid revascularization be individualized after discussion within a multidisciplinary team, including a neurologist.	I	C
In patients scheduled for CABG, with recent (<6 months) history of TIA/stroke:		
• Carotid revascularization should be considered in patients with 50–99% carotid stenosis.	IIa	B
• Carotid revascularization with CEA should be considered as first choice in patients with 50–99% carotid stenosis.	IIa	B
• Carotid revascularization is not recommended in patients with carotid stenosis <50%.	III	C
In neurologically asymptomatic patients scheduled for CABG:		
• Routine prophylactic carotid revascularization in patients with a 70–99% carotid stenosis is not recommended.	III	B
• Carotid revascularization may be considered in patients with bilateral 70–99% carotid stenoses or 70–99% carotid stenosis + contralateral occlusion.	IIb	B
• Carotid revascularization may be considered in patients with a 70–99% carotid stenosis, in the presence of one or more characteristics that may be associated with an increased risk of ipsilateral stroke, [c] in order to reduce stroke risk beyond the perioperative period.	IIb	C

CABG = coronary artery bypass grafting; CAS = carotid artery stenting; CEA = carotid endarterectomy

Recommendations for screening and management of concomitant lower extremity artery disease and coronary artery disease		
Recommendations	**Class[a]**	**Level[b]**
In patients with LEAD, radial artery access is recommended as the first option for coronary angiography/intervention.	I	C
In patients with LEAD undergoing CABG, sparing the autologous great saphenous vein for potential future use for surgical peripheral revascularization should be considered.	IIa	C
In patients undergoing CABG and requiring saphenous vein harvesting, screening for LEAD should be considered.	IIa	C
In patients with CAD, screening for LEAD by ABI measurement may be considered for risk stratification.	IIb	B

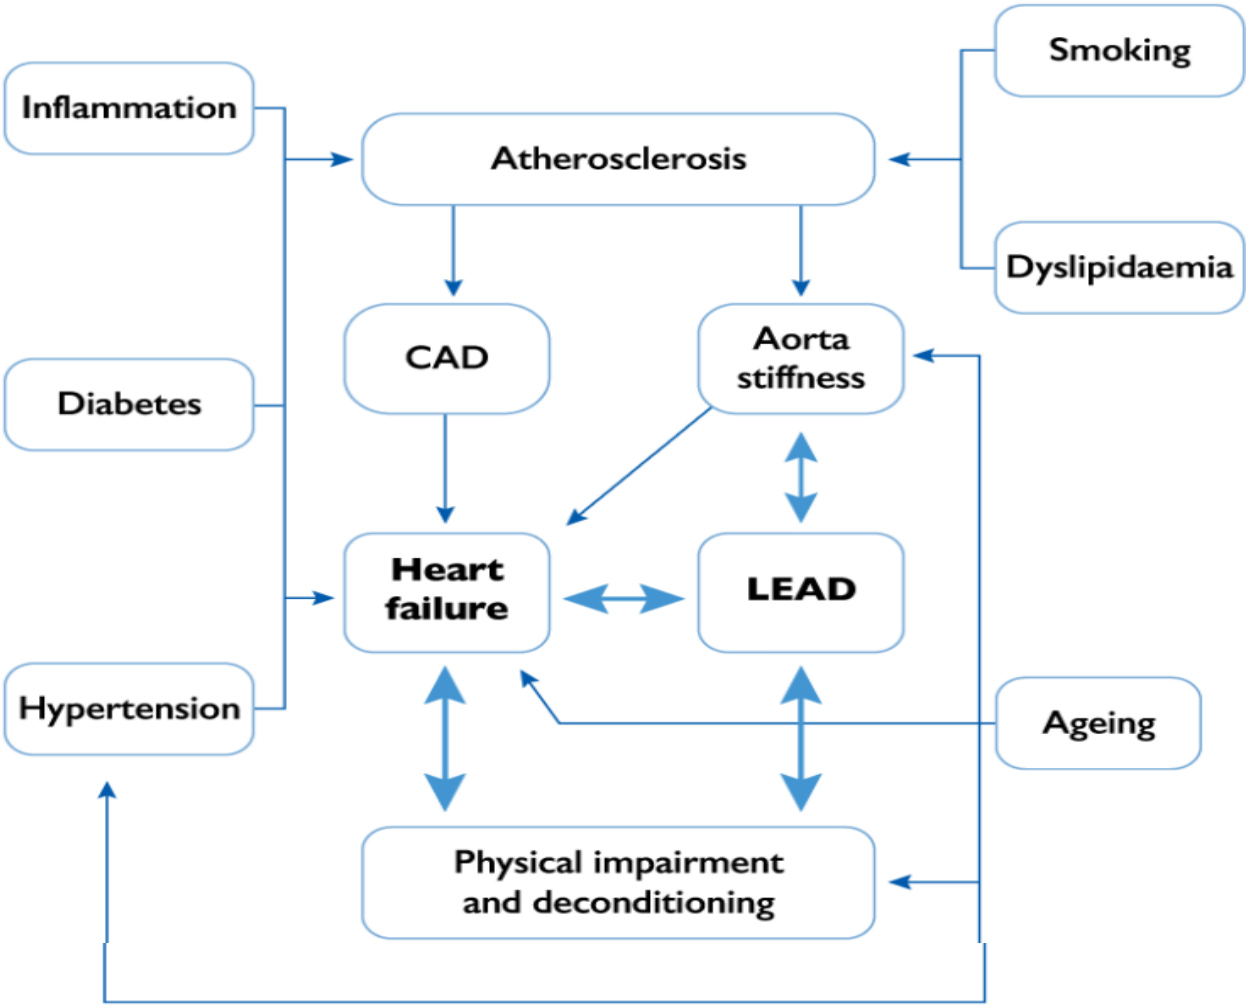
ABI = ankle-brachial index; CABG = coronary artery bypass grafting; CAD = coronary artery disease; LEAD = lower extremity artery disease;TIA = transient ischaemic attack.

[a]Class of recommendation - [b]Level of evidence.

Recommendation on screening for coronary artery disease in patients with carotid disease		
Recommendations	**Class[a]**	**Level[b]**
In patients undergoing elective CEA, preoperative CAD screening, including coronary angiography, may be considered.	IIb	B

Cardiac conditions other than CAD are frequent in patients with PADs. This is especially the case for heart failure and atrial fibrillation in patients with LEAD.

Figure 12 Interrelations between heart failure and lower extremity artery disease



Recommendations on the management of heart failure associated with PADs

Recommendations	Class[a]	Level[b]
Full vascular assessment is indicated in all patients considered for heart transplantation or cardiac assist device implantation.	I	C
In patients with symptomatic PADs, screening for heart failure with TTE and/or natriuretic peptides assessment should be considered.	IIa	C
Screening for LEAD may be considered in patients with heart failure.	IIb	C
Testing for renal artery disease may be considered in patients with flash pulmonary oedema.	IIb	C

LEAD = lower extremity artery disease;TTE = transthoracic echocardiography; PADs = peripheral arterial diseases

Recommendations on the management of atrial fibrillation associated with PADs

Recommendations	Class[a]	Level[b]
In patients with LEAD and atrial fibrillation, oral anticoagulation:		
• is recommended when CHA_2DS_2-VASc score ≥2	I	A
• should be considered in all other patients.	IIa	B

LEAD = lower extremity artery disease; PADs = peripheral arterial diseases; CHA2DS2VASC = Congestive heart failure; Hypertension; Age ≥75 years; Diabetes mellitus; prior Stroke or TIA; Vascular disease; Age 65–74 years; Sex Category female.

Recommendations on the management of valvular heart disease associated with PADs

Recommendations	Class[a]	Level[b]
Screening for LEAD and UEAD is indicated in patients undergoing TAVI or other structural interventions requiring an arterial approach.	I	C

LEAD = lower extremity artery disease; PADs = peripheral arterial diseases; TAVI = transcatheter aortic valve implantation; UEAD = upper extremity artery disease.

Heart Failure: From Research to Clinical Practice

Md. Shahidul Islam

Abstract

"Heart failure: from research to clinical practice", a collection of selected reviews, which comes out also as a book, covers essentially all important aspects of heart failure, including the pathogenesis, clinical features, biomarkers, imaging techniques, medical treatment and surgical treatments, use of pacemakers and implantable cardioverter defibrillators, and palliative care. The reviews include essential background information, state of the art, critical and in-depth analysis, and directions for future researches for elucidation of the unresolved issues. Everyone interested in heart failure is expected to find this compilation helpful for a deeper understanding of some of the complex issues.

Keywords

"Heart failure: from research to clinical practice" is a collection of reviews that cover diverse aspects of the pathophysiology, clinical features, diagnosis, treatment, follow up, and palliative care of patients with different types of heart failure in diverse clinical settings. Heart failure is a major and expensive public health problem, requiring numerous office-visits, and hospitalizations, in all countries of the world: in the developing countries it is more often due to hypertension and valvular heart diseases, whereas in the developed countries it is more often due to ischemic heart diseases and cardiomyopathies. Worldwide, the prevalence of heart failure, particularly heart failure with preserved ejection fraction (HFpEF) is increasing. Some heart failure patients whose left ventricular ejection fraction is in the "mid-range", resemble HFpEF patients, while others resemble HFrEF (heart failure with reduced ejection fraction). The factors that determine the recovery of HFrEF to HFmrEF (heart failure with mid-range ejection fraction), or the deterioration of HFpEF to HFmrEF or HFrEF, and the prognostic importance of such changes in the ejection fraction over time, will continue to be active areas of research in the coming years. Our understanding of HFpEF, which is highly heterogeneous, and highly prevalent, is still poor and numerous studies will be needed to clarify many of the unresolved issues. Echocardiography is the most commonly used imaging technique for evaluation of heart failure, but in many countries

even this basic resource is not available. On the other hand, in many developed centers, advanced imaging techniques, like the cardiac magnetic resonance imaging are being used as a highly reliable and powerful technique for morphological and functional assessment of the heart, including for the identification of fibrosis and infiltrations, and for the identification of the major types of cardiomyopathies.

Based on strong evidence, most HFrEF patients are treated with angiotensin converting enzyme inhibitors (ACE-I), or angiotensin receptor blockers (ARB), and beta-blockers. However, many eligible HFrEF patients are not receiving ACE-I/ARB and beta-blockers in maximal tolerable doses in real life. On the other hand, the benefits of ACE-I/ARB plus beta blockers in HFpEF and HFmrEF are less clear. Still many HFpEF and HFmrEF patients are treated with ACE-I/ARB plus beta blockers, mostly because the patients have hypertension. Treatment of HFrEF patients with the neprilysin inhibitor sacubitril plus angiotensin receptor inhibitor valsartan (ARNI) improves clinical outcomes and reduces mortality further. It is likely that the use of ARNI for the treatment of HFrEF will keep increasing. There is some evidence suggesting that ARNI is beneficial even in the treatment of HFpEF, but we have to wait for more convincing results.

Heart failure patients with congestion must be treated with loop diuretics taking care to avoid both overuse, and under-use of the diuretics. Those who are truly resistant to the loop diuretics, may need treatment with bolus injection plus continuous infusion of the loop diuretics, or by sequential nephron blockade with loop diuretics plus a thiazide diuretic. It is necessary for the clinicians to be familiar with the basic pharmacodynamics and pharmacokinetics of the diuretics, and to know how to use the diuretics optimally in different clinical settings.

For optimal care of the heart failure patients, it is useful to have well-structured plans for regular follow up of the patients, preferably through outpatient units dedicated to the treatment of such patients. It is important to identify groups of patients who are likely to benefit most from management by the primary care physicians, specialists in internal medicine, or cardiologists. In addition to clinical assessments, serial measurement of cardiac biomarkers, and if possible, estimation of the left ventricular filling pressure by echocardiography can be helpful during follow up of the heart failure patients. It is expected that mobile monitoring devices and telecommunication technologies will be developed through multidisciplinary approaches, and will be increasingly used for the management and follow up of heart failure patients in the future. It is also beneficial for the heart failure patients to participate in cardiac rehabilitation programs for trying different modalities of exercise training.

Treatment of heart failure patients must be tailored to individual patients taking into consideration the co-existing diseases that many patients have. Many heart failure patients have chronic obstructive lung diseases, chronic kidney disease, diabetes, and central sleep apnea. About half of the heart failure patients have moderate renal failure. Treatment by ACE-I/ARB is beneficial even in HFrEF patients with moderate renal failure. The benefits of ACE-I/ARB in HFrEF patients with severe renal failure is not well established. In many such patients ACE-I/ARB may severely impair the renal function, and in some it may be essential to discontinue these medicines. Some HFrEF patients who do not tolerate ACE-I/ARB may benefit from hydralazine plus isosorbide dinitrate, a treatment modality, which is probably underused. In the treatment of heart failure patients with diabetes, sodium-glucose-co-transporter 2 inhibitors appear highly promising. Some heart failure patients may have hypothyroidism, hyperthyroidism, or “low T3 syndrome”, which aggravates heart failure; early detection and cautious treatment of these conditions are essential for successful treatment of heart failure.

Many heart failure patients develop different types of bradyarrhythmias that require pace maker implantation. Others need implantation of pacemaker and implantable cardioverter defibrillator. It is important to carefully choose the most appropriate types of devices (pacemakers, implantable cardioverter defibrillator), and the most appropriate pacing modes for treating these

heterogeneous group of patients. The choice of the devices and the pacing modes need to be made following a structured approach based on many factors including the aetiological factors. Some selected heart failure patients with moderate to severe mitral regurgitation can be helped by the treatment of mitral regurgitation by percutaneous interventions using transcatheter technologies.

A selected group of heart failure patients, including those who are waiting for heart transplantation, will benefit from implantation of left ventricular assist devices. Technological advances and clinical experiences in this field are increasing although prevention and management of serious complications remain challenging obstacles. Heart failure is a progressive disease; patients with advanced heart failure will eventually approach the end of life like anyone else. It is reasonable to initiate a conversation with the patients, on palliative care at an "appropriate" time, and integrate palliative care with ongoing curative treatment for a while, to improve patient satisfaction and quality of life. Clinicians need to be more familiar with the methods of palliative care of heart failure patients, aimed at reducing the symptoms, reducing the level of distress among the patients and the families, reducing the rates of hospitalization, and improving the quality of life as much as possible.

The reviews included in "Heart failure: from research to clinical practice", which also comes out as a book, cover most of the topics mentioned above to a considerable detail, including essential background information, through critical and in depth analysis of the controversial issues, to the directions for future researches. Everybody, including the nurses, doctors, students and scientists, from the beginners to the experts, are likely to find at least some of the contents of this collection informative, useful, interesting, and stimulating to a variable extent.

Transition of Left Ventricular Ejection Fraction in Heart Failure

Yasuhiko Sakata, Kanako Tsuji, Kotaro Nochioka, and Hiroaki Shimokawa

Abstract

Along with a worldwide epidemiological transition and dramatic increase in the elderly population, both the incidence and prevalence of heart failure (HF) are increasing worldwide. This epidemic of HF is characterized by an increase of HF with preserved left ventricular ejection fraction (LVEF) (HFpEF) and a decrease of HF with reduced LVEF (HFrEF). Of note, transition between HFpEF and HFrEF has been recently highlighted, since it significantly relates with prognosis. Our recent studies indicated that temporary changes in LVEF are common and associated with prognosis in patients with HF. In this chapter, we summarize recent findings on temporal changes in LVEF and their prognostic impact in HF patients, acknowledging that further studies are needed to fully elucidate the pathophysiology of LVEF recovery and deterioration to improve clinical outcomes of HF patients, and also to develop therapies targeting novel pathways of myocardial recovery.

1 Burden of HF

Along with the aging of society, the increase in patients with HF is an emerging public healthcare issue worldwide (Benjamin et al. 2017; Ambrosy et al. 2014; Shimokawa et al. 2015). In the United States, data from the National Health and Nutrition Examination Survey (NHANES) 2011–2014 indicate that 6.5 million people aged ≥20 years have HF (Benjamin et al. 2017), and prevalence of HF is projected to increase 46% from 2012 to 2030, resulting in more than 8 million people aged ≥18 years with HF (Heidenreich et al. 2013). In Europe, although precise estimates of HF are scarce, Bleumink et al. reported in 2004 from the Rotterdam Study that lifetime risk for HF at age of 55 was 33% for men and 29% for women, indicating that among individuals at this age, almost 1 in 3 will develop HF during their remaining lifespan (Bleumink et al. 2004). Information from Asia is also limited (Sakata and Shimokawa 2013; Guo and Lip 2013; Pillai 2013). However, it is assumed that a considerable number of patients develop HF every year, particularly when a recent epidemiologic transition and a dramatic increase in the elderly population

are taken into consideration (Sakata and Shimokawa 2013; Omran 1971; Zuckerman et al. 2014; Yusuf et al. 2001; Reddy and Yusuf 1998).

2 Geographic Differences in the Burden of HF

Significant geographic differences exist in the etiologies and risk factors for HF (Benjamin et al. 2017; Sakata and Shimokawa 2013). While hypertension is strongly associated with HF incidence in all regions, this association is particularly strong in Latin America, the Caribbean, Eastern Europe, and sub-Saharan Africa. In contrast, IHD is the leading cause of HF in the developed countries, while HF due to valvular and/or rheumatic heart disease remains common in East Asia, South Asia and Asia-Pacific countries (Benjamin et al. 2017). Notably, along with epidemiologic transition, the prevalence of HF with IHD has recently increased, especially in Asia and developing countries (Sakata and Shimokawa 2013; Reddy and Yusuf 1998). In particular, in certain areas of Asia and Africa, a considerable number of younger patients with cardiovascular disease have susceptibility to HF (Benjamin et al. 2017; Sakata and Shimokawa 2013). Indeed, it is reported that, despite a minimal association of IHD with HF in sub-Saharan Africa (Khatibzadeh et al. 2013), more than 40% of patients with newly diagnosed cardiovascular disease have HF, whereas only 10% have IHD, and HF is observed individuals in sub-Saharan Africa at a much younger age than in Western countries (Damasceno et al. 2012; Sliwa et al. 2008).

3 Classification of HF by LVEF

Although not the perfect parameter by which to stratify patients with HF, left ventricular ejection fraction (LVEF) has been historically used in clinical trials for this purpose. An unintentional result of this has been the realization that LVEF can be used to discern the benefits of HF therapies; namely, between HF with reduced LVEF (HFrEF) and HF with preserved LVEF (HFpEF) (Ponikowski et al. 2016; Yancy et al. 2013). There has been a debate as to whether HFrEF and HFpEF have different pathophysiological entities. It is now recognized, however, that they are distinct entities despite the fact that patients with HFrEF and HFpEF have similar clinical signs and symptoms (Komajda and Lam 2014). It is because of bimodal distribution of LVEF in epidemiologic studies and registries for HF (Borlaug and Redfield 2011; Gaasch et al. 2009) as well as the differences between HFrEF and HFpEF in patient characteristics (Bursi et al. 2006; Owan et al. 2006; Tsuji et al. 2017); LV remodeling patterns (Zile et al. 2004; Kitzman et al. 2002; Lam et al. 2007); functional consequences (particularly in the LV end-systolic pressure–volume relationship) (Borlaug et al. 2009; Lam et al. 2007; Kawaguchi et al. 2003; Schwartzenberg et al. 2012); cellular, subcellular, and interstitial characteristics (van Heerebeek et al. 2006; Borbely et al. 2005; van Heerebeek et al. 2008; Aurigemma et al. 2006); and responsiveness to HF therapies (Massie et al. 2007, 2008; Lee et al. 2004). Importantly, in the era of HF burden, it is well recognized that the proportion of HFpEF is increasing, while that of HFrEF is decreasing (Owan et al. 2006; Steinberg et al. 2012; Shiba et al. 2011). From Japan, we recently revealed that an increase in symptomatic HF with IHD was mostly attributable to the increase in HFpEF with IHD among patients registered in the Chronic Heart Failure Analysis and Registry in the Tohoku District (CHART) Studies (Fig. 1) (Ushigome et al. 2015).

4 HF with Mid-range LVEF

Until recently, the most appropriate LVEF cut-off to differentiate HFrEF and HFrEF could not be agreed upon, since cut-offs for HFrEF or HFpEF vary among studies (Lam and Solomon 2014). Meanwhile, an LVEF cut-off of 50% for HFpEF has been embraced in the clinical guidelines so as to clearly discern HFpEF from HFrEF, leaving an LVEF gap around 40–50% as a grey zone, termed "HF with mid-range LVEF (HFmrEF)" for HF patients with an LVEF of 40–49% in the European Society of Cardiology (ESC) (Ponikowski et al. 2016) and "HFpEF, borderline" for HF patients with an

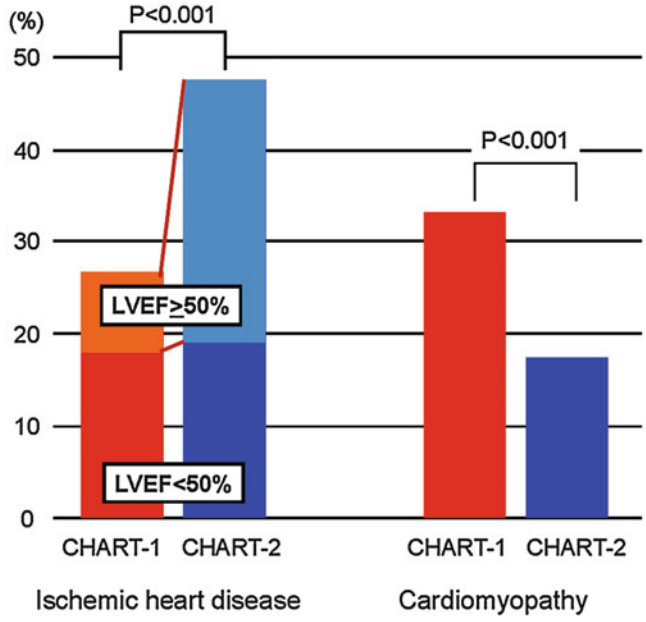

Fig. 1 Trends in etiologies of symptomatic HF in the CHART Studies. As an etiology of symptomatic HF, prevalence of IHD was significantly increased from the CHART-1 (Registration period 2000–2004, N = 1,006) to the CHART-2 (Registration period 2006–2010, N = 3,676) Study, while that of cardiomyopathy was decreased. Increase of HF with IHD was mostly attributable to that of HF with IHD and LVEF > 50%. CHART, Chronic Heart Failure Analysis and Registry in the Tohoku District; *HF* heart failure, *IHD* ischemic heart disease, *LVEF* left ventricular ejection fraction. This figure was made based on the data by Ushigome et al. (2015)

LVEF of 41–49% in the American College of Cardiology Foundation (ACCF)/American Heart Association (AHA) (Yancy et al. 2013). To examine the clinical features of HFmrEF patients, several studies have examined HFmrEF patients in the setting of hospitalized acute HF (Cheng et al. 2014; Kapoor et al. 2016) and reported that HFmrEF may generally resemble HFpEF, although HFmrEF with an etiology of ischemia exceptionally may more resemble HFrEF. Lam et al. summarized available data from studies comparing HFmrEF with HFrEF and HFpEF. While acknowledging slightly different LVEF cut-offs among studies, they found (1) the clinical characteristics of HFmrEF are intermediate between those of HFrEF and HFpEF; (2) patients with HFmrEF are younger and more predominantly male compared with those with HFpEF; (3) several cardiovascular risk factors are common among HFrEF, HFmrEF, and HFpEF, but patients with HFmrEF more likely have hypertension (60–77%) than those with HFrEF; (4) a significant proportion of patients with HFmrEF are diabetic (28–48%); and (5) patients with HFmrEF are more likely to have IHD (65–72%) than those with HFpEF, but to have a similar rate to those with HFrEF (Lam and Solomon 2014). In the CHART-2 Study, we examined 3480 consecutive HF patients with echocardiography data, consisting of 2154 HFpEF (LVEF $\geq$ 50%), 596 HFmrEF (LVEF 40–49%) and 730 HFrEF (LVEF < 40%). We found that clinical characteristics of HFmrEF were intermediate between those of HFrEF and HFpEF (Tsuji et al. 2017), consistent with former studies (Cheng et al. 2014; Kapoor et al. 2016). In addition, we also found that the prognostic factors of HFmrEF were intermediate between those of HFrEF and HFpEF. In contrast, the prognosis of HFmrEF more resembled that of HFpEF, while the prognostic impacts of cardiovascular medications in HFmrEF were similar to those in HFrEF: use of beta blockers was associated with better prognosis in both HFrEF and HFmrEF, but not in HFpEF, while statin use

was associated with better prognosis in HFpEF, but in neither HFrEF nor HFmrEF (Tsuji et al. 2017). These results indicated that HFmrEF may represent an overlap zone between HFrEF with higher-end LVEF and HFpEF with lower-end LVEF, rather than an independent entity of HF.

5 Changes in LVEF and Transitions Among HF Categories

Recent clinical guidelines have clearly classified patients into HFrEF, HFmrEF, or HFpEF on the basis of LVEF at HF diagnosis (Ponikowski et al. 2016; Yancy et al. 2013). However, little is known about changes in EF after the initial diagnosis. Dunlay et al. examined temporal changes in LVEF by echocardiography from initial HF diagnosis (to death or last follow-up) in a community cohort of incident HF patients in Olmsted County, Minnesota, USA (Dunlay et al. 2012). Among 1233 HF patients diagnosed between 1984 and 2009, LVEF increased in HFrEF patients by an average 6.9% over 5 years ($P < 0.001$), while it decreased in HFpEF patients (45.3%, N = 559) by an average 5.8% over 5 years ($P < 0.001$). Overall, 39% of HFrEF patients had an EF $\geq$ 50% and 39% of HFpEF patients at the initial diagnosis had an EF < 50% at some point there (Dunlay et al. 2012). Clarke et al. examined 2413 patients in Kaiser Permanente Colorado with a primary discharge diagnosis of HF between 2001 and 2008 and at least 2 measurements of LVEF separated by $\geq$ 30 days. On estimation of transition probabilities at 5-year follow-up, there was a 13% probability for HFrEF patients to transition to HFpEF (95% CI, 10–17%), a 31% probability to remain as HFrEF (95% CI, 23–38%), and a 56% probability of death (95% CI, 47–66%). In contrast, there was a 15% probability for HFpEF patients to remain as HFpEF (95% confidence interval [CI], 11–19%), a 33% probability to transition to HFrEF (95% CI, 26–40%), and a 52% probability of death (95% CI, 43–61%) (Clarke et al. 2013). We also examined transitions in LVEF among 2154 HFpEF (LVEF $\geq$ 50%), 596 HFmrEF (LVEF 40–49%) and 730 HFrEF (LVEF < 40%) patients registered in the CHART-2 Study (Tsuji et al. 2017) (Fig. 2). We found that HFmrEF and HFrEF, but not HFpEF, dynamically transitioned to other categories, mostly within a year; from registration to 1 year, HFrEF transitioned to HPpEF and HFmrEF by 18% and 22%, respectively, and HFmrEF transitioned to HFpEF and HFrEF by 44% and 16%, respectively. It was noted, however, that unlike patients with HFmrEF and HFrEF, HFpEF patients transitioned to HFmrEF and HFrEF by only 8% and 2%, respectively, indicating that subsequent progressive systolic contractile dysfunction is not a representative manifestation of HFpEF. This finding is inconsistent with that of Clarke et al. (Clarke et al. 2013), in which HFpEF patients dramatically transitioned to HFrEF or death. These observations, however, clearly indicate that LVEF dramatically changes after diagnosis, warranting a need to establish when and in which HFrEF, HFmrEF, and HFpEF patients we should repeat LVEF measurement. In the 2016 ESC guidelines (Ponikowski et al. 2016), however, echocardiography is only recommended for the assessment of myocardial structure and function in subjects with suspected HF in order to establish a diagnosis of either HFrEF, HFmrEF or HFpEF, but there is no recommendation for the LVEF follow-up. In this regard, our finding may indicate that we should repeat LVEF measurement at least within a year after the initial evaluation, particularly in HFrEF and HFmrEF patients. However, serial LVEF assessments after 1-year could be clinically important in each patient, since dynamic LVEF fluctuation is often observed after the 1-year follow-up in the CHART-2 Study (Tsuji et al. 2017).

6 HF with Recovered LVEF

It should be emphasized that patients with mid-range EF are not necessarily transitioning from HFpEF to HFmrEF then HFrEF: the ACCF/AHA guidelines also categorized a subset of patients with LVEF > 40% who previously had

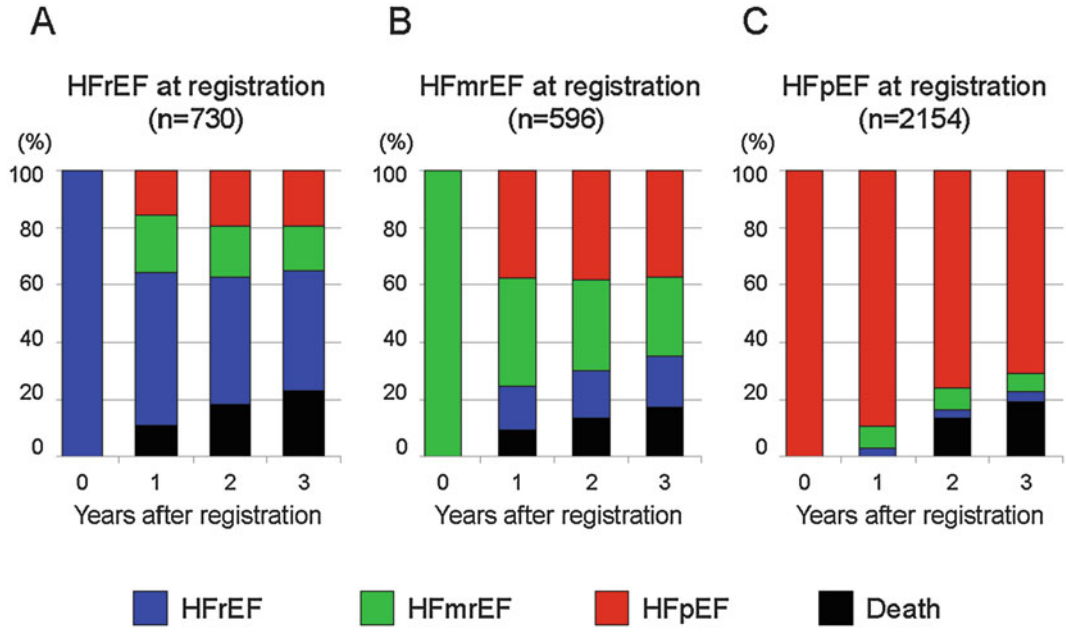

Fig. 2 Transitions of HF among heart failure patients by LVEF. (**a**) HFrEF, (**b**) HFmrEF, and (**c**) HFpEF patients. HF, heart failure; HFmrEF, HF with mid-range left ventricular ejection fraction; HFpEF, HF with preserved left ventricular ejection fraction; HFrEF, HF with reduced left ventricular ejection fraction; LVEF, left ventricular ejection fraction. This figure was made based on the data by Tsuji et al. (2017)

HFrEF as "HFpEF, improved", since these patients with improved or recovered EF may be clinically distinct from those with persistently preserved or reduced EF (Yancy et al. 2013). Indeed, substantial heterogeneity exists within patients with HFmrEF, since HFmrEF includes both patients with de novo HF and those who have recovered their systolic function from HFrEF (Nadruz et al. 2016; de Groote et al. 2014; Basuray et al. 2014). Studies of implantable cardioverter-defibrillator (ICD) therapy also suggest a subpopulation of HF patients with recovered LVEF (Naksuk et al. 2013; Zhang et al. 2015). Naksuk et al. reported that 25 of 91 (27%) patients undergoing ICD generator exchange had LVEF improvement from 31 ± 7% at baseline to 49 ± 8% at the time of ICD generator replacement ($P < 0.0001$) (Naksuk et al. 2013), while Zhang et al. reported that 40% of 538 patients with repeated LVEF assessments after ICD implantation for primary prevention of sudden cardiac death had an improved LVEF during follow-up and 25% had LVEF improved to ≥ 35% (Zhang et al. 2015).

7 Prognostic Impacts of Changes in LVEF

It has remained unknown whether changes in LVEF are associated with subsequent clinical outcomes in patients with HF. Dunlay et al. reported that decreases in LVEF over time were associated with increased mortality whereas increases were associated with improved survival, indicating that progressive systolic contractile dysfunction may, at least in part, contribute to the outcomes of HFpEF (Dunlay et al. 2012). Among patients with chronic HF registered in the CHART-2 Study, we also reported that, regardless of HF stage at registration, HFrEF patients at 1 year had increased incidence of death, while HFpEF at 1 year had better prognosis (Tsuji et al. 2017). These observations strongly

indicate that LVEF changes are obvious prognostic predictors.

Nadruz et al. studied 944 patients with HF, consisting of 620 with HFrEF, 107 HF with midrange LVEF and no recovery of LVEF (LVEF was consistent between 40% and 55%) (non-recovered HFmrEF), 170 HF with recovered midrange LVEF (LVEF 40–55% but previous LVEF < 40%) (recovered HFmrEF) and 47 HFpEF (LVEF > 55%) (Nadruz et al. 2016). They found that the clinical characteristics and values of predicted peak oxygen consumption and the minute ventilation/carbon dioxide production slope in cardiopulmonary exercise testing were comparable between non-recovered HFmrEF and recovered HFmrEF, which were intermediate between HFrEF and HFpEF. Importantly, the multivariable Cox regression analysis showed that a composite incidence of death, left ventricular assistant device implantation and transplantation in recovered HFmrEF was comparable to that in HFpEF, and was significantly lower than those in HFrEF (HR, 0.25; 95% CI 0.13–0.47) and non-recovered HFmrEF (HR, 0.31; 95% CI 0.15–0.67). Based on these observations, they concluded that recovered systolic function within the HFmrEF population is a marker of a more favorable prognosis (Nadruz et al. 2016).

LVEF improvement may have less effect in reducing arrhythmogenicity. In their prospective cohort study, Zhang et al. also reported that LVEF changes after ICD implantation for primary prevention of sudden cardiac death were inversely associated with all-cause mortality and appropriate shocks for ventricular tachyarrhythmias. Ruwald et al. reported that only one ventricular arrhythmia event occurred among 55 subjects with LVEF recovery > 50% in the Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT) trial (Ruwald et al. 2014). However, it remains to be elucidated whether LVEF recovery after ICD implantation is essentially beneficial, particularly for arrhythmogenicity, since Zhang et al. also reported that the risk of an appropriate shock remained in patients whose follow-up LVEF improved to > 35%, albeit that this risk was markedly decreased (Zhang et al. 2015). Naksuk et al. also reported that the incidence of appropriate ICD shocks was similar between those with and without LVEF recovery after ICD implantation (Naksuk et al. 2013).

8 Factors Related to Changes in LVEF

Although little is known about factors related to changes in LVEF, the presence of IHD has recently been considered to play an important role in the clinical course of HFpEF patients (Hwang et al. 2014). HFpEF patients with IHD had greater decreases in LVEF and increased mortality during the follow-up. Thus, it is possible that HFmrEF may constitute a precedent stage of HFrEF among the subpopulation of HFpEF with IHD, possibly consisting of those in the early phase of cardiac remodeling after acute ischemic myocardial damage or those with chronic myocardial ischemia. In contrast, patients with partially recovered or early stages of myocarditis or cardiomyopathy and those who have just started to be treated with cardiovascular medications, including renin-angiotensin system (RAS) inhibitors and beta-blockers, may subsequently constitute a subset of recovered LVEF population.

Dunlay et al. reported that greater declines in LVEF were observed in older individuals and those with coronary disease, while greater increases were observed in women, younger patients, individuals without coronary disease, and those treated with evidence-based medications (Dunlay et al. 2012). Using multistate Markov modeling, Clarke et al. reported that patients who were adherent to beta-blockers were more likely to transition from HFrEF to HFpEF (HR 1.53; 95% CI 1.10–2.13) than those who were nonadherent, whereas adherence to neither angiotensin-converting enzyme nor angiotensin II receptor blocker was associated with LVEF transition, and that patients with a previous myocardial infarction were more likely to transition from HFpEF to HFrEF (HR 1.75; 95% CI 1.26–2.42), underlining that LVEF is a dynamic

factor related to sex, coexisting conditions, and drug therapy. In the CHART-2 Study, the simple linear regression analysis indicated that IHD etiology was negatively and female sex was positively associated with LVEF increase at 1-year in all three groups, indicating that an increase in LVEF in the HFrEF and HFmrEF groups was greater and a decrease in LVEF in the HFpEF group was smaller in females and in those without IHD (Tsuji et al. 2017). Importantly, the multivariable linear regression analysis revealed that patients with HFpEF, HFmrEF and HFrEF had different sets of factors related to LVEF change from baseline to 1-year: female sex was significantly associated with increase in LVEF, while history of stroke with LVEF decrease in HFpEF, IHD histology and LV dilatation were significantly associated with LVEF decrease in HFmrEF, and hyperuricemia, elevated BNP levels, IHD histology, and LV dilatation were significantly associated with LVEF decrease in HFrEF (Tsuji et al. 2017). These observations indicate that different approaches are required to preserve or improve LVEF by LVEF categories.

9 LVEF Maintenance After Recovery

It is unclear whether pharmacotherapy should be continued in patients with HF with recovered LVEF (Hopper et al. 2014). Moon et al. retrospectively examined 42 patients with idiopathic dilated cardiomyopathy who recovered from systolic heart failure (LVEF 26.5 ± 6.9% at initial presentation) to a near-normal state (LVEF ≥ 40%, and a ≥ 10% increase in absolute value) (Moon et al. 2009). Patients were monitored for recurrence of LV systolic dysfunction for 41.0 ± 26.3 months after recovery (LVEF 53.4 ± 7.6%) from LV dysfunction. LV systolic dysfunction reappeared (LVEF 27.5 ± 8.1%) during the follow-up period in 19% (8 of 42) of patients and the recurrence was significantly correlated with the discontinuation of anti-heart failure drugs. Park et al. retrospectively studied 85 consecutively enrolled patients with dilated cardiomyopathy (DCM) who achieved a restoration of LV systolic function and were followed up for 50 ± 33 months after recovery from LV dysfunction without discontinuation of standard medication for heart failure (Park et al. 2014). They observed recurrence of LV dysfunction in 33 patients, which was associated with age, diabetes, and LV end-diastolic dimension (LVEDD) at initial presentation in the multivariate analysis.

Studies on withdrawal of these drugs in HF are scarce and small. Hopper et al. examined whether withdrawal of beta-blockers or RAS inhibitors could be a risk in mixed populations of chronic stable HF trials and reported that withdrawal of beta-blockers and RAS inhibitors likely had untoward effects on cardiac structure, symptoms, and major outcomes (Hopper et al. 2014). Swedberg et al. examined 15 patients with congestive cardiomyopathy who had improved conspicuously on chronic administration of a beta-blocker: after withdrawal of the beta-blocker, they observed a pronounced deterioration of clinical condition in 6 patients (40%), and a significant decrease in LVEF, and signs of compromised diastolic function with pathological apex curves and an increase in third heart sound in all of the remaining patients (Swedberg et al. 1980). Importantly, they also reported that all these changes were reversed within a few weeks to a few months after re-administration of beta-blockers. Morimoto et al. examined the influence of tapering and then stopping metoprolol over a period of 14 weeks in 13 patients with DCM who had been receiving this agent for ≥30 months, 10 of whom were in NYHA functional class I (Morimoto et al. 1999). They reported that, while 6 patients remained stable, 7 patients deteriorated (2 sudden deaths and 2 deaths from worsening HF) during the 4-month follow-up period, and that LVEF fell from 38 ± 14% to 34 ± 14% ($P < 0.05$). With these observations, they concluded that beta-blockers should not be stopped in DCM patients treated with BB. Regarding discontinuation of RAS inhibitors, Maslowski et al. reported that after discontinuation of long-term captopril treatment in 5 patients with heart failure, cardiac

performance was not impaired and electrolyte balance was not adversely affected by the abrupt withdrawal of captopril in the short term (Maslowski et al. 1981). However, at least middle-term discontinuation of RAS inhibitors appears to be harmful in patients with chronic HF although any effect on LVEF itself has not been reported (Pflugfelder et al. 1993). Pflugfelder et al. reported that withdrawal of quinapril from patients with heart failure resulted in a slow progressive decline in clinical status among 224 participants with stable chronic HF; exercise tolerance, NYHA functional class, quality of life, and clinical status of HF deteriorated in patients withdrawn to placebo after $\geq$10 weeks of single-blind quinapril therapy, which occurred gradually over a 4–6-week period (Pflugfelder et al. 1993). These lines of evidence clearly indicate that continuation of medical therapy is mandatory to prevent reoccurrence of LV systolic dysfunction in HF patients with recovered LVEF.

However, given a report that discontinuation of HF medications after recovery did not lead to decompensation over 29 months' follow-up in patients with peripartum cardiomyopathy (PPCM), further investigations to confirm the harm of drug discontinuation after LVEF recovery are warranted (Amos et al. 2006). Furthermore, it should be noted that we cannot conclude any cause-effect relationships between drug discontinuation and outcomes based on the findings of retrospective studies, since the observations could be confounded by other reasons that may modulate the risk of recurrence independently. Indeed, patients who have blood pressure- or renal function-related intolerance of HF medications are most likely to have their medications discontinued, as well as to have the highest risk of future adverse outcomes.

10 Conclusion

Temporary changes in LVEF are common and associated with prognosis in patients with HF. Further prospective observational studies or randomized clinical trials are needed to fully elucidate the pathophysiology of LVEF recovery and deterioration to improve clinical outcomes of HF patients, and also to develop therapies targeting novel pathways of myocardial recovery.

Combination Therapy of Renin Angiotensin System Inhibitors and β-Blockers in Patients with Heart Failure

Kotaro Nochioka, Yasuhiko Sakata, and Hiroaki Shimokawa

Abstract

Renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system play crucial roles in heart failure with reduced ejection fraction (HFrEF). Clinical trials provide strong evidence of prognostic benefits for combination therapy with angiotensin-converting enzyme inhibitor (ACEI) and β-blocker in the treatment of HFrEF. Angiotensin receptor blocker (ARB) is not superior to ACEI in improving mortality and an alternative for patients who are intolerant to ACEI. Prognostic evidence for triple therapy which combined angiotensin receptor blocker (ARB) and ACEI in addition to β-blocker therapy, is still controversial in HFrEF. Moreover, a recent clinical trial showed that triple therapy did not provide additional benefit compared with ACEI or ARB therapy alone in mildly symptomatic HFrEF. Of note, the triple therapy can even cause harm and renal dysfunction in HF with a history of hypertension. Direct renin inhibitor (DRI) has the theoretical benefit of upstream RAAS inhibition at the point of pathway activation. However, the results from clinical trials do not support upstream renin inhibition by DRI in addition to standard therapy with ACEI in patients with HFrEF. Angiotensin receptor-neprilysin inhibitor (ARNI) which combines a neprilysin inhibitor and ARB valsartan have a unique mode of action targeting both RAAS and the natriuretic peptide systems. In contrast to the evidence in HFrEF, clinical value of combination therapy with RAAS inhibitors and β-blocker is not well established in HF with preserved EF (HFpEF). The heterogeneity of diagnostic criteria and baseline characteristics of HFpEF need further evidence for the combination therapy. However, a recent clinical trial of LCZ696 showed promising results in reducing NT-proBNP in patients with HFpEF.

Angiotensin receptor blocker · Angiotensin receptor-neprilysin inhibitor · Angiotensin-converting enzyme · Direct renin inhibitor · Ejection fraction · Heart failure · Mineralocorticoid receptor antagonist · Prognosis · Renin-angiotensin-aldosterone system · β-blocker

1 Introduction

The renin-angiotensin-aldosterone system (RAAS) is a signaling pathway responsible for regulating blood pressure and fluid balance (Garg and Yusuf 1995; Yusuf et al. 2003; Paul et al. 2006; Kobori et al. 2007). (Fig. 1) The RAAS

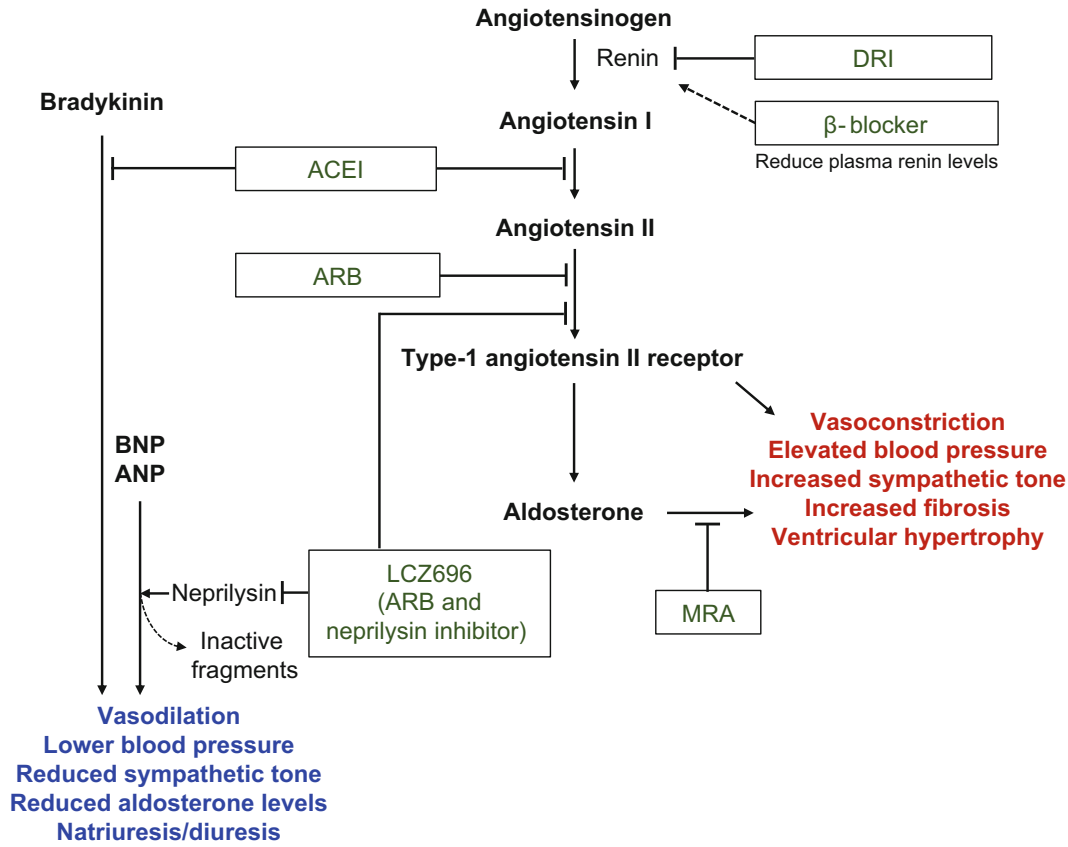

Fig. 1 Renin-angiotensin-aldosterone pathway. Abbreviations; *ACEI* angiotensin converting enzyme inhibitor, *ARB* angiotensin receptor blocker, *DRI* direct renin inhibitor, *MRA* Mineralocorticoid receptor antagonist

plays a crucial role in heart failure with reduced ejection fraction (HFrEF). Blocking RAAS by angiotensin-converting enzyme inhibitor (ACEI), angiotensin receptor blocker (ARB) and mineralocorticoid receptor antagonist (MRA) improve prognosis in HFrEF and are recommended by professional guidelines (Writing Committee et al. 2013; Ponikowski et al. 2016a) β blocker has ability to reverse the neurohumoral effects of the sympathetic nervous system (Eichhorn et al. 1991) and lowers plasma renin levels (Holmer et al. 1998) with ensuing symptomatic and prognostic benefits, and thus attained recommendation by the guidelines (Writing Committee et al. 2013; Ponikowski et al. 2016a). This section summarizes evidence of combination use with RAAS inhibitors and beta blockers in HF, especially in HFrEF.

2 ACEI in HFrEF

The first study demonstrating prognostic benefit by ACEI in HFrEF patents was the CONSENSUS (Cooperative North Scandinavian Enalapril Survival Study) in 1987 (Group CTS 1987; Swedberg and Kjekshus 1988). The CONSENSUS demonstrated that, in 253 HFrEF patients with NYHA (New York Heart Association) class IV, treatment with enalapril (2.5-40 mg/day) significantly reduced the risk of mortality at 6-month (26% in enalapril vs. 44% in placebo) and 1-year (36% vs. 52%). In the CONSENSUS, the reduction in mortality by enalapril was attributed to significantly lower risk of mortality resulting from progression of HFrEF (a reduction of 50%) (Group CTS 1987). The findings from the CONSENSUS was confined to severe HFrEF

patients and no data on prognosis were available for patients with mildly symptomatic HF. Following the accomplishment of the CONSENSUS, the SOLVD (Studies of Left Ventricular Dysfunction) trial showed that treatment with enalapril over a mean of 41.4 months reduced the risk of death by 16% (95% confidence interval; 5–26%) among HFrEF patients with mild-to-moderate symptoms (SOLVD Investigators et al. 1991; The SOLVD Investigators 1990). Align with the CONSENSUS, the beneficial effect of enalapril for prognosis in the SOLVD was due to reduction of death from progression of HF. Besides survival benefits, patients receiving enalapril experienced hypotension more frequently than those receiving placebo in both the CONSENSUS and SOLVD.

3 ARB in HFrEF

ARBs (angiotensin II receptor blockers) are antagonists of angiotensin II type I receptor, which have less side effects, such as coughs and angioedema, as compared with ACEIs. Evidence of ARB in HFrEF is still limited. Head-to-head comparison between ACEI and ARB was conducted in the ELITE (Evaluation of Losartan in the Elderly) II trial enrolling 3,152 HFrEF (EF $\leq$ 40%) patients age 60 years or older with NYHA class II-IV. The results of ELITE II demonstrated no significant difference in mortality between ARB losartan and ACEI captopril (Pitt et al. 2000; Willenheimer 2000). In addition, the investigators observed significant fewer adverse event rates in losartan group (Pitt et al. 2000; Willenheimer 2000). Furthermore, the CHARM (Candesartan in Heart failure Assessment of Reduction in Mortality and morbidity)-Alternative trial showed that an ARB candesartan comparing placebo was generally well tolerated and reduced cardiovascular mortality and morbidity in 2,028 HFrEF (EF < 40%) patients who are intolerance to ACE inhibitors (Granger et al. 2003). Based on these results, professional guidelines recommended ARB is considered as an alternative for patients who cannot tolerate ACEI due to cough or angioedema which are adverse effects of ACEI (Writing Committee et al. 2013; Ponikowski et al. 2016a).

4 MRA in HFrEF

Increasing evidence suggested that ACEI did not effectively suppress the production of aldosterone based on the pathophysiological observations (Borghi et al. 1993; Staessen et al. 1981; Struthers 2004; Andrew 2002). Hence, the RALES trial was initialized to evaluate the role of MRA in addition to ACEI in the treatment of advanced HFrEF (Pitt et al. 1999; Weber 1999). Specifically, the RALES (Randomized Aldactone Evaluation Study) aimed to determine whether spironolactone would reduce mortality in patients with advanced HF and an EF < 35%, who were already on standard medical therapy (ACEI, if tolerated, and diuretics). The RALES clearly demonstrated that adding 25 mg of spironolactone to standard therapy reduced all-cause mortality in HFrEF (EF < 35%) patients (Pitt et al. 1999). The success of the RALES with severe HFrEF patients prompted the subsequent EMPHASIS-HF trial (Zannad et al. 2011) which investigated MRA eplerenone in the treatment of moderate HFrEF with mild symptoms, reinforcing the benefits of MRA in HFrEF. Evidence from these trials established ACEI (ARB if in non-tolerated to ACEI) (Writing Committee et al. 2013; Ponikowski et al. 2016a; Cohn and Tognoni 2001) and MRA as standard therapies in HFrEF.

5 β-Blocker in HFrEF

β-blockers have ability to reverse the neurohumoral effects of the sympathetic nervous system (Eichhorn et al. 1991) and lowers plasma renin levels (Holmer et al. 1998) with ensuing symptomatic and prognostic benefits with recommendation by the guidelines (Writing Committee et al. 2013; Ponikowski et al. 2016a). In 1974, Finn Waagstein et al. first reported that practolol

dramatically improved patient's clinical status in a 59-year woman with HFrEF and suggested benefits of a β-blocker, practolol in patients with HFrEF (Waagstein et al. 1974; Waagstein and Rutherford 2017). A subsequent study from his group demonstrated the clinical benefits of the β-blocker in patients with HFrEF (Waagstein et al. 1974, 1975; Waagstein and Hjalmarson 1976).

6 Combination Therapy with ACEI and β-Blocker in HFrEF

Since angiotensin II increase the sympathetic drive, which was proven to be harmful in patients with HF. Combining ACEI/ARB with β blocker could provide summed blockage to the sympathetic nervous system with additional benefit. (Fig. 1) The prognostic value of the combination therapy with ACEI and β-blocker was demonstrated by the US Carvedilol trial (Packer et al. 1996). In NYHA II-IV HFrEF (EF < 40%) patients receiving ACEI, a mean daily dose of 45 ± 27 mg of carvedilol had a 65% lower risk of death than those given placebo during follow-up of 6.5 months and of extended 15 months. (Table 1) The results from the US Carvedilol were clear in terms of survival benefit by carvedilol. However, since carvedilol exerts pharmacologic effects atypical of and in addition to its action on adrenergic receptors, (Yoshikawa et al. 1996; Foody et al. 2002) it was not clear that all β-blockers would prolong survival in HFrEF patients. The beneficial effects of other β-blockers were confirmed in the CIBIS-II (Cardiac Insufficiency Bisoprolol Study II; bisoprolol) and MERIT (Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure; mrtoprolol) (Packer et al. 1999a, b). The value of carvedilol was further confirmed in severe HFrEF by the COPERNICUS (Carvedilol Prospective Randomized Cumulative Survival) trial, which enrolled 2,289 HFrEF (EF < 25%) patients with HF symptom at rest or on minimal exertion (Packer et al. 2001). In the COPERNICUS, the addition of carvedilol to ACEI, diuretics, and digitalis for a mean of 10.4 months decreased the rate of death by 35% (95%CI; 19–48%, P < 0.001) and the rate of death or hospitalization by 24% (13–33%, P < 0.001). (Table 1) The COPERNICUS provided further evidence that suppressing the neurohormonal axis can delay the progression of HF in HFrEF and improve survival in the acute setting.

Along with recognition of improved prognosis in HFrEF by combination therapy with β-blocker and ACEI, one question arose on the order of treatments, β-blocker first or ACEI first? To answer this, the CIBIS-III trial was designed comparing initial monotherapy with either bisoprolol or enalapril for 6 months followed by their combination for 6–24 months on mortality and hospitalization (Willenheimer et al. 2005). Regardless of order of initiation treatment, the combination use of a β-blocker to an ACE inhibitor further reduces mortality. Of note, the investigators observed the bisoprolol-first arm was associated with numerically increased risk of worsening HF (HR 1.25 [95%CI 0.87–1.81], P = 0.23). The risk of worsening HF in bisoprolol-first strategy, however, could be improved with greater experience of up titration of the β-blocker.

7 Triple Therapy of ACEI, ARB and β-Blocker in HFrEF

There is no study to test specifically prognostic impact of triple therapy, such as ARB add-on therapy to ACE inhibitor and β-blocker in the large clinical HF trial. However, the role of triple therapy in HF patients has also been evaluated in three trials, the Val-Heft (Valsartan Heart Failure Trial), the CHARM (Candesartan in Heart failure Assessment of Reduction in Mortality and Morbidity)-Added, and the SUPPORT (supplemental benefit of ARB in hypertensive patients with stable heart failure using olmesartan) (Cohn and Tognoni 2001; McMurray et al. 2003; Sakata et al. 2015). (Table 2) In 2001, the Val-Heft evaluated the long-term effects of the addition of an ARB valsartan to standard therapy (approximately 93% in ACEI use; 35% in β-blocker use) in 5,010 HFrEF (EF < 40%) patients with NYHA

II-IV who randomly assigned to receive ARB valsartan or placebo. Mortality was similar in the two treatment groups. However, a post-hoc analysis of the Val-Heft revealed that patients who received triple therapy of ACEI, ARB and β-blocker had a significantly increased mortality (P = 0.009), and a trend toward an increase in the composite endpoint defined as cardiac arrest with resuscitation, hospitalization for HF, or administration of intravenous inotropic or vasodilator drugs for 4 h or more without hospitalization (P = 0.10) (Cohn and Tognoni 2001). In contrast, in the CHARM-Added which enrolled 2,548 HFrEF (EF < 40%) patients with NYHA II–IV, triple therapy (56% in β-blocker use) was associated with a reduction in the composite of cardiovascular death or HF hospitalization (0·85 [95% CI 0.75–0.96], P = 0.011), when compared to placebo. In addition, there was no difference in all-cause death (HR 0·88 [0.72–1.08], P = 0.22) (McMurray et al. 2003; Swedberg et al. 1999).

Given the different results between Val-Heft and CHARM-added, the value of ARB add-on therapy to ACEI was controversial. In 2015, the SUPPORT, which investigated whether an additive treatment with an ARB olmesartan, reduces the mortality and morbidity in 1,147 HF patients with a history of hypertension (7% in NYHA class III; 72% in β-blocker use; 81% in ACEI use; 19% of EF ≤ 40%), provided additional information of triple therapy (Sakata et al. 2015; Sakata et al. 2013). The composite event rates of all-cause death, non-fatal acute myocardial infarction, non-fatal stroke, and hospitalization for worsening HF were not different between olmesartan and control groups (HR 1.18 [0.96–1.46], P = 0.112), whereas renal dysfunction developed more frequently in the olmesartan group (HR 1.64 [1.19–2.26], P = 0.003). Furthermore, a post-hoc analysis of the SUPPORT trial suggested that triple therapy may be harmful in patients with HF: among patients already receiving an ACEI and β-blocker, adding olmesartan was associated with increased incidence of the primary endpoint (HR 1.47 [1.11–1.95], P = 0.006), all-cause death (HR 1.50 [1.01–2.23], P = 0.046), and renal dysfunction (HR 1.85 [95% CI 1.24–2.76], P = 0.003) (Sakata et al. 2015). The results of the SUPPORT and Val-Heft indicate no benefit of triple therapy, which is in contract to what was observed in the CHARM-added trial (Cohn and Tognoni 2001; McMurray et al. 2003; Danser and van den Meiracker 2015). This discrepancy could be explained by the differences in patients' demographics; the majority of the patients in the CHARM-Added had NYHA class III (73%), in contrast to 38% in the Val-Heft, and 7% in the SUPPORT. Thus, although the routine use of triple therapy may be avoided in mildly symptomatic HF with a history of hypertension, it remains to be examined whether the triple combination therapy could be beneficial for HF patients with severe symptoms. A large trial comparing ARB added on to ACEI, β-blocker, and MRA (quad therapy) has not been performed yet (Table 3).

8 Comprehensive Blockade with Direct Renin Inhibitor, Aliskiren, ACEI and β-Blocker in HFrEF

The pathophysiological concept of a complete RAAS blockade was further tackled by direct renin inhibitor (DRI) (Rahuel et al. 2000; Wood et al. 2003). DRI provides another pharmacologically distinct means of suppressing the RAAS, with the theoretical advantages of blocking an enzyme with only one known substrate, angiotensinogen, providing the theoretical benefit of upstream RAAS inhibition at the point of pathway activation. (Fig. 1) Adding Aliskiren, a first-in-class orally active DRI on ACEI and β-blocker has shown favorable neurohumoral effects in terms of reducing plasma BNP (brain natriuretic peptide) levels compared with placebo in the ALOFT (Aliskiren Observation of Heart Failure Treatment) study (McMurray et al. 2008) which included HFrEF patients with NYHA II-IV, current or past history of hypertension, and plasma BNP > 100 pg/mL who had been treated with an ACEI and β-blocker (mean age 68 years; mean EF 31%; NYHA II 62%). Furthermore, aliskiren was associated with a significant

**Reference = The enalapril group

reduction in urinary aldosterone excretion, supporting the hypothesis that a DRI strategy may reduce aldosterone escape with prognostic benefit. However, the results of the ASTRONAUT (AliSkiren TRial ON Acute heart failure oUTcomes) and ATMOSPHERE (Aliskiren Trial to Minimize OutcomeS in Patients with HEart failuRE) trials did not support this hypothesis in terms of prognosis (Gheorghiade et al. 2013; McMurray et al. 2016). In the ASTRONAUT, HFrEF (EF $\leq$ 40%,) patients with BNP $\geq$ 400 pg/mL (or N -terminal pro-BNP [NT-proBNP] $\geq$1,600 pg/mL), and signs and symptoms of fluid overload were randomized to aliskiren or placebo. Patients assigned aliskiren experienced a significant and sustained drop in blood levels of NT-proBNP through 12 months follow-up (Gheorghiade et al. 2013). However, no statistical difference was observed in the event rates for composite of cardiovascular death or HF hospitalization (aliskiren, 35.0% vs. placebo 37.3%; HR 0.93; 95%CI [0.79–1.09], P = 0.36) at 12 months. In addition, hyperkalemia, renal dysfunction and hypotension were reported more frequently in the aliskiren group. Given by the non-beneficial impact with greater side effect by aliskiren, the ASTRONAUT trial implies that there might be a ceiling to the benefit with RAAS modulation, and further inhibition beyond ACEI does not provide any incremental benefit. This argument was reinforced by the results from the ATMOSPHERE trial. The ATMOSPHERE trial randomized 2,336 patients with NYHA II-IV and elevated BNP to receive enalapril alone, 2,340 to receive aliskiren, and 2,340 to receive combination therapy with aliskiren and enalapril (combination therapy) (McMurray et al. 2016; Krum et al. 2015). The primary composite outcome of all-cause death and HF hospitalization occurred in 32.9% of the combination therapy group, in 34.6% in the enalapril group (HR 0.93; 95%CI [0.85–1.03], P = 0.17) and in 33.8% in the aliskiren group (vs. enalapril, 0.99 [0.90–1.10], P = 0.91). Adverse event rates for aliskiren alone group were similar to those of enalapril alone. However, like the ASTRONAUT trial, in the ATMOSPHERE trial, there was a higher risk of hypotensive symptoms in the combination therapy group than in the enalapril alone group (13.8% vs. 11.0%, P = 0.005), and higher risks of an elevated serum creatinine level (4.1% vs. 2.7%, P = 0.009) and an elevated potassium level (17.1% vs. 12.5%, P < 0.001). The results from the ASTORONOUT and ATMOSPHERE do not support upstream renin inhibition in addition to standard therapy with ACEI in patients with HFrEF.

9 Comprehensive Blockade for RAAS and Natriuretic Peptide System in HFrEF

LCZ696 (sacubitril/valsartan) is a new class of agents called angiotensin receptor-neprilysin inhibitors (ARNIs) which combines a neprilysin inhibitor and an ARB valsartan. LCZ696 has a unique mode of action targeting both RAAS and the natriuretic peptide systems because sacubitril inhibits the neprilysin, which increases the level of natriuretic peptides rather than leading to additional blockage. (Fig. 1) Recent data from the PARADIGM-HF (Prospective Comparison of Angiotensin Receptor-Neprilysin Inhibitor with Angiotensin-Converting Enzyme Inhibitor to Determine Impact on Global Mortality and Morbidity in Heart Failure) trial suggests more comprehensive RAAS modulation with other RAAS axis blocking agents may have led to clinical benefit in HF patients and reduced EF (McMurray et al. 2014; McMurray et al. 2013). The PARADIGM-HF randomized 8,399 NYHA II-IV HFrEF ($\leq$40% and $\leq$35% were used at different time points in the trial) patients to LCZ696 or enalapril. With a median follow-up of 27 months, the trial was stopped early due to a positive interval efficacy analysis. The LCZ696 added to standard therapy with 93% of patients already taking β-blocker and 54% taking MRA led to a reduction in the primary composite outcome of cardiovascular death or HF hospitalization (21.8% vs. 26.5%; HR 0.80 95%CI [0.73–0.87], P < 0.001) as well as each of the individual components of the composite outcome. Of note, LCZ696 had a significant reduction in all-cause death (17.0% vs. 19.8%; HR 0.84 95%

CI [0.76–0.93], P < 0.001). LCZ696 was generally well tolerated except for a higher rate of hypotension and there was no difference in the rates of angioedema. Following the PARADIGM-HF, the US Food and Drug Administration approved LCZ696 for the treatment of HF. Furthermore, professional HF guidelines endorse LCZ696 as a class I recommendation for the management of symptomatic HFrEF (Ponikowski et al. 2016b; Jessup et al. 2016). Although this high-quality clinical study is the largest and the most globally represented trial in HFrEF patients, concerns have been raised regarding the generalizability of the trial results in real-world HF population due to inclusion/exclusion criteria, run-in period and lower dose of enalapril in the control arm (Yandrapalli et al. 2017; Yancy et al. 2017).

10 RAAS Inhibitor, β-Blocker and Those Combination in HF and Preserved EF (HFpEF)

Approximately half of HF patients have an EF of 50% or higher (heart failure and preserved ejection fraction; HFpEF) (Owan et al. 2006). The randomized trials with RAASI [ACEI (Cleland et al. 2006) or ARB (Massie et al. 2008)] monotherapy failed to show prognostic benefits in HFpEF patients. For instance, a prespecified subgroup analysis of I-PRESERVED (Irbesartan in Heart Failure with Preserved Ejection Fraction Study) suggested that ARB monotherapy did not provide beneficial impact on prognosis in HFpEF (HR0.87[0.75–1.02], P for interaction of ARB to β-blocker = 0.14) Moreover, the effect of β-blockers monotherapy has not been evaluated in an adequately powered study with HFpEF patients (Conraads et al. 2012; Liu et al. 2014; van Veldhuisen et al. 2009; Yamamoto et al. 2013). In addition, evidence of combination therapy of RAAS inhibitor and β-blocker is predominant in HFrEF. However, several data exist on combination therapy for prognosis in HFpEF by three large clinical trials; CHARM-preserved, I-PRESERVED, and SUPPORT (Yusuf et al. 2003; Massie et al. 2008; Miura et al. 2016).

The CHARM-Preserved enrolled 3,025 patients with HFpEF (EF > 40%) and NYHA II-IV, and a history of hospitalization for a cardiac reason. In the CHARM-Preserved, there was no difference in the primary outcome of cardiovascular death or HF hospitalization between the candesartan and placebo groups (22% vs. 24%; HR 0.89 [95%CI 0.77–1.03], P = 0·118) (Yusuf et al. 2003). However, a signal was observed toward lower event rate for HF hospitalization in candesartan (0.85 [0.72–1.01], P = 0·072). Similar results were observed in the I-PRESERVED including 4,128 symptomatic HF (NYHA II-IV) patients with HFpEF (EF ≥ 45%) who were 60 years or older (Massie et al. 2008; Carson et al. 2005). In the I-Preserved, ARB Irbesartan did not improve the outcome defined by the composite of death from any cause or hospitalization for a cardiovascular cause (heart failure, myocardial infarction, unstable angina, arrhythmia, or stroke) in HFpEF. Post-hoc analysis from the SUPPORT, in HFpEF, the addition of olmesartan to β-blocker was significantly associated with lower event rate for all-cause death (HR 0.32 [0.12–0.90] P = 0.03), whereas addition to ACEI (1.85 [0.87–3.96], P = 0.11) or that to combination of ACEI and β-blocker (1.65 [0.93–2.94], P = 0.09) was not (Miura et al. 2016). In 2014, the TOPCAT (Treatment of Preserved Cardiac Function Heart Failure With an Aldosterone Antagonist) trial including patients with EF ≥45%, who had to have either a HF hospitalization within 12 months before randomization or, if not, an elevated brain natriuretic peptide (BNP; BNP ≥100 pg/mL or N-terminal pro-BNP ≥360 pg/mL) within 60 days before randomization, showed no difference between MRA spironolactone and placebo groups in the primary composite outcome of cardiovascular death, aborted cardiac arrest, or HF hospitalization (Pitt et al. 2014; Desai et al. 2011). However, in post-hoc analysis of the TOPCAT trial, spironolactone was associated with a significant reduction in the primary outcome for those in the United States, Canada, Brazil, and Argentina but not those in Russia/Georgia (Pfeffer et al. 2015). These lines of evidence call for further trials to assess clinical effect of combination therapy of

RAAS inhibitor and β-blocker in HFpEF (Desai and Jhund 2016). To assess efficacy and safety of LCZ696 in HFpEF, the PARAMOUNT (Prospective comparison of ARNI with ARB on Management Of heart failUre with preserved ejectioN fracTion) trial was conducted in HFpEF (≥45%) patients with NYHA II-III, and NT-proBNP>400 pg/mL comparing LCZ696 (200 mg) with valsartan (160 mg) for 36 weeks (Solomon et al. 2012). NT-proBNP was significantly reduced at 12 weeks in the LCZ696 group compared with the valsartan group suggesting that LCZ696 may improve prognosis in HFpEF (Solomon et al. 2012). In near future, PARAGON-HF (Prospective Comparison of ARNI with ARB Global Outcomes in HF With Preserved Ejection Fraction) trial (Solomon et al. 2017; Filippatos et al. 2015) will provide evidence of whether LCZ696 is prognostically superior to ARB alone in patients with chronic symptomatic HFpEF (EF ≥ 45%).

11 Conclusions

With concrete evidence, RAAS blockade by combination with ACEI and β-blocker is a gold standard in the treatment of HFrEF. ARB clearly represent an alternative of treatment for patients who are intolerant to ACEI. Triple therapy with ACEI, ARB and β-blocker does not provide additional benefit in mildly symptomatic HFrEF. Furthermore, triple therapy can even cause harm and renal dysfunction in HF with a history of hypertension. Sacubitril inhibits the neprilysin which increases the level of natriuretic peptides rather than leads to additional blockage, and reduces NT-proBNP levels greater than an ARB in HFpEF. Whether this effect would translate into improved outcomes, is tested by PARAGON-HF trial. Given by the heterogeneity of diagnostic criteria and baseline characteristics of HFpEF, clinical benefit of combination therapy with RAASIs and β-blocker is controversial, and we need further evidence in HFpEF.

Combination of Hydralazine and Isosorbide-Dinitrate in the Treatment of Patients with Heart Failure with Reduced Ejection Fraction

Noémi Nyolczas, Miklós Dékány, Balázs Muk, and Barna Szabó

Abstract

The use of direct acting vasodilators (the combination of hydralazine and isosorbide dinitrate -Hy+ISDN-) in heart failure with reduced ejection fraction (HFrEF) is supported by evidence, but rarely used.

However, treatment with Hy+ISDN is guideline-recommended for HFrEF patients who cannot receive either angiotensin-converting enzyme inhibitors or angiotensin receptor blockers due to intolerance or contra-indication, and in self-identified African-American HFrEF patients who are symptomatic despite optimal neurohumoral therapy.

The Hy+ISDN combination has arterial and venous vasodilating properties. It can decrease preload and afterload, decrease left ventricular end-diastolic diameter and the volume of mitral regurgitation, reduce left atrial and left ventricular wall tension, decrease pulmonary artery pressure and pulmonary arterial wedge pressure, increase stroke volume, and improve left ventricular ejection fraction, as well as induce left ventricular reverse remodelling. Furthermore, Hy+ISDN combination has antioxidant property, it affects endothelial dysfunction beneficially and improves NO bioavailability. Because of these benefits, this combination can improve the signs and symptoms of heart failure, exercise capacity and quality of life, and, most importantly, reduce morbidity and mortality in well-defined subgroups of HFrEF patients.

Accordingly, this therapeutic option can in many cases play an essential role in the treatment of HFrEF.

1 Introduction

The use of the combination of hydralazine and isosorbide-dinitrate (Hy+ISDN) was the first therapeutic intervention in heart failure with reduced ejection fraction (HFrEF) whose beneficial effect on survival was proven in a placebo-controlled, randomized trial (Cohn et al. 1986). Two randomized, placebo-controlled trials have now demonstrated a significant reduction in all-cause mortality in well-defined HFrEF patient populations due to the effects of this direct vasodilator drug combination (Cohn et al. 1986; Taylor et al. 2004), nonetheless, the use of Hy+ISDN is almost negligible worldwide (Golwala et al. 2013; Maggioni et al. 2013; Damasceno et al. 2012). There is no other therapeutic option which is supported by such high-level evidence but is neglected to such an extent by physicians.

The fact that the combination of Hy+ISDN takes a back seat in HFrEF therapy is partly due to changes in the concept of the pathophysiology of heart failure. While in the 1950s and 1960s the cardiorenal paradigm prevailed and heart failure was predominantly treated with the use of digitalis and diuretics, the haemodynamic concept, which established the use of vasodilators, came to dominate in the 1970s and 1980s. From the 1990s onwards, the treatment of heart failure based on the neurohumoral concept became prevalent, supplemented by highly effective neurohumoral antagonists (ACE inhibitors -ACEi-, beta receptor blockers -BB-, mineralocorticoid receptor antagonists -MRA-, angiotensin receptor blockers -ARB-, and angiotensin receptor neprylisin inhibitors -ARNI-). However, due to the dominance of this paradigm, treatment based on the haemodynamic concept was largely overlooked, along with the potential use of vasodilator treatment. Hydralazine is no longer available in many European countries, and where it is available it is very rarely used. However, much research indicates that, despite the unequivocal pathophysiological significance of abnormally elevated neurohumoral activation, we should not ignore the hemodynamic approach either when interpreting the processes of chronic heart failure, or when optimizing therapies (Johnson et al. 2002; Lisy et al. 2000; Stevenson 1999; Stevenson et al. 1995).

When treating a patient with heart failure, using optimal doses of neurohumoral antagonists is essential, but we must also strive to create the optimal hemodynamic status. This involves supporting an appropriate reduction in the heart rate, peripheral vascular resistance, left atrial filling pressure, and an increase in stroke volume and cardiac output, which in some cases cannot be achieved only with the use of neurohumoral antagonists (Stevenson 1999; Stevenson et al. 1995). In chronic heart failure, reduction of the preload and afterload, as well as atrial and ventricular wall tension, is also an important therapeutic goal, the achievement of which often unavoidably involves the use of direct vasodilators (Lisy et al. 2000; Stevenson 1999; Stevenson et al. 1995). In addition, neurohumoral antagonists sometimes cannot be used due to contraindications or intolerance, or patients may remain symptomatic despite use of the neurohumoral antagonists. In such cases, it is important to remember the direct-acting vasodilator combination Hy+ISDN, which if used with caution and according to the evidence and current guideline recommendations (Ponikowski et al. 2016; Yancy et al. 2013) can reduce symptoms and improve quality of life of many HFrEF patients, and reduce morbidity and mortality in some clinical situations.

This chapter presents an overview of the mechanism of action of the Hy+ISDN combination and a review of evidence, guideline recommendations, and practical guidance.

2 Mechanism of Action

2.1 Hydralazine

Hydralazine is primarily an arterial vasodilator that mainly reduces the tone of arterioles, while influencing venous tones less. The exact

intracellular pathways mediating its effects are not completely understood, but it reduces peripheral vascular resistance directly by relaxing vascular smooth muscle cells (Knowles et al. 2004). As an arterial vasodilator, it reduces systemic peripheral resistance, relieves the left ventricular ejection, and therefore – by lowering the afterload – increases left ventricular stroke volume and improves the left ventricular ejection fraction. Further beneficial hemodynamic consequences of afterload reduction include a decrease in the severity of mitral regurgitation, which is often observed in HFrEF due to left ventricular spherical remodelling. Moreover, a decrease in the volume of mitral regurgitation reduces left atrial wall tension, and beneficially affects redistribution of blood flow. One drawback of the effect of arteriolar vasodilation is that it causes a reflex increase in sympathetic activity with all the adverse consequences of this, particularly in cases of mild heart failure. It is notable that the use of hydralazine, particularly in advanced heart failure, does not decrease blood pressure significantly and does not affect kidney perfusion unfavourably. The drug is also known to have antioxidant properties (Daiber et al. 2005) and a beneficial effect on endothelial dysfunction. Hydralazine can prevent nitrate tolerance presumably by inhibition of a membrane-associated oxidase. Previous studies demonstrated that nitrate tolerance is associated with an increase in vascular reactive oxygen species production. The membrane-associated oxidase is likely involved in this process. Hydralazine inhibits this oxidase and reduces the production of reactive oxygen species and prevents nitrate tolerance (Bauer and Fung 1991; Gogia et al. 1995; Münzel et al. 1996).

2.2 Nitrates

Nitrates are primarily venodilators, although their arterial vasodilator activity is not negligible if there is a marked rise in systemic vascular resistance. They decrease the tone of veins and therefore decrease venous inflow into the right heart, decrease pulmonary artery pressure and pulmonary arterial wedge pressure, decrease left atrial pressure, and – as a consequence of the decrease in diastolic inflow into the left ventricle – decrease left ventricular preload, as well as left ventricular diastolic volume and pressure. They reduce the size of the mitral ostium in the dilated left heart, thus reducing relative mitral regurgitation. Isosorbide dinitrate, like nitrites and organic nitrates, is considered an NO donor. Nitrates can inhibit mitogenesis, proliferation of vascular smooth muscle cells and development of myocardial hypertrophy (Garg and Hassid 1989; Calderone et al. 1998) as well as mitigate left ventricular remodelling (Jugdutt and Khan 1994). When nitrates are used, nitrate tolerance should be taken into account. Nitrate tolerance can be avoided not only by temporarily discontinuing the nitrate effect or by temporarily lowering plasma nitrate levels, but with the use of certain drugs such as hydralazine (Gogia et al. 1995), ACEi (Elkayam et al. 1999), or carvedilol (Watanabe et al. 1998).

By means of the hemodynamic effects described above, hydralazine and nitrate reduce left ventricular and left atrial wall tension, both of which play a pathophysiologic role in heart failure (e.g. by inducing and maintaining neurohumoral activation). The combination of hydralazine and nitrate reduces both left and right ventricular filling pressure and increases cardiac output. As a result of the beneficial haemodynamic effects of the Hy+ISDN combination, left ventricular ejection fraction is improved, left ventricular end-systolic and end-diastolic diameters are decreased, thus reverse left ventricular remodelling is developed.

3 Evidence

Although several observational studies have demonstrated the favourable hemodynamic and clinical effects of hydralazine (Franciosa et al. 1977; Chatterjee et al. 1980) and nitrates

(Franciosa et al. 1978a, b; Leier et al. 1983) as individual treatments, clearly beneficial results in hard endpoints have only been achieved with the combination of the two agents.

3.1 V-HeFT I Trial (Vasodilator Heart Failure Trial I) (Cohn et al. 1986)

The first large, multicentre, randomized, placebo-controlled study that assessed the survival of HFrEF patients was the V-HeFT I trial, published in 1986. In the study 642 men with mild-to-moderate heart failure who were being treated with digoxin and diuretics were enrolled. Eligibility criteria were as follows: left ventricular dilatation (cardiothoracic ratio >0.55 on chest x-ray or left ventricular end-diastolic diameter index >2.7 cm/m^2 on echocardiography) or left ventricular ejection fraction <45% on radionuclide ventriculography and reduced exercise tolerance as assessed by spiroergometry (peakVO_2 <25 ml/kg/min). Patients were randomized to placebo, alpha-receptor blocking prazosin, and Hy+ISDN using a ratio of 3:2:2. The starting dose of prazosin was 2.5 mg four times daily, and the target dose was 5 mg four times daily (20 mg), the average prescribed dose was 18.6 mg per day, the starting dose of hydralazine was 37.5 mg four times daily and the target dose 75 mg four times daily (300 mg), the average dose was 270 mg per day, and the isosorbide dinitrate starting dose was 20 mg four times daily, while target dose was 40 mg four times daily (160 mg) with an average dose of 136 mg per day. Mean follow-up time was 2.3 years.

Within the primary endpoint of the study, defined as the cumulative mortality at 2 years, the Hy+ISDN combination resulted in a relative risk reduction of 34% ($p < 0.028$) compared to placebo. For the entire follow-up period however, the reduction in mortality in the Hy+ISDN group was only at the border of statistical significance ($p = 0.053$). Use of prazosin did not improve patient survival.

In addition to the survival benefit of Hy+ISDN, the combination also increased left ventricular ejection fraction significantly in both the short- (8 weeks) and long term (1 year) (2.9% and 4.2%, respectively, $p < 0.001$). This effect was absent for the placebo and prazosin groups. It is notable that treatment with Hy+ISDN did not significantly reduce systolic blood pressure in the short- or long-term, although a slight but statistically significant short-term decrease in diastolic blood pressure (−1.8 mmHg, $p < 0.05$) was detected. In the long-term, this minimal decrease in diastolic blood pressure was not found to be significant.

In summary, the V-HeFT I study demonstrated that the combination of Hy+ISDN can improve the survival of HFrEF patients significantly.

3.2 V-HeFT II Trial (Vasodilator Heart Failure Trial II) (Cohn et al. 1991)

After the appearance of ACEi and the demonstration of their positive effects on morbidity and mortality, the V-HeFT II study was organized to compare the therapeutic effects of ACEi and the Hy+ISDN combination. In this study, published in 1991, 804 men on digitalis and diuretic therapy for mild-to-moderate heart failure were enrolled. Patients were randomized to treatment groups with ACEi enalapril, or Hy+ISDN in a 1:1 ratio. The inclusion criteria, as well as the starting and the target doses of hydralazine and isosorbide dinitrate, were identical to those used in the VeHFT I trial. The target dose of enalapril was 20 mg. The average daily dose of enalapril (15 mg) in this study was similar to the average daily dose of enalapril in the overwhelmingly successful ACEi studies (CONSENSUS I (The CONSENSUS Trial Study Group 1987) – 18.4 mg/day; SOLVD-Treatment (The SOLVD Investigators 1991) – 16.6 mg/day; SOLVD Prevention (The SOLVD Investigators 1992) – 16.7 mg/day). The average dose of hydralazine was 199 mg, while the average dose of isosorbide dinitrate was 100 mg, both of which were somewhat lower than the average doses given in V-HeFT I. Patients were followed on average for 2.5 years.

Mortality after 2 years, predetermined as a major end-point for the trial, was significantly lower in the enalapril arm (18%) than in the Hy +ISDN arm (25%) ($p = 0016$). This trend persisted in the later study, but the difference in mortality across the entire follow-up period was no longer found to be significantly different between the two groups ($p = 0.08$). We emphasize that the favourable mortality rate observed in the enalapril-treated group was the consequence of a lower incidence of sudden cardiac death in this group ($p = 0.015$ without premonitory symptoms, $p = 0.032$ with premonitory worsening). There was no significant difference between the two groups in terms of mortality from pump failure ($p = 0.44$). Also notable is the fact that only the survival probability of patients with mild heart failure (NYHA I-II) was significantly different ($RR = 0.52$) in the enalapril and Hy +ISDN arms. The survival effect of the two treatment groups containing patients of NYHA III-IV class (nearly half the whole sample) was similar ($RR = 0.99$).

There was no significant difference in heart-failure-related (18.9% – enalapril vs. 18.4% – Hy +ISDN) and other CV-related hospitalization (26.7% in each group) across the whole VeHFT II patient population.

A significant improvement was observed in left ventricular ejection fraction for both the Hy +ISDN and enalapril treated patients ($p = 0.0001$); however, the beneficial effect of Hy+ISDN was significantly more pronounced than that of enalapril ($p = 0.026$). Peak VO2 measured by spiroergometry significantly increased during Hy+ISDN treatment ($p < 0.0001$), while this benefit was absent in the enalapril-treated group. Exercise capacity of patients also significantly improved in the Hy +ISDN group compared to enalapril-treated patients (Ziesche et al. 1993).

Blood pressure decreased in both treatment groups, but the reduction in systolic (−5 mmHg) and diastolic blood pressure (−4 mmHg) in the enalapril group was higher than that in the Hy+ISDN group (0 mmHg in systolic, −1 mmHg in diastolic blood pressure). Heart rate was significantly higher in patients treated with Hy+ISDN than in the enalapril group during the follow-up.

The two forms of treatment were associated with side effects almost in the same proportions, but the treatments were well tolerated in both groups. In the Hy+ISDN group, headaches ($p < 0.05$) were significantly more frequent, while enalapril was associated with a higher proportion of hypotension ($p < 0.05$) and coughing ($p < 0.05$) as well as a significantly higher increase in serum urea ($p < 0.01$) and creatinine ($p = 0.02$) and a significantly higher level of potassium.

In summary, the V-HeFT II study showed that the combination of the direct-acting vasodilator Hy+ISDN is less favourable in terms of survival than the ACEi enalapril. However, this weaker survival effect of Hy+ISDN was predominantly attributable to higher mortality (in particular, a higher proportion of sudden cardiac death) in the subgroup of patients with mild heart failure. It is reasonable to assume that the arrhythmogenic side effects of the Hy+ISDN combination were primarily a consequence of the reflex increase in sympathetic activity due to the effect of arterial vasodilator hydralazine, an effect which has been well documented in patients with mild heart failure. An important subgroup observation of the V-HeFT I study is consistent with the above statement – that the use of the Hy+ISDN combination in patients with mild heart failure and left ventricular ejection fraction of over 35% does not improve survival (Carson et al. 1996).

3.3 A-HeFT (African American Heart Failure Trial) (Taylor et al. 2004)

After the V-HeFT I trial evaluating the effect of Hy+ISDN compared to placebo, and the V-HeFT II study assessing the effect of the direct vasodilator combination compared to ACEi enalapril, a

further trial was organised to evaluate the effect of Hy+ISDN treatment in addition to optimal drug therapy in HFrEF. The A-HeFT study, published in 2004, compared the effect of a fixed-dose Hy+ISDN combination (37.5 mg Hy + 20 mg ISDN per tablet) with placebo in 1050 self-identified African American patients in NYHA functional class III and IV despite optimal background heart failure therapy. The starting dose of Hy+ISDN was one tablet three times daily, and the target dose was two tablets three times daily. A further inclusion criterion was the evidence of left ventricular dysfunction: The left ventricular ejection fraction was required to be $\leq$35%, or left ventricular ejection fraction of <45% combined with dilated left ventricle (left ventricular end-diastolic diameter > 6.5 cm, or left ventricular end-diastolic diameter index >2.9 cm/m^2 on the basis of echocardiography). Patients were treated with ACEi (69.5%) or ARB (16.9%), BB (73.8%), digoxin (59.6%), spironolactone (38.9%), and diuretics (89.8%). Seventeen percent had an implantable cardioverter defibrillator, and 2% had received cardiac resynchronization therapy.

The A-HeFT study was terminated prematurely. The mean duration of follow-up was 10 months. Termination was due to the extremely high decrease (43%) in the relative risk of death in the Hy+ISDN group ($p = 0.01$). The Hy+ISDN combination reduced mortality due to heart failure at the highest rate (75%); however, the decrease in sudden cardiac death was not significant.

A further significant positive effect was observed in the Hy+ISDN group according to the composite endpoint defined as the primary endpoint of the study (death from any cause, first hospitalization for heart failure during the 18 months of the study, and change in the quality of life at 6 months) ($p = 0.01$). The risk of first hospitalization for heart failure decreased by 33% ($p = 0.001$), quality of life score improved significantly ($p = 0.02$), and, according to later analysis, left ventricular ejection fraction increased and left ventricular end-diastolic dimension decreased significantly (Cohn et al. 2007).

Compared to placebo, Hy+ISDN decreased blood pressure slightly but significantly. Systolic blood pressure decreased by 1.9 Hgmm in the Hy+ISDN group and 1.2 Hgmm in the placebo group, while diastolic blood pressure decreased by 2.4 Hgmm in Hy+ISDN but increased 0.8 Hgmm in the placebo group ($p < 0.001$). There was no significant difference in heart rate between the two groups.

As far as side effects are concerned, headaches and dizziness were more frequently experienced in the Hy+ISDN arm, while heart failure progressed in significantly more cases in the placebo arm.

In summary, the A-HeFT study demonstrated that the fixed-dose combination of Hy+ISDN on top of standard therapy for HFrEF, including neurohumoral antagonists, can increase survival among African American patients with advanced heart failure.

The extension of the A-HeFT trial (X-A-HeFT) (Yancy et al. 2007), designed for ethical reasons to make the Hy+ISDN fixed-dose combination available from the time of A-HeFT study termination until FDA approval, further confirmed the beneficial effects of Hy+ISDN in this patient population. The study demonstrated low mortality and morbidity, symptomatic improvement, good compliance, and safety and tolerability of Hy+ISDN in the former 198 A-HeFT patients for about 7 months.

3.4 Summary of the Evidence

These three placebo-controlled, randomised mortality trials and their retrospective analyses proved that the Hy+ISDN combination improves the left ventricular ejection fraction significantly compared to both placebo (Cohn et al. 1986) and enalapril (Cohn et al. 1991). Beyond improving left ventricular ejection fraction, the vasodilator combination also decreases left ventricular end diastolic dimension (that is, it causes left

ventricular reverse remodelling) (Cohn et al. 2007), which is currently regarded as one of the strongest predictors of survival in HFrEF. Furthermore, Hy+ISDN treatment increases peak VO2 and exercise tolerance significantly (Ziesche et al. 1993), which is also considered to be a very important prognostic parameter. The Hy+ISDN combination significantly reduces heart muscle mass compared to placebo, where the opposite tendency is observed (Cohn et al. 2007). The vasodilator combination affects left ventricular sphericity index beneficially (Cohn et al. 2007) and decreases the level of plasma natriuretic peptides significantly (Cohn et al. 2007). In addition, Hy+ISDN decreases symptoms and improves quality of life.

In addition to these effects on surrogate endpoints the direct vasodilator combination can decrease the morbidity and mortality of HFrEF patients.

3.5 Systematic Reviews, Meta-Analyses, Registry Data

Since the publication of the three large, randomized, placebo-controlled mortality studies, several reviews and meta-analyses have evaluated the efficacy of the Hy+ISDN combination. A systematic review and meta-analysis that evaluated the data from seven randomized trials and 2626 patients published by Farag et al. (2015) confirmed that the Hy+ISDN combination significantly reduced total mortality and cardiovascular mortality in HFrEF compared to placebo. However, according to this review the evidence is not sufficient to support the sole use of either drug in HFrEF.

Using data from the American Heart Association's *Get With The Guidelines – Heart Failure* (GWTG-HF) registry, linked to Medicare claims, Khazanie et al. (2016) assessed the use and outcomes of Hy+ISDN among African American patients and patients of other races not on ACEi or ARB due to contraindications or intolerance during hospitalization for heart failure. The use of the combination of Hy+ISDN at discharge was low among both African American patients (22.7%) and patients of other races (18.2%). However, the cumulative incidence rates of mortality, all-cause readmission, and cardiovascular readmission at 3 years were similar between treated and untreated African American and non-African American patients, meaning that – taking into account the remarkable differences in baseline treatment and significant potential for selection bias – interpretation of the results of this study is challenging (Taylor 2016). Moreover, the findings of this observational study do not in any way reduce the value of the results of earlier randomized, controlled survival trials.

3.6 Ongoing Clinical Trials

There is currently no ongoing clinical trial in chronic heart failure that is using the Hy+ISDN combination, either in HFrEF or in HFpEF.

The GALACTIC trial (NCT00512759) is currently ongoing in acute heart failure assessing whether it is safe, effective and cost-effective to reduce preload and afterload by the combination of hydralazine and nitrate and additional vasodilators early in the non-ICU setting, targeting a systolic blood pressure of 90–110 mmHg.

4 Guideline Recommendations

The current guidelines for the management of heart failure published by the European Society of Cardiology (ESC) in 2016 (Ponikowski et al. 2016) and the American College of Cardiology and American Heart Association (ACCF/AHA) in 2013 (Yancy et al. 2013) recommend the use

of the direct vasodilator combination in two clinical situations:

1. *In case of ACEi and ARB intolerance or contraindication.*
   (a) ESC guideline: "Hydralazine and isosorbide dinitrate may be considered in symptomatic patients with HFrEF who can tolerate neither an ACE-I nor an ARB (or they are contra-indicated) to reduce the risk of death." This is a Class IIb recommendation with a "B" level of evidence.
   (b) ACCF/AHA guideline: "A combination of hydralazine and isosorbide dinitrate can be useful to reduce morbidity or mortality in patients with current or prior symptomatic HFrEF who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated." This is a Class IIa recommendation with a "B" level of evidence.
2. *In self-identified African-American HFrEF patients with NYHA Class III-IV despite optimal treatment.*
   (a) ESC guideline: "Hydralazine and isosorbide dinitrate should be considered in self-identified black patients with LVEF <35% or with an LVEF <45% combined with a dilated LV in NYHA Class III–IV despite treatment with an ACE-I, a beta-blocker and an MRA to reduce the risk of HF hospitalization and death." This is a Class IIa recommendation with a "B" level of evidence.
   (b) ACCF/AHA guideline: "The combination of hydralazine and isosorbide dinitrate is recommended to reduce morbidity and mortality for patients self-described as African Americans with NYHA class III–IV HFrEF receiving optimal therapy with ACE inhibitors and beta blockers, unless contraindicated." This is a Class I recommendation with an "A" level of evidence.

Although the 2013 ACCF/AHA guidelines were updated in 2016 (Yancy et al. 2016) and 2017 (Yancy et al. 2017), they were not modified concerning the use of the Hy+ISDN combination.

4.1 The Use of Hy+ISDN Combination in Case of ACEi and ARB Intolerance or Contraindication

When a patient cannot receive either an ACEi or an ARB because of intolerance or contraindication, use of the Hy+ISDN combination is supported by the results of the V-HeFT I study (Cohn et al. 1986), which clearly demonstrated that the survival of patients receiving digitalis and diuretic therapy without an RAAS antagonist was significantly improved by the use of the direct vasodilator combination.

However, patients who presently cannot tolerate either an ACEi or an ARB can be treated with survival-enhancing treatment strategies (BB, and MRA) in addition to diuretics and/or digitalis, and it has not been demonstrated that direct vasodilators maintain their favourable mortality-reducing effects when BB and MRA are in use. However, considering the cases of ACEi and ARB intolerance, the beneficial effect of direct vasodilator treatment in these clinical situations seems to be at least likely.

Combined ACEi and ARB intolerance are most common in patients with significant hypotension and renal function impairment. The cough caused by ACEi as a result of bradykinin accumulation usually disappears with the use of ARB. However, hypotension, renal function impairment and hyperkalaemia, which is related to angiotensin suppression, are common side effects of ACEi and ARB.

Patients who are intolerant to ACEi and ARB due to significant hypotension or renal function impairment are generally hemodynamically unstable with advanced heart failure. If these patients are treated with only digitalis and diuretics, the introduction of BB is usually unsuccessful due to haemodynamic instability. Moreover, patients who cannot tolerate an ACEi because of impaired renal function cannot receive MRA either. Thus, ACEi and ARB intolerant patients, despite the fact that they should receive BB and MRA in accordance with the guidelines, still receive only digitalis and diuretics in the majority of cases. In this situation, the findings of the V-HeFT I study most probably hold true.

It is also important to note that if these ACEi-, ARB-, BB-, and MRA-intolerant severe heart failure patients receive direct vasodilator combinations in addition to diuretics and/or digitalis, they usually achieve hemodynamic stability, their blood pressure increases, and renal function improves. In this stable hemodynamic situation an attempt can be made to reintroduce ACEi, and then BB and MRA. Thus, instead of treating patients solely with diuretics and/or digitalis, which usually leads to a rapid progression of disease or even death, a much more advantageous optimal treatment strategy may be created for patients. Based on these considerations, the Hy+ISDN combination may currently be considered the most effective tool for breaking through ACEi and ARB intolerance.

However, it should be emphasized that all ACEi- and ARB-intolerant patients who can tolerate BB and MRA therapy should receive them, in addition to direct vasodilators. The Hy+ISDN combination should not be used to treat patients who have not previously showed intolerance or contraindication to ACEi and ARB.

The introduction of ARNI in HFrEF therapy does not affect this indication as patients who cannot receive either an ACEI or an ARB due to intolerance or contraindication should not receive an ARNI either.

4.2 The Use of the Hy+ISDN Combination in Self-Identified African-American HFrEF Patients with NYHA Class III-IV Despite Optimal Treatment

This indication is supported by the results of the A-HeFT study (Taylor et al. 2004) performed in an African-American patient population. According to the indication, in all self-identified African-American HFrEF patients who remain symptomatic despite optimal treatment with ACEi or ARB, BB and MRA, treatment should be supplemented with the combination of Hy+ISDN according to the ACCF/AHA guideline (Yancy et al. 2013), or at least the use of Hy+ISDN should be considered in accordance with the ESC guideline (Ponikowski et al. 2016).

The introduction of ARNI in the treatment of HFrEF may slightly modify the use of the Hy+ISDN combination in this patient population. The appropriate therapeutic strategy seems to be the following: As first step, replacement of ACEi or ARB with ARNI therapy is recommended in all patients who remain symptomatic despite optimal treatment with ACEi or ARB, BB and MRA. If still symptomatic, the addition of Hy+ISDN therapy should be considered in self-identified African-American HFrEF patients as second step. However, the combination of Hy+ISDN and ARNI has not yet been investigated, therefore caution is advised, especially as regards careful blood pressure monitoring.

As well-known that African-Americans respond to ACEi and some BB treatment less favourably; however, they respond to the Hy+ISDN combination better than Caucasian patients (Exner et al. 2001; Carson et al. 1999). In the background of these observations there are partly genetic differences. The DNA sub-study of the A-HeFT trial proved that NO synthase and aldosterone synthase polymorphism is associated with an enhanced Hy+ISDN effect (McNamara et al. 2006, 2009). McNamara et al. (2014) found that GNB3 825 T homozygotes respond in an outstandingly favourable way to Hy+ISDN

therapy. Moreover, all three polymorphisms are much more common in African-Americans than in other populations (McNamara et al. 2006, 2009, 2014; Rosskopf et al. 2002; Marroni et al. 2005; Barbato et al. 2004).

Confirmation of the results of the A-HeFT study in other racial groups was obtained from a small study (Mullens et al. 2009) in which the proportion of Caucasian patients was 80%. This study demonstrated the beneficial hemodynamic, mortality, and morbidity effects of Hy+ISDN in combination with optimal neurohumoral therapy in mostly Caucasian patients. Many experts consider the use of direct vasodilators in other racial patient populations with advanced heart failure despite optimal heart failure therapy as a beneficial treatment option. It is important to note, that the previous ESC guideline for the diagnosis and treatment of acute and chronic heart failure (published in 2012) (McMurray et al. 2012) recommended the use of the Hy+ISDN combination regardless of race: "Hy+ISDN may be considered to reduce the risk of HF hospitalization and risk of premature death in patients with an EF $\leq$45% and dilated LV (or EF $\leq$35%) and persisting symptoms (NYHA class II–IV) despite treatment with a BB, ACE inhibitor (or ARB), and an MRA (or ARB)." This recommendation was Class II/b with a "B" level of evidence.

According to the available data, the direct vasodilator combination may have a more favourable effect in African-Americans, but its beneficial hemodynamic and mortality effect (similar to that of ACEi enalapril in advanced heart failure -NYHA III-IV-) was demonstrated in the V-HeFT II study with predominantly Caucasian patients. It is important to note that direct vasodilators do not cause neurohumoral activation in cases of severe heart failure compared to mild heart failure, and therefore have no or less arrhythmogenic effects, and presumably do not increase the risk of sudden death, or increase it minimally. The beneficial effect of the vasodilator combination may increase independently of race when it is administered with neurohumoral antagonists, particularly with such BB that have been proven to be effective at treating heart failure and reducing sudden cardiac death.

A large, randomized, controlled, multicentre trial which assesses the effect of Hy+ISDN in non-African-American patients who remain symptomatic despite optimal neurohumoral antagonist therapy is warranted.

5 Practical Guidance (Following the Structure of the Web Addenda of 2016 ESC Guidelines for the Diagnosis and Treatment of Acute and Chronic Heart Failure) (Ponikowski et al. 2016)

It is very important that the recommendations of the guidelines are closely followed in daily clinical practice. The Web Addenda of 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure (Ponikowski et al. 2016) provide excellent practical guidance about the use of ACEi, ARB, BB, MRA, diuretics and ivabradine. Based on this practical guidance, we now review the optimal use of Hy+ISDN.

Why?

– Because HY+ISDN therapy improves symptoms, quality of life, and exercise capacity, as well as reduces hospitalization and mortality.

To whom?

– *Indications:*
  - In patients with HFrEF who cannot receive either an ACEi or an ARB due to intolerance or contraindication
  - In self-identified African-American patients with LVEF $\leq$35% or with an LVEF <45% combined with a dilated left ventricle in NYHA class III-IV despite optimal treatment with ACEi or ARB, BB and MRA
– *Contraindications:*
  - Known allergic reaction to either hydralazine or isosorbide dinitrate

  - Isosorbide dinitrate should not be given with avanafil, riociguat, sildenafil, tadalafil, or vardenafil
- *Cautions:*
  - Symptomatic or severe asymptomatic hypotension (systolic blood pressure < 90 mmHg).
  - Hydralazine is metabolised in the liver and its inactive degradation products are excreted in the urine. However, the effects of renal or hepatic failure on the pharmacokinetics of hydralazine are still not exactly known. Caution is needed in cases of renal and hepatic failure.
  - Hydralazine can increase the bioavailability of drugs that undergo significant first-pass metabolism (e.g. lidocaine, morphine, propranolol).

What dose?

- Hydralazine: starting dose 37.5 mg three-four times daily, target dose: 75 mg three-four times daily (in case of low blood pressure the starting dose may be lower, as low as 12.5 mg three times daily)
- Isosorbide dinitrate: starting dose 20 mg three-four times daily, target dose: 40 mg three-four times daily (in case of low blood pressure the starting dose may be lower, as low as 20 mg o.d. or b.i.d.)

Where and when?

- In the community in stable patients
- In hospital in patients hospitalized with worsening heart failure
  - after relieving fluid retention
  - the Hy+ISDN combination may be initiated with caution before achieving euvolaemia in selected patients who are intolerant to ACEi and ARB and who are intolerant to BB due to unstable heart failure.

How to use?

- Start with a low dose
- Dose should be increased at not less than 4 weeks in the community. More rapid dose up-titration may be performed in patients who are in hospital or who are otherwise closely monitored. If a non-fixed-dose combination is used, hydralazine and isosorbide dinitrate can be titrated separately
- Efforts should be made to reach the target dose or, if this fails, to reach the maximum tolerated dose
- Attention should be paid to blood pressure
- Patient education is particularly important in this treatment to increase adherence

Side effects and their frequencies:

- hypotension (symptomatic 5–6%)
- headaches (18–48%)
- dizziness/light-headedness (22–29%)
- fainting (2–3%)
- flushing of the face and neck (8–10%)
- gastrointestinal complaints (10–12%)
- rash (7–9%)
- arthralgia (15–17%)
- drug-induced lupus erythematosus (5%)

Problem solving:

- Asymptomatic hypotension
  - no treatment modification is usually required
- Symptomatic hypotension
  - Before reducing the dose of hydralazine and/or isosorbide dinitrate because of symptomatic hypotension, check whether the patient is taking any other non-disease-modifying blood-pressure-lowering agent (such as calcium-channel blockers) and reduce dose of this drug or stop, if possible
  - If the patient has no signs or symptoms of fluid retention, reduce the dose of diuretic or stop diuretic therapy

- If a patient tolerates ACEi/ARB, BB and MRA, dose-titration of these drugs should be preferred. Do not stop or decrease the dose of neurohumoral antagonists in order to introduce or increase the dose of hydralazine and/or isosorbide dinitrate

– Headache
  - Headaches are common but often improve with time
– Drug-induced lupus erythematosus (a rare side effect of hydralazine therapy which can arise months to years after introduction of the drug).
  - This is a reversible adverse reaction and resolves after discontinuation of treatment with drug

Advice to the patient:

– Explain the beneficial effects of treatment (improvement of symptoms, quality of life and exercise capacity, decrease in morbidity and mortality)
– Encourage patients to report adverse effects (i.e. symptomatic hypotension, dizziness/light-headedness, fainting, flushing of the face and neck, gastrointestinal complaints headache, rash, arthralgia)
– Alcohol and hot weather may increase dizziness/light headedness and fainting. Advise patients to avoid them, if possible.
– To prevent dizziness/light-headedness and fainting, advise patients to sit up or stand up slowly, especially in the morning, and to sit or lie down at the first sign of any of these side effects.

6 Summary

Despite the current lack of use of the Hy+ISDN combination, it can be a very effective element in HFrEF therapy when used in accordance with guidelines. Appropriate use of direct vasodilators can contribute to reducing the symptoms, improving the quality of life, and reducing the morbidity and mortality of self-identified African American patients who receive optimal neurohumoral antagonist therapy. In a well-selected HFrEF population under close control, the direct vasodilator combination may be used in patients of other races who are symptomatic despite optimal pharmacological and device therapy.

The Hy+ISDN combination can also play an important role in treating patients who cannot receive either ACEi or ARB due to intolerance or contraindication. This is partly because it can reproduce the balance vasodilator properties, preload and afterload decreasing effects of ACEi and ARB, despite the lack of a direct effect on the RAAS system. This property is also of relevance in treating patients who, despite ACEi and ARB intolerance, tolerate BB and MRA. Moreover, and perhaps even more importantly, Hy+ISDN can be successfully used to treat patients with advanced heart failure who, besides having ACEi- and ARB-intolerance, do not tolerate either BB or MRA. In this latter case, Hy+ISDN can be used not only as a therapeutic alternative to ACEi or ARB, but can help overcome ACEi- and ARB-intolerance, thereby facilitating the introduction of optimal neurohumoral antagonist therapy (ACEi/ARB/ARNI, BB, MRA) instead of digitalis and diuretic treatment.

Taking these factors into consideration, it is clear that the direct vasodilator combination Hy+ISDN is in many cases indispensable, and plays an important role in the treatment of HFrEF.

The Art and Science of Using Diuretics in the Treatment of Heart Failure in Diverse Clinical Settings

Md. Shahidul Islam

Abstract

It is important to understand the rationale for appropriate use of different diuretics, alone or in combination, in different heart failure patients, under diverse clinical settings. Clinicians and nurses engaged in heart failure care, must be familiar with different diuretics, their appropriate doses, methods of administration, monitoring of the responses, and the side-effects. Inappropriate use of diuretics, both under-treatment and overtreatment, and poor follow-up can lead to failures, and adverse outcomes. Adequate treatment of congestion, with rather aggressive use of diuretics, is necessary, even if that may worsen renal function temporarily in some patients. Diuretic treatment should later be titrated down, by early recognition of the euvolemic sate, which can be assessed by clinical examination, measurement of the natriuretic peptides, and when possible, echocardiographic estimation of the left ventricular filling pressure. You need to treat patients, who are truly resistant to the loop diuretics, by administering the diuretics as intravenous bolus injection followed by continuous infusion, and/or by sequential nephron blockade by adding the thiazide diuretics. You need to use the diuretics based on a sound understanding of the pathophysiology of the disease process, the pharmacokinetics and pharmacodynamics of the diuretics, even when strong evidences for your choices might be lacking. Some patients may benefit from injection of loop diuretics together with hypertonic saline, and others from injection of loop diuretics with albumin. Patient education, and regular follow up of the treatment of heart failure patients, in out-patient settings are important for reducing the rates of complications, and for reducing the needs for urgent hospitalizations.

1 Introduction

Diuretics are used in the treatment of heart failure to reduce volume overload, the symptoms of congestion, and death from acute decompensation of heart failure. It is important to use diuretics appropriately and adequately: inadequate use of diuretics in acute decompensation of heart failure (ADHF) may lead to death, or will increase the risk for re-admission to the hospital, whereas overtreatment with diuretics will reduce tissue perfusion and impaired renal function. Treatment of chronic heart failure patients by loop diuretics reduces mortality, acute deterioration of heart failure, hospitalization, and improves symptoms and exercise capacity (Faris et al. 2012; Ponikowski et al. 2016).

It is important to assess the volume status of heart failure patients carefully to decide whether diuretic treatment is necessary, and once started, treatment with diuretics must be followed up regularly. Clinicians assess the right heart filling pressure, and the left heart filling pressure by integrating the following findings from the physical examination: increased jugular venous pressure, hepatojugular reflux, dependent edema, ascites, gallop heart sounds, and pulmonary rales. Accurate clinical assessment of right heart filling pressure and left heart filling pressure by physical examination is, however, difficult. In one study, trainee doctors in cardiovascular medicine accurately assessed, by physical examination, the right heart pressure in 67% of the cases, and the left heart pressure in 55% of the cases. The accuracy was higher for the experienced cardiologists (82% and 71% for the right heart pressure, and left heart pressure respectively) (From et al. 2011). The accuracy of assessment of the right heart pressure and the left heart pressure was not increased by including echocardiographic data or by knowing plasma natriuretic peptide level. It is, therefore, essential that doctors are taught and trained in physical examination skills during bedside teaching. The accuracy of the clinical assessment of the right and left heart filling pressures is better when the physicians are more experienced.

Heart failure patients with congestion must be treated by loop diuretics, given orally or through intravenous routes. Some heart failure patients will need infusion of loop diuretics, others may need loop diuretics in combination with other types of diuretics. It is necessary to be familiar with the basic pharmacokinetics and the pharmacodynamics of the commonly used diuretics, their dosage, and the rationale for combining different diuretics, when that is needed. In this review, I shall discuss the use of different diuretics for the treatment of chronic heart failure, and ADHF in different clinical settings, mainly from the perspective of a practicing clinician. For a better understanding of the issues involved, it is desirable that the readers read the whole review rather than only a few selected sections. In your day do day practice, you may also need to take into consideration the local traditions, and guidelines used in your hospital, and the updated guidelines from major societies.

2 The Parenteral Loop Diuretics

The most widely used intravenous loop diuretic is furosemide. When administered intravenously, the efficacy of the three loop diuretics furosemide, torsemide, and bumetanide, is the same, only the potency, and the duration of action are different. This means that you need to inject less mg of a diuretic that is more potent. Torsemide is more potent than furosemide, and bumetanide is more potent than torsemide. When given intravenously, 40 mg of furosemide is roughly equivalent to 10 mg of torsemide and 1 mg of bumetanide. When maximally effective, these loop diuretics cause excretion of 20% of the filtered sodium, which means that about 200–250 mmol of sodium is excreted in 3–4 l of urine in 3–4 h (Brater 2011).

Clinically, the natriuretic efficacy of a loop diuretic is more relevant than its potency. As alluded to earlier, the natriuretic efficacy, or the maximal natriuresis, as estimated from the upper plateau (the "ceiling") of the sigmoid-shaped

dose-response curve, is the same for the three loop diuretics. Once the ceiling of a single intravenous dose of a loop diuretic is reached, increasing the dose further, will cause more natriuresis, merely by prolonging the time during which the concentration of the diuretic in the plasma remains above the natriuretic threshold. High doses, above the nominal "ceiling" will increase the risk of the dose-related side effects of the diuretic. To induce further diuresis, it is preferable to inject the diuretic more frequently, (depending on the half-life, and duration of action of the diuretics), or give it as a continuous intravenous infusion after a bolus injection. In congestive heart failure, the elimination half-life of furosemide is 2.7 h, that of torsemide is 6 h, while that of bumetanide is only 1.3 h (Brater 1998).

The loop diuretics inhibit the Na^+-K^+-$2Cl^-$ cotransporter type 2 (NKCC2, product of the gene *SLC12A1*), which is located on the apical plasma membrane of the cells in the thick ascending limb of the loop of Henle. They also inhibit the Na^+-K^+-$2Cl^-$ cotransporter type 1 (NKCC1, product of the gene *SLC12A2*) expressed in many tissues. The NKCC1 of the inner ear may mediate the ototoxicity, and that of the vascular smooth muscle cells may mediate the direct vasodilation caused by intravenous injection of the loop diuretics.

Subcutaneous Administration of Furosemide: Furosemide has a pH of about 8.5–9, and for this reason it can cause skin reactions and discomfort when administered subcutaneously. More recently, a buffered furosemide preparation with pH 7.4 has been developed. Subcutaneous administration of this pH-neutral furosemide was as effective as intravenous furosemide in inducing natriuresis, urine-output, and weight loss in patients with ADHF (Gilotra et al. 2018). If larger studies confirm these findings, then subcutaneous furosemide can provide a new method of treating a selected group of heart failure patients at home. This may facilitate palliative treatment of heart failure.

3 Choice of the Oral Loop Diuretics

Most heart failure patients with symptoms and signs of congestion are treated by one of the three oral loop diuretics. The newer loop diuretics, torsemide and bumetanide have several theoretical and pharmacokinetic advantages over the commonly used furosemide. Oral absorption of furosemide is on the average ~ 50%. In contrast, the oral absorption of torsemide and bumetanide is about 80–100%, and the absorption is less variable compared to that of furosemide. In fact, oral absorption of furosemide is highly variable (from 10% to 100%) both from patient to patient, as well as in the same patient (Brater 2011; Murray et al. 1997). Absorption of the retard preparation of furosemide is even more variable, and it should not be used in the treatment of heart failure with congestion. In heart failure with congestion, the absorption of orally administered furosemide can be much slower because of the congestion of the intestinal walls, making it difficult for the plasma concentration of the drug to rise to the threshold for the induction of diuresis. In heart failure of NYHA class II or III the diuretic response to the loop diuretics is reduced by 1/3rd to 1/4th of the maximally effective dose (Brater 1998).

Note that in heart failure, absorption of the total amount of the orally ingested loop diuretics is not reduced (i.e. there is no malabsorption), but the absorption is delayed, especially during ADHF. After oral ingestion of a loop diuretic, it may take about 4 h (instead of normal about 1 h) for the concentration of the diuretic to reach the effective concentration at the luminal side of the nephron. For rapid action, as in the case of treatment of ADHF, inject the loop diuretic intravenously.

Another advantage of torsemide over furosemide, and bumetanide is its longer average duration of effect, which means that it may be enough to give it once per day. Because of the short half-life, furosemide, and bumetanide, when given once per day, or less frequently, can cause "post diuretic sodium retention", especially when

dietary salt intake is high. Such "rebound" reabsorption of sodium is less likely with torsemide, which is present in the tubular lumen for a longer period because of its longer half-life. Furosemide is mainly eliminated by the kidney, whereas torsamide and bumetanide are metabolized by the liver. In renal failure furosemide, but not torsamide or bumetanide can accumulate.

There is no good prospective randomized clinical trial that has studied the effects of torsemide as compared to furosemide. One study demonstrated that torsemide was better (compared to furosemide) in reducing the risk of readmission for heart failure (Murray et al. 2001). Another observational study found lower one-year mortality among patients treated with torsemide compared to those treated with furosemide (Cosin et al. 2002). However, torsemide (and bumetanide) are not available in many countries, and these drugs are more expensive. If the availability and the costs are not important considerations, some physicians would prefer to use torsemide instead of furosemide, for many heart failure patients. Most physicians, however, start with furosemide and switch to torsemide only when the effect of furosemide appears less satisfactory. An obvious alternative, in the latter situation, however, is just to increase the dose of furosemide, instead of switching to torsemide (or bumetadine).

4 Clinical Use of the Loop Diuretics

Understanding the mechanisms of actions of the loop diuretics is essential for their rational use in different clinical settings. As mentioned before, the loop diuretics block the NKCC2 located on the *luminal* surface of the cells of the thick ascending loop of Henle. The diuretics must reach the ultrafiltrate in the lumen of the nephron to exert their action. The concentration of the loop diuretics in the ultrafiltrate in the lumen of the nephron must reach a threshold level for blocking the NKCC2 for inducing diuresis. The loop diuretics are essentially *not* filtered through the glomerular membrane because they are >95% protein bound; instead they are actively secreted into the lumen of the proximal tubule through the organic anion transport 1 (OAT1, product of *SLC22A6* gene), organic anion transport 2 (OAT2, product of product of *SLC22A6* gene), and the multidrug-resistance associated protein 4 (product of the gene *ABCC4*). Nonsteroidal anti-inflammatory drugs, uric acid, and some uremic toxins can compete with the loop diuretics for transport through these transporters leading to resistance to the loop diuretics.

You need to identify the "threshold" dose of the loop diuretic that induces diuresis, when given as a single dose. The effect of a given dose of furosemide can be assessed clinically from the diuretic response, change in the bodyweight, and measurement of urine volume. Normal people are very sensitive to furosemide, but heart failure patients with congestions, and especially those with impaired renal function have higher thresholds.

Start furosemide at a dose of 20–40 mg orally once per day, and if necessary, titrate the dose up, based on the response. Maximal single oral dose of furosemide in patients with normal kidney function is usually 80 mg. In patients with impaired kidney function, the maximal single dose of furosemide can be as high as 240. (There are also 1 g tablets of furosemide). For people who need high dose, you can use 500 mg tablets. The maximal daily dose of furosemide in patients with impaired renal function is 600 mg, but some may need much higher dose, sometimes as high as 2000 mg, given in 4–6 divided doses per day.

If furosemide is not so effective, you can choose to increase the dose of furosemide or to change it to a more potent and better absorbed loop diuretic like torasemide. Start torasemide at a dose of 5–10 mg once in the morning. You can increase the dose up to 200 mg per day, based on the response. Maximal single dose of torsemide is 100 mg. Alternatively, you can use another more potent and well-absorbed loop diuretic bumetanide at a starting dose of 0.5–1 mg, and increase the dose, if necessary, up to 5 mg per day. Maximal daily dose of bumetanide is 10 mg. Because of its short duration of action, bumetanide should be given more frequently to avoid "post-diuretic sodium retention".

If you give short-acting loop diuretics like furosemide or bumetanide, once every other day, or even once per day, and if the patient's dietary salt intake remains high, then it is less likely to achieve negative sodium balance because of "post diuretic sodium retention".

5 Intermittent Injections Versus Continuous Intravenous Infusion of Loop Diuretics

It is common to give loop diuretics as intermittent intravenous injections, which result in variable concentrations of the diuretic in the lumen of the nephron. This approach works in the vast majority of the heart failure patients, but does not induce sufficient diuresis in some patients, especially in those with renal failure. If you first give a loop diuretic first as a bolus injection, followed by as a continuous intravenous infusion, that will maintain the concentration of the diuretics in the lumen of the nephron at an effective level during the infusion (Brater 2011). It is important that a loading dose of the loop diuretic is injected first before starting the continuous infusion. These patients must be treated in the hospital often in the intensive care unit. Continuous infusion is better than bolus injections in inducing diuresis and reducing the concentrations of the brain natriuretic peptides in the plasma (Ng and Yap 2018).

The intravenous loading doses of furosemide, bumetanide, and torsemide are 40 mg, 1 mg, and 20 mg respectively.

If creatinine clearance is >75 mL/min, then infuse furosemide, bumetanide, or torsemide at a rate of 10 mg, 0.5 mg, or 5 mg/h respectively.

If creatinine clearance is <25 mL/min, infuse furosemide first at a rate of 20 mg/h. Then, if necessary, give a second bolus dose of furosemide, and increase the infusion rate to 40 mg/h. For bumetanide the initial rate of infusion is 1 mg/h, which can be increased to 2 mg/h. For torsemide the initial rate of infusion is 10 mg/h, which can be increased to 20 mg/h.

If the creatinine clearance is 25–75 mL/min, infuse furosemide at a rate of 10 mg/h, and later on, if necessary, increase to 20 mg/h. For bumetanide, the initial rate is 0.5 mg/h, which can be increased later to 1 mg/h. Torsemide infusion can be started at a rate of 5 mg/h, and can later be increased to 10 mg/h.

Note that, in all cases, before changing to a higher infusion rate, you will need to inject a second loading dose of the respective diuretic.

6 Use of Diuretics in the Treatment of Acute Decompensated Heart Failure (ADHF)

It is essential to understand the limitations of diuretic treatment in ADHF; overreliance on the diuretic treatment alone may lead to fatal outcome. Rapid clinical assessment by an experienced physician is essential for the diagnosis of the cause of acute dyspnea, and for choosing the most appropriate treatment for an individual patient with ADHF. When available, point of care ultrasonography performed by an experienced person can give additional useful information than can be obtained by clinical examination alone (e.g. lung ultrasound can identify whether the patient has pulmonary edema, and ultrasound examination of the inferior vena cava can identify intravascular volume overload).

When patients present with acute pulmonary edema, hypoxemia, and particularly with hypercapnia, they will need rapid treatment by noninvasive ventilation (NIV), if treatment by supplemental oxygen does not relieve dyspnea, and does not correct hypoxia/hypercapnia. If they have contraindications to NIV, if they do not tolerate NIV, or do not improve with NIV (in about 30–120 min), then they should be intubated, and mechanically ventilated.

Patients who have flush pulmonary edema due to severe hypertension or renal artery stenosis, acute mitral- or aortic-regurgitation, will require afterload reduction by vasodilator therapy, for instance, by intravenous nitroglycerine. Patients with normal blood pressure and volume overload are more likely to benefit from intravenous loop diuretic therapy, but in case of poor response to

the diuretic therapy, they may need concomitant vasodilator therapy.

Many patients with ADHF have volume overload, while others have volume redistribution (Fallick et al. 2011). While diuretic therapy is more effective in those patients with volume overload, it can also reduce symptoms and improve oxygenation to some extent, even in those patients with volume redistribution. In most cases, initial therapy of ADHF patients with evidence of volume overload should include intravenous injection of a loop diuretic. It is important to administer intravenous furosemide early since the onset of diuresis may take up to 30 min (peak diuresis at 1–2 h). Some patients, for instance, those with end stage renal failure, or severe hypotension, are less likely to benefit from diuretics alone.

If the patient is not already on any diuretics, and if the kidney function is normal then give 20–40 mg furosemide intravenously as bolus. If there is no response inject double the dose i.e. 40–80 mg furosemide after 2 h. Two or more bolus injections per day of furosemide may be necessary. Usually 40–80 mg bolus injection of furosemide will be sufficient to induce adequate diuresis in patients who have nearly normal kidney function. Those patients, who have renal insufficiency or severe ADHF, will need higher bolus injections e.g. 160–200 mg of furosemide. When high doses of loop diuretics are necessary, it is better to give the diuretics as infusions (see below). This reduces risk of toxicity and ensures uniform concentration of the diuretics.

Initial doses of the loop diuretics for treating ADHF are often empirical, but it is useful to follow some method for the determination of the initial doses of the intravenous loop diuretics. For treating patients with ADHF, who are on chronic treatment with oral loop diuretics, the initial dose of the i.v. furosemide should be 2.5 times the patient's usual total daily oral maintenance dose, and this dose should be divided into two injections daily, as intravenous bolus injections. For instance, a patient is chronically on 40 mg oral furosemide daily, which is equivalent to 20 mg i.v. furosemide daily; give 2.5 times this dose i.e. $20 \times 2.5 = 50$ mg in two divided doses intravenously daily (total dose, in this case, 50 mg intravenous injection of furosemide daily). As mentioned before, if there is no response to the initial dose, then the dose may need to be doubled and repeated at 2 h intervals. In the DOSE (Diuretic Optimization Strategies Evaluation) trial, the patients in the "high dose strategy" group received a median dose of 773 mg furosemide in 3 days (Felker et al. 2011). Loop diuretic therapy using this "high dose strategy", causes significantly greater improvement of dyspnea, and greater fluid and weight loss (Felker et al. 2011). It has been shown that use of aggressive diuretic treatment in the emergency department can enable a faster transition to the oral diuretic therapy (Catlin et al. 2018). However, treatment according to the "high dose strategy" causes "worsening renal function" in significantly larger number of patients, but you should not worry about that since transient worsening of renal function during aggressive decongestion therapy does not alter prognosis negatively (Greene et al. 2013). Oral loop diuretics should be stopped at the time the patient is receiving intravenous loop diuretics, and should be restarted when congestion is sufficiently relieved, according to clinical assessment. Short-term changes in the hemoglobin concentration can be used as a surrogate marker for decongestion (van der Meer et al. 2013). In one study, oral loop diuretics were re-started after about 3 days of aggressive intravenous loop diuretic therapy (Catlin et al. 2018).

In addition to having a method for choosing the initial dose of the intravenous loop diuretic, it is also useful to have a preplanned algorithm for subsequent intravenous diuretic therapy. A convenient algorithm for this, especially in patients with worsening renal function, is to increase the dose of the bolus and the infusion rate of the diuretic, if necessary, in combination with a thiazide diuretic, in a stepwise fashion, guided by the daily urine output (Grodin et al. 2016a). The steps of this algorithm are as follows:

Step 1. Current oral dose of furosemide: ≤ 80 mg/day.
Suggested dose of intravenous furosemide:
Intravenous bolus: 40 mg
Infusion rate: 5 mg/h

Step 2. Current oral dose of furosemide: 81–160 mg/day.
Suggested dose of intravenous furosemide:
Intravenous bolus: 80 mg
Infusion rate: 10 mg/h
Oral dose of thiazide diuretic: Metolazone 5 mg once daily

Step 3. Current oral dose of furosemide: 161–240 mg/day.
Suggested dose of intravenous furosemide:
Intravenous bolus: 80 mg
Infusion rate: 20 mg/h
Oral dose of thiazide diuretic: Metolazone 5 mg twice daily

Step 4. Current oral dose of furosemide: > 240 mg/day.
Intravenous bolus: 80 mg
Infusion rate: 30 mg/h
Oral dose of thiazide diuretic: Metolazone 5 mg twice daily

Choose one of the four steps mentioned above based on the urine output assessed at the start, after 24 h, 48 h, 72 h, and 96 h as listed below:

At the start:
If the urine output is >5 L/day: reduce the current dose of diuretic
If the urine output is 3–5 L/day: continue current dose of diuretic
If the urine output is <3 L/day: Choose step 1, 2, 3, or 4 (as mentioned above) depending on the current oral dose of furosemide.
B. At 24 h:
If the urine output is >5 L/day: reduce the current dose of diuretic
If the urine output is 3–5 L/day: continue current dose of diuretic
If the urine output is <3 L/day: Advance to the next step: if you chose step 1 before, advance to step 2, and so on.
C. At 48 h:
If the urine output is >5 L/day: reduce the current dose of diuretic
If the urine output is 3–5 L/day: continue current dose of diuretic
If the urine output is <3 L/day: Advance to the next step: if you chose step 2 before, advance to step 3, and so on.
C. At 48 h:
If the urine output is >5 L/day: reduce the current dose of diuretic
If the urine output is 3–5 L/day: continue current dose of diuretic
If the urine output is <3 L/day: Advance to the next step: if you chose step 2 before, advance to step 3, and so on. If there is persistent volume overload consider adding levosimendan, or nitroglycerine
C. At 72 and 96 h:
If the urine output is >5 L/day: reduce the current dose of diuretic
If the urine output is 3–5 L/day: continue current dose of diuretic
If the urine output is <3 L/day: Advance to the next step: if you chose step 3 before, advance to step 4. If there is persistent volume overload, consider levosimendan or nitroglycerine, left-ventricular assist device, dialysis or ultrafiltration.

It has been reported that treatment of persisting congestion in ADHF by using the algorithm outlined above results in more fluid loss, and weight loss, compared to the standard diuretic therapy, without further impairment of the renal function (Grodin et al. 2016a).

Note that every patient is different. You need to choose the appropriate dose and regime for intravenous diuretic therapy for the individual patient based on different factors some of which are not mentioned above. For instance, you need to be cautious in using intravenous diuretics in patients who have aortic stenosis, and in some patients who have right ventricular dysfunction.

In right ventricular failure with normal afterload (as in acute right ventricular infarction), the preload should not be reduced excessively by excessive use of diuretics. Often right ventricular diastolic filling pressure of 8–12 mm Hg is optimal in right ventricular failure.

Use of Dopamine. Patients with ADHF and renal dysfunction may benefit from treatment with low dose dopamine (2 μg/kg/min) combined with loop diuretics. However, improved clinical outcomes were achieved only in the patients with HFrEF, and not in patients with HFpEF (Wan et al. 2016).

7 Use of Two Different Classes of Diuretics in the Treatment of Heart Failure

Loop Diuretic Plus a Mineralocorticoid Receptor Antagonist (MRA): Many patients with heart failure are already on treatment with a loop diuretic, and an MRA (spironolacton or eplerenone). If not already on an MRA, add a MRA to the treatment of heart failure patients, who qualify for treatment with a MRA, for improving survival (see the section "use of the mineralocorticoid receptor antagonists (MRA) in the treatment of heart failure"). In addition, it may be reasonable to add MRA to the treatment of heart failure patients, who are on loop diuretic, and who have low or low-normal plasma potassium. Combining a loop diuretic, and a MRA may have the effects of "sequential nephron blocking" (see below) since they block sodium reabsorption in two different parts of the nephron. For improving the survival of the eligible patients, spironolacton is used at a low dose (usually 12.5–25 mg/day). If the aim of adding a MRA to the loop diuretic therapy is to increase diuresis or to treat hypokalemia then you need to use spironolactone at a higher dose (up to 100 mg/day). However, high dose spironolactone (100 mg/day) to treat congestion in ADHF, and to overcome diuretic resistance does not improve clinical outcomes (Butler et al. 2017).

Loop Diuretic Plus a Thiazide Diuretic: Treat heart failure patients initially with only a loop diuretic (often in combination with a MRA), and if necessary, increase the dose of the loop diuretic successively to the maximal recommended dose. Over the time, the natriuretic response to a given dose of a loop diuretic gradually decreases. Some people call it the "breaking phenomenon". The mechanism of the "breaking phenomenon" include decrease of extracellular volume, activation of the renin-angiotensin-aldosterone system, as well as functional and structural "nephron remodeling". The advantage of the "breaking phenomenon" is that it provides an adaptive mechanism to protect from volume depletion during long term diuretic therapy. On the other hand the same mechanisms that lead to the "breaking phenomenon" can lead to "diuretic resistance" if the congestion persists.

If the loop diuretic alone fails to achieve decongestion you may need to add a thiazide diuretic on top of the loop diuretic therapy. In this scenario, the loop diuretic will block the reabsorption of sodium chloride in the thick ascending limb of the loop of Henle, and the thiazide diuretic will do the same in the distal segments of the nephron. This approach, which is called "sequential nephron blocking" can induce large diuresis, when resistance to the loop diuretics develops. As alluded to in the previous paragraph, one major mechanism of resistance to the loop diuretic is "nephron remodeling". While the loop diuretics inhibit sodium chloride reabsorption in the loop of Henle, these drugs, indirectly, stimulate sodium chloride reabsorption in the distal nephron. In fact, prolonged use of the loop diuretics leads to the hypertrophy of the distal convoluted tubule, the connecting tubule and the collecting duct. The thiazide diuretics inhibit the Na^+-Cl^- cotransporters (NCC, product of *SLC12A3* gene) located in these sites. Multiple signaling mechanisms, including increased delivery of sodium to the distal nephron, aldosterone, hypokalemia, metabolic alkalosis, circulating proteases filtered into the nephron, increase the activity of the thiazide-sensitive NCC by direct or indirect mechanisms.

Any of the thiazide diuretics can be used for sequential nephron blockade. For the treatment of ADHF patients in the hospital, you can use hydrochlorothiazide at doses of 25–50 mg twice daily, chlortaidone at a dose of 50 mg once daily or metolazon at a dose of 5 mg once (or twice) daily. It probably does not matter which thiazide diuretic you choose. Many use metolazon partly because it has a longer duration of action compared to hydrochlorothiazide. However, metolazone is poorly absorbed, has elimination half-life of 2 days which makes titration of its dose in acute situations difficult (Brater 2011). Metolazone is effective in patients with GFR < 20 ml/min, but this is not a special property of metolazon; other thiazide diuretics can be given in equivalent doses if metolazon is not available. The loop diuretic and the thiazide diuretics can be given at the same time; thiazide diuretics have longer duration of action compared to the loop diuretics. When given together the thiazide diuretics support continued diuresis after the diuresis induced by the shorter acting loop diuretics start to diminish. For outpatient use, the longer acting thiazide diuretics can be given 2–3 times weekly, rather than daily (for example metolazone 2.5 mg or other thiazide diuretic in equivalent doses 2–3 times weekly) (Jentzer et al. 2010).

Some clinicians prefer to combine a thiazide diuretic with a loop diuretic at an earlier stage instead of first trying loop diuretics at a maximal recommended dose. Others prefer not to do so, since combining a thiazide diuretic with a loop diuretic increases the risk of massive diuresis, and hypokalemia. Before starting long term treatment with a loop diuretic plus a thiazide diuretic, make sure that you have a plan for regular follow up to monitor the plasma sodium and potassium concentration.

If hypokalemia develops, it may be necessary to add a potassium-sparing diuretic that act on the distal tubule. The choices in this situation are spironolactone, triamterene, and ameloride. Spironolactone may not be an obvious choice because it is possible that the patient is already on low dose spironolactone (which is not effective in preventing hypokalemia when given in low dose). Moreover, it is difficult to titrate the dose of spironolactone. Tiamterene should not be used because it must be converted to the active drug in the liver. The best choice, in this situation, is ameloride which acts directly and is easy to titrate.

Loop Diuretic Plus Acetazolamide: The most well-known action of acetazolamide is inhibition of carbonic anhydrase, but it also inhibits or downregulates the Cl^-/HCO_3 exchanger plendrin, which is expressed in the distal nephron (Soleimani 2015). Acetazolamide by itself is a weak diuretic, but can cause profound diuresis when combined with a thiazide diuretic, or a loop diuretic. An occasional heart failure patient, who has severe metabolic alkalosis during treatment with a loop diuretic may benefit from addition of acetazolamide (Imiela and Budaj 2017).

8 Thiazide and Thiazide-like Diuretics

Thiazides are weak diuretics and you will not use thiazide diuretics alone for the treatment of vast majority of your heart failure patients. Thiazides and thiazide-like diuretics inhibit the NCC located in the distal convoluted tubules of the kidney. As mentioned before, in selected cases of heart failure patients, usually, those, who do not respond to maximal recommended doses of loop diuretics, you may need to add a thiazide diuretic to the treatment by a loop diuretic (see the section "Loop diuretic plus a thiazide diuretic"). Commonly used thiazide and thiazide-like diuretics are hydrochlorothiazide, bendroflumethiazide, chlorthalidone, metolazone, and indapamide. Equipotent doses of these are hydrochlorothiazide 25 mg, bendroflumethiazide 2.5 mg, chlorthalidone 12.5 mg, metolazone 2.5 mg, and indapamide 2.5 mg.

Usual initial dose of bendroflumethiazide is 2.5 mg and usual daily dose is 2.5–10 mg. Initial dose of hydrochlorothiazide is 25 mg and usual daily dose is 12.5–100 mg. Initial dose of metolazone is 2.5 mg and usual daily dose is 2.5–10 mg. Initial dose of indapamide is 2.5 mg and usual daily dose is 2.5–5 mg (Ponikowski et al. 2016).

The duration of action of bendroflumethiazide and metolazone is 12–24 h (up to 48 h), that of

hydrochlorotiazide is 6–12 h (up to 24 h), that of chlorthalidone is 24–72 h, and that of indapamide is 36 h (Roush et al. 2014). In renal failure, the duration of action of hydrochlorothiazide, bendroflumethiazide, and chlorthalidone can be dramatically prolonged.

9 Monitoring of Kidney Function in Heart Failure Patients During Treatment with Diuretics

It is essential to monitor kidney functions during treatment of heart failure patients with diuretics. For this, it is useful to measure both plasma urea and creatinine since the ratio between the two gives useful information. In SI units the normal range of plasma urea is 2.5–10.7 mmol/L, and that of plasma creatinine is 62–106 μmol/L. A urea: creatinine >100:1 suggests prerenal cause, 40–100:1 suggests normal or postrenal cause, and < 40:1 suggests renal cause. In some laboratories urea is measured as Blood Urea Nitrogen (BUN), which is expressed as mg/dl, and plasma creatinine is also expressed as mg/dl. In this system a BUN:creatinine of > 20:1 suggests prerenal cause, 10–20:1 suggests normal or postrenal cause, and < 10:1 suggests renal cause.

A marked increase of plasma urea with little or minimal increase of plasma creatinine (urea:creatinine > 100:1) during treatment with diuretics, indicates dehydration (during dehydration the passive absorption of urea increases). In such situation you may choose to reduce the dose of the diuretic, if the patient does not have acute pulmonary edema or acute symptoms of congestion. You may consider to reduce the dose of the ACE-I/ARB temporarily during the use of the diuretic, in some patients who have heart failure with preserved left ventricular ejection fraction (HFpEF).

On the other hand, you should continue treatment with the diuretic using the same dose or even a higher dose, if the patient has pulmonary edema or marked symptoms and signs of congestion. This will probably cause further rise of urea and creatinine, but you will need to continue the treatment with the diuretic. In fact, continued treatment with the diuretic under such situations may eventually reduce the plasma creatinine by reducing the central venous pressure, and thereby reducing the renal venous pressure, which when elevated, contributes to the reduction of the GFR.

It is important that you do not stop treatment with the diuretic because of excessive fear of impaired renal function or hypotension, as long as there are signs of volume overload. It has been demonstrated that continued treatment with diuretics, to reduce volume overload, even when the diuretic treatment impairs renal function, reduces mortality (Testani et al. 2010).

10 Follow Up of Heart Failure Patients Treated with Diuretics in Outpatient Units

It is very useful to have an outpatient unit dedicated to the follow up of the heart failure patients. In these units, trained nurses can follow up the patients through telephone contacts, and regular office visits. The nurse titrates the doses of not only the diuretics but also of other heart failure medicines. It is useful for nurses to have clear written instructions specifically designed for the follow up, and the nurses must be able to consult doctors experienced in the treatment of heart failure, whenever needed.

The nurses will give information to the patients about heart failure in general, and about the diuretic treatment in particular. Patients should receive written instructions about the use, monitoring of weight, and the side effects of the treatment by the diuretics. They should receive information about restriction of intake of fluids, and salt, and information about low salt diets. They will limit fluid intake to about 1.5–2 l per day. They should take the diuretics before breakfast or lunch so that the salts consumed during the meals can be excreted. Absorption of loop diuretics is better if taken on an empty stomach. They should not take the diuretics after 16:00 if they want to avoid nocturia. Patients will weigh themselves before breakfast, and dressing, after voiding every morning. They will contact the nurse if they have increased breathlessness,

swelling of the legs, or if the body weight increases more than 1 kg over 3 days. They should contact the nurse if they feel dizziness or lightheadedness, which may indicate excessive use of diuretics. In this regard measurement of blood pressure by the patients at home can be very helpful. They should contact the nurse if they have diarrhea or vomiting that persists for more than 2–3 days.

Start treatment by a loop diuretic, usually furosemide, at a low dose e. g. 20–40 mg once daily. After initiating a diuretic or increasing the dose, follow up the patient after 3 days (it can often be done through telephone contacts). Measure plasma sodium, potassium, creatinine, urea and eGFR prior to the office visits. During the office visit enquire about symptoms, examine for signs of congestions, dehydration, and hypovolemia; measure heart rate, blood pressure and bodyweight. Examine for jugular venous pressure, pulmonary rales, edema of the legs or sacrum. Ascertain the cause of fluid retention (excessive intake of fluid or salt, non-compliance, NSAID, atrial fibrillation, infection). Usually, treatment by a diuretic should reduce body weight at a rate of about 0.5 kg/day. If the rate of weight reduction is satisfactory then maintain the current dose of the diuretic; if the rate of weight reduction by furosemide 40 mg once daily, is less than expected, increase the dose of furosemide to 80 mg once daily. Increase furosemide doses by 40 mg increments. If the patient is on furosemide 80 mg once daily, and the rate of weight reduction is not satisfactory, then increase the dose to 80 mg + 40 mg + 0 mg daily, and later on, if necessary, to 80 mg + 80 mg + 0 mg. If you prefer to use torsemide or bumetanide remember that 40 mg oral furosemide is roughly equivalent to 10 mg torsemide, and 0.5 mg bumetanide. In fact, oral torsemide is preferable to furosemide because of its more reliable, near 100% absorption, and longer duration of action.

The nurse will consult with the heart failure specialist doctor if the patient's symptoms do not improve, if the patient doesn't attain dry weight, and if the patient appears to need higher doses of furosemide. The nurse will not combine a loop diuretic with a thiazide diuretic; this should be done in consultation with the heart failure specialist doctor keeping in mind that these patients will need frequent monitoring of plasma electrolytes.

Some of these patients cannot be treated in the outpatient settings. If the patient's symptoms are not improving despite furosemide in doses more than 80 mg twice daily, if the patient's body weight have increased excessively, if the patient has signs of severe decompensated heart failure, if the patient has edema in the legs reaching above the knees, if the patient's general condition is poor, or if the patient has multiple concurrent illnesses, it may be essential to admit the patient to the hospital. This decision must be based on consultation with the heart failure specialist doctor.

Avoid overtreatment by diuretics. Reduce the dose of the diuretic after the dry weight has been restored, to avoid dehydration and impaired renal function. The goal is to use the lowest possible dose of a diuretic that maintains the dry weight. In many stable chronic heart failure patients, it is possible to down-titrate the diuretics (Martens et al. 2018). Remember that treatment with diuretics must be individualized; in some patients diuretics can be stopped as cardiac function improves, while others will need a maintenance dose of the diuretic to maintain the dry weight. If the patient is on the maintenance dose of a diuretic, then reduce the dose only if there are signs of volume depletion e. g. weight loss more than 1 kg compared to the dry weight, symptomatic postural hypotension, or rise of plasma urea by more than 25%. If you reduce the dose of a diuretic, contact the patient after 48 h to assess the consequences of the dose reduction. Do not reduce the maintenance dose of a diuretic if the patient has signs of congestion like peripheral edema, and elevated jugular venous pressure, even if the patient has hypotension or an increase in the plasma urea. Such patients often need hospitalization and attention by heart failure specialist doctors.

Many problems can arise during the treatment with diuretics, and the problems need to be handled promptly. In case of hypotensive symptoms, you can temporarily withhold 1–3 doses of the diuretic, reduce the dose of the diuretic by one

tablet, and reassess the blood pressure in 3 days. Patients may avoid hypotensive symptoms if they do not change positions abruptly. In patients who have heart failure with reduced ejection fraction (HFrEF), treatment with ACE-I/ARB should be continued during the treatment with diuretics. In some patients who have heart failure with preserved ejection fraction (HFpEF), the treatment with ACE-I/ARB may sometimes be reduced or withhold, temporarily, during the treatment with diuretics.

Hypokalemia can be treated by long acting potassium chloride tablets 750 mg three times daily for 3 days, and perhaps by addition of spironolactone if there are indications to add MRA. Note that spironolactone, used at a low dose, for improving survival in heart failure, does not act as a good potassium sparing agent. It is also not easy to titrate spironolactone for treating hypokalemia. If a potassium-sparing diuretic is desired, and if there is no indication for adding an MRA, then it is better to try amiloride.

Hyponatremia may be treated by reducing the intake of fluid. Do not reduce the dose of the diuretic for treating hyponatremia, if the patient needs diuretic for the treatment of congestion. If the response to the diuretic is inadequate make sure that the patient is not drinking too much fluid, consider increasing the dose of the diuretic, consider giving diuretic in 2–3 divided doses, instruct patients to take the diuretic in empty stomach, and consider changing to torsemide, or bumetanide, which are better absorbed. In case of impaired renal function during treatment by the diuretics, check for signs of dehydration, eliminate the nephrotoxic drugs like NSAID, and perhaps in patients with HFpEF, consider reducing the dose of ACE-I/ARB.

Metabolic alkalosis can often develop in patients treated with diuretics, especially when patients also have hypokalemia. This is due to reduced effective arterial blood volume leading to increased secretion of renin, angiotensin II, and aldosterone. A reduction in the glomerular filtration rate reduces the filtered load of bicarbonate. Angiotensin II increases Na^+-H^+ exchange and increased HCO_3^- absorption in the proximal tubule due to increased H^+ in the lumen. Aldosterone increases H^+ secretion in the distal tubule which generates new HCO_3^-, which is reabsorbed together with Na^+. Moreover, Cl^- depletion causes failure of pendrin a Cl^--HCO_3^- exchanger. Hypokalemia causes metabolic alkalosis also by shifting hydrogen ions from the plasma to the intracellular compartment in exchange for potassium. All these processes aggravate metabolic alkalosis. Metabolic alkalosis is often corrected by administering potassium chloride or potassium sparing diuretics. In rare cases, severe metabolic alkalosis, may need to be treated by acetazolamide given at a dose of 250–500 mg twice daily.

Diuretic treatment must be titrated down once the euvolemic state has been reached. Early recognition of the euvolemic state is necessary for avoiding excessive use of diuretics with risks for worsening of the renal function. Clinical examination alone is often not enough for early identification of the euvolemic state. Serial measurement of the B-type natriuretic peptide (BNP) or N-terminal pro-B-type natriuretic peptide (NT-proBNP) can be helpful for early identification of the euvolemic state. For each patient it is possible to identify a "dry" natriuretic peptide level, which corresponds to clinical stability, and lack of volume overload. The aim of the diuretic treatment should be to reduce the concentration of the natriuretic peptide level to as close as possible to the "dry" level. Combining clinical examination, measurement of the natriuretic peptides, and when possible, Doppler echocardiographic biomarkers of left ventricular filling pressure, can help optimal use of the loop diuretics, and optimization of heart failure care in outpatient settings (Dini et al. 2017).

Treatment by Intravenous Diuretics in the Outpatient Unit: A cost-effective method for treating patients with intravenous diuretic could be to treat the patients, for short period, in the outpatient unit, instead of admitting them to the hospital. This approach is suitable for patients who have modest volume overload. Buckley et al. combined bolus injection of loop diuretics with continuous infusion over 3 h in an outpatient unit

(Buckley et al. 2016). They used a standardized algorithm for choosing the dose of the bolus injection of the diuretic from the patient's home oral diuretic dose. For instance, people who were on 80 mg oral furosemide received 40 mg i.v. furosemide as bolus followed by continuous infusion. Those who were on more than 160 mg oral furosemide received 200 mg. i.v. furosemide as bolus followed by continuous infusion. If this group of patients did not have adequate urine output by 90 min, they received a second bolus injection of 200 mg furosemide followed by infusion. In addition to the i. v. bolus injection of furosemide, all the patients received continuous intravenous infusion of furosemide at a rate of 20 mg/h for 3 h (total 60 mg infused over 3 h). Patients who were on 300 mg oral furosemide received also pretreatment by a thiazide diuretic (metolazone 1.25–10 mg, or hydrochlorothiazide 12.5–50 mg). This treatment resulted in a median urine output pf about 1 l and a median weight loss of 1 kg in 3 h (Buckley et al. 2016).

11 Monitoring of Plasma Sodium and Potassium Concentration in Heart Failure Patients during Treatment with Diuretics

After starting treatment with a loop diuretic, the maximum natriuresis (and diuresis) occurs often with the first dose. Subsequent doses of the diuretics also cause large diuresis if the patient is still in a state of volume overload. Later on, as the volume status improves, the sodium retaining mechanisms are activated, and the effects of the loop diuretic are diminished (this is sometimes called "diuretic breaking").

After starting the treatment with, or after increasing the dose of a loop diuretic, it takes, on the average about 2–3 weeks to reach a steady state, when the intake of sodium and potassium is equal to the excretion of sodium and potassium. Once the steady state is reached, continued treatment with the same dose of the loop diuretic will maintain the weight loss that has been achieved. Thus, plasma potassium and sodium concentrations should be measured frequently during the first 2–3 weeks. After 2–3 weeks, there is no need to measure the plasma sodium and potassium routinely. However, if the dose of the loop diuretic is increased, if a new diuretic is added, or if there is increased volume overload, then you need to check the concentrations of plasma sodium and potassium again.

The kaliuretic effect of the loop diuretic lasts longer than the natriuretic effect. Some patients will need oral potassium tablet supplements during this period. Hypokalemia is less common when only loop diuretic is used, but, it is more common when a thiazide diuretic is combined with a loop diuretic. While loop diuretics induce hypokalemia and hyponatremia usually during the first 2–3 weeks, the thiazide diuretics can induce hyponatremia and hypokalemia at any time, ever after several months or years after starting the therapy (Barber et al. 2015). Thus, if a thiazide diuretic is used, plasma concentration of potassium and sodium should be measured regularly during the treatment by the drug.

Most patients with heart failure are treated with loop diuretics. If the patient is already on a thiazide diuretic (for instance as part of the treatment for hypertension) at the time when you start treatment with a loop diuretic, then it is better to stop the thiazide diuretic. Combine thiazide diuretics with loop diuretics, usually, when the loop diuretics given in maximal recommended doses do not work satisfactorily. As mentioned before, these patients are at high risk for developing hypokalemia, and hyponatremia, at any time after starting the treatment, and they must be followed up by measurement of plasma potassium and sodium frequently.

In heart failure, hypokalemia caused by the loop diuretics and the thiazide diuretics increases overall mortality, cardiovascular deaths, and deaths due to cardiac arrhythmia (Cooper et al. 1999). The risk for hypokalemia is less in patients who receive mineralocorticoid receptor antagonists (MRA), either alone, or in combination with the potassium-losing diuretics. However, these latter group of patients have higher risk of developing hyperkalemia. About 2–5% of patients develop severe hyperkalemia (plasma potassium

concentration > 6 mmol/I) during the treatment with MRAs. For this reason, plasma potassium concentration should be measured 1 week after starting the treatment with the MRA, 1 month later, when the dose of the drug is increased, and when an worsening of the electrolyte status is suspected (for instance, in case of vomiting, diarrhea, worsening heart failure or renal failure). During recent years, the use of MRA in heart failure has increased, and this has led to an increase in the rate of hospital admission due to hyperkalemia, and even deaths from hyperkalemia, in some countries (Juurlink et al. 2004). Heart failure patients who are on MRA must be followed up by frequent monitoring of plasma potassium concentration, but in practice, it turns out that this is often not done (Shah et al. 2005).

If hyperkalemia develops, check if the patient is on NSAID, potassium-containing salt-substitutes, or any herbal preparations, which should be discontinued. Advise the patients to avoid potassium-rich foods. In some cases it will be appropriate to add a loop diuretic that can increase kaliuresis. If the patient has metabolic acidosis, you can give sodium bicarbonate, which will reduce plasma potassium concentration. If the plasma potassium concentration still remains above > 5.5 mmol/l, then you need to reduce the dose of, or discontinue the MRA, and in some cases even ACE-I or ARB, temporarily or permanently.

12 Use of the Mineralocorticoid Receptor Antagonists (MRA) in the Treatment of Heart Failure

In heart failure, the MRAs (spironolactone and eplerenone) are not used primarily as diuretics. The doses of MRAs used in the treatment of heart failure are usually 12.5–50 mg per day. At such low doses MRAs do not have much diuretic action although they reduce potassium excretion to some extent, and thereby reduce the risk of hypokalemia. (For comparison, in the treatment of ascites due to cirrhosis of liver, MRAs are used in doses as high as 200–400 mg per day for inducing diuresis). The pharmacokinetics of spironolactone is complicated because it is converted to many active metabolites. Note also that high dose of spironolactone (e.g. 100 mg/day), which is a diuretic dose, does not improve congestion or symptoms in ADHF (Butler et al. 2017).

MRAs reduce mortality in heart failure partly by reducing the risk of hypokalemia, and consequent cardiac arrhythmias, but mainly by blocking the direct action of aldosterone on the heart. Before starting treatment with MRAs you need to make sure that the patient can be frequently monitored for changes in the plasma potassium and creatinine concentration. Do not start MRAs in patient whose plasma potassium concentration is $\geq$5 mmol/L, and the estimated glomerular filtration rate is $\leq$30 ml/min per 1.73 m^2. The indications for treatment with MRAs in heart failure are based on several randomized clinical trials. Give MRAs to: 1. patients who have symptomatic heart failure and LVEF <35%; 2. to patients after STEMI and with LVEF<40% and symptomatic heart failure or diabetes mellitus. 3. In the treatment of HFpEF the effect of spironolactone is less clear. Post-hoc analysis of the TOPCAT (Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist) study suggests that spironolactone reduces hospitalization and cardiovascular death in HFpEF, but only in "the Americas".

Start treatment with spironolactone 12.5 mg or 25 mg daily, and after 4 weeks double the dose. Endocrine side effects occur in about 10% of patients treated with spironolactone. If endocrine side effects occur then switch to eplerenone starting with 25 mg daily, and then switching after 4 weeks to 50 mg daily. If the eGFR is 30–49 ml/min/1.73 m2 then start spironolactone at a dose of 12.5 mg daily or every other day and double the dose after 4 weeks. If you want to switch to eplerenone because of endocrine side effects, start treating with 25 mg every other day, and then double the dose to 25 mg daily after 4 weeks.

13 Use of the Vasopresin Receptor Antagonists (VRA) in the Treatment of Heart Failure

VRAs increase excretion of electrolyte-free water (aquaresis), and should theoretically be useful in the treatment of hospitalized heart failure patients with congestion, and severe hyponatremia (P-Na <120 mmol/l) despite water restriction. Recent studies, however, have shown that tolvaptan, a VRA, does not induce clinical improvement despite greater weight- and fluid-loss (Felker et al. 2017; Konstam et al. 2017). Unlike MRAs, VRAs do not reduce mortality. The prohibitive costs of VRAs, risk for hepatotoxicity, risks for overcorrection of hyponatremia, are additional reasons for extremely low use of VRAs in clinical practice in the treatment of heart failure.

14 Diuretic Treatment of Heart-Failure Patients with Hyponatremia

About 20% of patients hospitalized for heart failure have hyponatremia. In most cases hyponatremia in heart failure is not primarily due to diuretic treatment *per se* rather due to multiple other factors related to heart failure. These factors include increased secretion of ADH due to low cardiac output, increased thirst due to high angiotensin II, reduced ability of the kidney to excrete free water due to reduced renal perfusion, and reduced urine flow through the distal segment of the nephron. In some cases hyponatremia is due to diuretics especially when a thiazide diuretic is combined with a loop diuretic. In heart failure, even mild hyponatremia is associated with worse prognosis. In one study, patients who had serum sodium 132–135 mmol/l had significant increase in in-hospital, and 30 day mortality (Klein et al. 2005). Heart-failure patients who have serum sodium <125 mmol/l, due to heart failure, often have "end-stage" heart failure.

It is important to determine whether hyponatremia is mainly depletional or dilutional. This can be done by clinical assessment, and by assessment of the relevant laboratory parameters. For instance, if a patient with hyponatremia is on oral furosemide 160 mg twice daily, and does not have any obvious signs of congestion, then his hyponatremia could probably be depletional. Intravenous infusion of isotonic saline may be sufficient to treat depletional hyponatremia. Severe depletional hyponatremia (serum sodium < 125), however, should be treated by slow infusion of hypertonic (3%) saline making sure that serum sodium concentration does not increase at a rate faster than 10 mmol/l per 24 h (better aim for 6 mmol/l per 24 h). During treatment, serum sodium must be measured frequently. At the same time potassium and magnesium stores should also be replenished (Verbrugge et al. 2015).

On the other hand, dilutional hyponatremia in heart failure is more difficult to treat. If hyponatremia is severe (<120 mmol/l), or if there are symptoms attributable to hyponatremia, then it should be treated by fluid restrictions (< 1000 ml/day). ACE-I/ARB should be continued. If the patient is on a thiazide diuretic combined with a loop diuretic, then the thiazide diuretic should be stopped. The loop diuretic should not be stopped especially if the patient has congestion. The loop diuretics can indirectly promote free water excretion by reducing the concentration gradient in the renal medulla; this reduces water reabsorption in the collecting duct. Some patients with hyponatremia and persistent congestion may benefit from infusion of small volume hypertonic saline combined with high dose furosemide (see the section "use of hypertonic saline infusion with high dose loop diuretic in the treatment of heart failure").

VRAs (e.g. tolvaplan) have a potential role in the treatment of severe hyponatremia in heart failure, when other measures fail. These drugs increase serum sodium, but they are rarely used because of prohibitive cost, risk for overcorrection, and potential for liver toxicity.

In one study, 32% of the heart failure patients with hyponatremia received no specific therapy, 55% was treated by fluid restriction, 6% by

isotonic saline, 3% by hypertonic saline, and 4% by tolvaplan (Dunlap et al. 2017). Most of these patients had hyponatremia at the time of discharge from the hospital. There is no evidence that treatment of hyponatremia in heart failure improves clinical outcome.

15 Diuretic Treatment of Heart-Failure Patients with Hypoalbuminemia

In hypoalbuminemia, the delivery of free loop diuretics to the luminal site of action is reduced. Loop diuretics are >95% protein bound. In hypoalbuminemia less loop diuretic binds to the albumin, and more diuretic diffuses into the tissue. Thus, less loop diuretic is secreted into the nephron. If the patient has albuminuria, then the secreted loop diuretic binds to the albumin in the lumen of the nephron, which reduces the free form of the loop diuretic at the site of the action.

In treatment of heart failure patients with hypoalbuminemia, the main option is not to infuse albumin rather to increase the dose of the diuretic so that sufficient loop diuretics bind to albumin, secreted into the nephron, and are available in free form at the site of the action. To achieve this, the dose of the loop diuretic should be 2–3 times higher than normal dose. If the patient, in addition to hypoalbuminemia, has decreased glomerular filtration rate, then you may need to increase the dose of the loop diuretic another 2–4 fold (Brater 2011). Thus, these patients may need huge dose of loop diuretics, which may need to be given in repeated doses. Another approach is to add a thiazide diuretic to the regime of the loop diuretic therapy (see the section "Loop diuretic plus a thiazide diuretic").

The benefits of using loop diuretics combined with albumin in hypoalbuminemia remains controversial. If the treatment approach mentioned in the preceding paragraph does not give result, and if the patient has severe hypoalbuminemia (e. g. <20 g/l), then you can try treatment with loop diuretic combined with albumin. If combination of loop diuretics with albumin induces more diuresis than loop diuretics alone, then you can repeat the treatment; otherwise do not repeat this expensive treatment.

There are different ways of combining the loop diuretics and albumin. You can premix a maximal dose of a loop diuretic with 25 g albumin, and infuse the mixture over about 30 min. Alternatively, you can first infuse 25–50 g of albumin, and after 30 min infuse the loop diuretics. Albumin expands intravascular volume within 30–60 min (Duffy et al. 2015).

Note that modest hypoalbuminemia in heart failure is not associated with short-term adverse clinical outcome in patients treated with diuretics (Grodin et al. 2016b).

16 Use of Hypertonic Saline Infusion with High Dose Loop Diuretic in the Treatment of Heart Failure

In some patients with refractory congestive heart failure, infusion of small-volume hypertonic saline, combined with high dose furosemide, improves weight loss, reduces length of hospitalization, improves mortality, and reduces re-hospitalization rate (Gandhi et al. 2014).

Investigators have used different protocols for combining furosemide with hypertonic saline. Some have used i.v. furosemide 125–1000 mg with 150 ml f 1.4–4.6% hypertonic saline, two times per day (Paterna et al. 2015; Licata et al. 2003). Others have used i.v. furosemide 250 mg plus 150 ml 3% hypertonic saline two times per day (Paterna et al. 2011). (If you add 80 mmol NaCl to 500 ml of normal saline, you get 3% hypertonic saline). Mix furosemide with 150 ml of 3% saline and infuse it over 30 min two times per day for 1–2 days (Paterna et al. 2011).

The mechanism by which hypertonic saline increases the effect of high dose furosemide is not fully clear. Hypertonic solution increases availability of furosemide in its intraluminal site of action (it shifts the dose response curve of furosemide at the top and to the left). Due to its osmotic effect, hypertonic saline mobilizes fluid from the interstitial space to the vascular

compartment. It is also possible that hypertonic saline alters the autoregulation of blood flow in the kidney resulting in an increase of blood flow to the superficial nephrons which has short loop of Henle (the salt-losing nephrons).

17 Resistance to the Loop Diuretics

When loop diuretics given in maximal recommended doses fail to relieve congestion, then it is said that there is resistance to the loop diuretics. There is however, no standardized operative definition of diuretic resistance. In clinical practice, it is important to monitor response to the diuretics by monitoring the daily weight changes. Some patients who apparently have resistance to the loop diuretics are probably not receiving maximal recommended doses of the diuretics. In other cases, apparent diuretic resistance could be due to poor compliance, unrestricted fluid/salt intake, or intake of NSAID. It has been shown that, in most cases, true diuretic resistance, is due to resistance at the tubular level, rather than due to reduced delivery of the diuretic to its luminal site of action (Ter Maaten et al. 2017). True diuretic resistance should be treated by continuous infusion of the loop diuretics and/or sequential nephron blockade by addition of a thiazide diuretic (see section on "loop diuretic plus a thiazide diuretic"). In some selected cases, for instance, in patients with acute pulmonary edema, respiratory failure, and oliguria, ultrafiltration should be tried, when maximal doses of the diuretics given in frequent doses fail to relieve the symptoms (Regolisti and Fiaccadori 2013; Costanzo et al. 2007).

18 Concluding Remarks

Treatment of chronic heart failure with congestion, and ADHF, in the hospitals or in the outpatient settings, needs careful considerations, for choosing the most appropriate regime of treatment, for an individual patient, depending on many factors. Treatment must be individualized, avoiding both under-treatment and overtreatment, over time. In some patients, aggressive diuretic therapy, even in the face of worsening renal function, can be necessary for decongestion. Patient education, regular follow-up, and monitoring through outpatient "heart-failure units" are important ingredients for success. Treatment of severe heart failure patients with congestion, who are resistant to the loop diuretics, can be challenging, but good results can be obtained by bolus injections followed by continuous infusion of the loop diuretics, and sequential nephron blockade, following a structured step-up approach.

Clearly, many large, prospective, clinical trials will be needed for understanding many of the unresolved issues; meanwhile navigating the diuretic treatment through different phases of the natural history of chronic heart failure, will remain an art based on experiences of the clinicians. It is important for the clinicians to familiarize themselves with the treatment protocols that others have tried in different clinical situations, and try those in their own practices, when necessary, even in the absence of strong evidence.

Treatment of Heart Failure with Preserved Ejection Fraction

Adriana Mihaela Ilieşiu and Andreea Simona Hodorogea

Abstract

Heart failure with preserved ejection fraction (HFpEF) is a growing epidemiologic problem affecting more than half of the patients with heart failure (HF). HFpEF has a significant morbidity and mortality and so far no treatment has been clearly demonstrated to improve the outcomes in HFpEF, in contrast to the efficacy of treatment in heart failure with reduced ejection fraction (HFrEF).

The failure of proven beneficial drugs in HFrEF to influence the outcome of patients with HFpEF could be related to the heterogeneity of the disease, its various phenotypes and multifactorial pathophysiology, incompletely elucidated yet. The diagnosis of HFpEF could be demanding or even inaccurate. Moreover, the therapeutic strategies were influenced by different cut-offs used to define preserved ejection fraction (EF). From this perspective, the current guidelines have classified HFpEF by an EF $\geq$ 50%, together with a distinct entity, heart failure with mid-range ejection fraction (HFmrEF), defined by an EF ranging from 41–49%.

New therapies have been developed to interfere with the mediator pathways of HFpEF at the cellular and molecular level, including mineralocorticoid receptor antagonists, soluble guanylate cyclase stimulators, or angiotensin receptor-neprilysin inhibitors. A number of antidiabetic drugs, such as sodium/glucose cotransporter 2 inhibitors and dipeptidyl peptidase-4 inhibitors are promising options, being under research in large clinical trials. Until the results of ongoing trials shed light on these therapies, guidelines recommend empirical treatment for established HFpEF, and emphasize the crucial role of addressing cardiovascular comorbidities leading to HFpEF, in particular arterial hypertension.

Keywords

Clinical trials · Comorbidities · Heart failure · Preserved ejection fraction · Prognosis · Treatment

Heart failure with preserved ejection fraction (HFpEF) has emerged as a distinct form of heart failure along with the increased prevalence of the elderly population. In epidemiological studies there is less morbidity and mortality from HFpEF compared to heart failure with reduced ejection fraction (HFrEF), but the commonly associated cardiovascular and non-cardiovascular comorbidities have an unfavorable impact on its evolution (Chioncel et al. 2017). Therapies that have proven effective in HFrEF have not been shown to improve long-term prognosis in HFpEF, and data on potential therapies

targeting the pathophysiologic pathways of HFpEF are still inconclusive, so the current guidelines do not contain any firm indication on the therapy of choice in patients with HFpEF.

1 Therapies Proven to Be Beneficial in Heart Failure with Reduced Ejection Fraction

1.1 Angiotensin Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Targeting the renin-angiotensin-aldosterone system (RAAS) activation by counteracting the deleterious effects of angiotensin II on cardiovascular system (hypertrophy, fibrosis, vasoconstriction and remodeling) using angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs), along with aldosterone blockade by mineralocorticoid receptors antagonists (MRAs), has been shown to improve the outcome in HFrEF. The evidence for RAAS blockade as a therapeutic target in HFpEF is less clear, since the treatment has not demonstrated similar benefits.

Small studies using ACEIs (quinapril and enalapril) or ARBs (losartan and valsartan) had inconsistent results on different end-points such as exercise tolerance, NYHA functional class, quality of life or hospitalization in HFpEF patients (Zi et al. 2003; Aronow and Kronzon 1993; Warner et al. 1999; Parthasarathy et al. 2009).

The three large randomized controlled trials (RCTs) using ACEIs (perindopril) and ARBs (candersartan and irbesartan) in HFpEF patients had as primary composite endpoint death or time to first hospitalization.

In the Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial, the efficacy of perindopril 4 mg/day compared with placebo was assessed in 850 elderly patients (>70 years) with HFpEF, EF > 45% and evidence of diastolic dysfunction (Cleland et al. 2006). The study was neutral, without significant reduction in the primary endpoint, although a significant reduction in heart failure hospitalizations was observed after 1 year, but not for the entire study duration. The study was prematurely stopped and was underpowered due to lower than expected enrolment and event rate and a high proportion of discontinued treatment in the perindopril group, with 35% cross-over to open-label ACEI at the end of the study.

In the CHARM-Preserved arm of the Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) program of trials, the efficacy of candesartan was evaluated on the composite endpoint of cardiovascular death and heart failure hospitalization in HFpEF patients. 3023 elderly patients with NYHA functional class II–IV, prior hospitalization for heart failure and EF > 40% were enrolled. At baseline, 19% of the patients were taking ACEI, 61% had NYHA functional class II, and the mean EF was 54%. The primary outcome was not significantly different between the candesartan group versus placebo, but candesartan had a modest benefit in reducing the hospitalizations for heart failure which was marginally statistically significant only after adjustment for small differences in baseline characteristics (unadjusted $p = 0.118$; adjusted $p = 0.051$) (Yusuf et al. 2003).

The second and largest RCTs trial assessing ARBs efficacy in HFpEF after CHARM-Preserved was The Irbesartan in Heart Failure with Preserved Ejection Fraction Study (I-Preserve) (Massie et al. 2008). 4128 patients ≥60 years, with NYHA class II–IV and EF > 45% were assigned to irbesartan (targeting the dose to 300 mg) or placebo. The main composite outcome of the study was all-cause death or cardiovascular hospitalization for heart failure, myocardial infarction, unstable angina, arrhythmia, or stroke. At the end of the study there were no significant differences in the irbesartan arm vs placebo for the main outcome and for the secondary outcomes, including death, cardiovascular hospitalizations or worsening heart failure. Of note, there was a high rate (34%) of irbesartan discontinuation by the end of the study, and a considerable number of the patients had concomitant use of multiple RAAS inhibitors (ACEI, spironolactone) and also beta-blocker during the study.

The different results between CHARM-Preserved and I-PRESERVE trials may rely on the differences in the baseline characteristics of patients. CHARM–Preserved enrolled younger patients, with less severe symptoms of heart failure, fewer women, much higher proportions of ischemic heart disease, lower baseline ACEI use and lower baseline EF (55% vs. 60%), contributing to the noted, minor differences in the results. Although CHARM–Preserved did not achieve its primary end point, the positive result on hospitalizations for heart failure leads to a class IIb indication, level of evidence B, for the ARBs to decrease hospitalizations for patients with HFpEF in the 2013 ACCF/AHA Guideline for the Management of Heart Failure (Yancy et al. 2013).

1.2 Mineralocorticoid Receptor Antagonists

Aldosterone, by activation of the vascular and cardiac mineralocorticoid receptors, induces fibrosis, hypertrophy and endothelial dysfunction contributing to the vascular and cardiac remodeling and increased left ventricular (LV) diastolic stiffness (Komajda and Lam 2014; Borlaug and Paulus 2011; Weber 1989, 2001; Weber and Brilla 1991; Brilla et al. 1993a; Chapman et al. 1990; Weber et al. 1992; Brilla et al. 1993b). MRAs might have promising effects in HFpEF by improving LV diastolic dysfunction, the major pathophysiologic mechanism of the disease. After the beneficial effects of aldosterone on LV diastolic function in several small studies the impact of aldosterone on LV diastolic dysfunction (assessed by echocardiography) and maximal exercise capacity was tested in Aldosterone receptor Blockade in Diastolic Heart Failure (Aldo-DHF) trial (Roongsritong et al. 2005; Mottram et al. 2004; Mak et al. 2009; Edelmann et al. 2013). Aldo-DHF included 422 ambulatory patients with HFpEF (EF > 50%), NYHA class II-III and peak O2 $\leq$ 25 mL/Kg/min. In patients treated with spironolactone, there was an improvement in LV diastolic dysfunction (E/E′ ratio modestly but significantly decreased compared to placebo group over 12 months along with decrease in LV mass and natriuretic peptides), but maximal exercise capacity, NYHA class or quality of life did not improve. The mild symptoms of patients with HFpEF randomized in the trial and the minimal effect of spironolactone on functional exercise capacity in HFrEF trials are some possible reasons for the neutral results of Aldo-DHF trial. Nevertheless, MRAs are strongly recommended (class I indication) in HFrEF and LV ejection fraction (LVEF) $\leq$35%, to reduce mortality and HF hospitalization (Pitt et al. 1999; Zannad et al. 2011).

In the large TOPCAT (Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist) trial, the effects of spironolactone in elderly patients with HFpEF were evaluated on a composite outcome of cardiovascular mortality, aborted cardiac arrest, or hospitalization for heart failure (Pitt et al. 2014). TOPCAT trial included 3445 patients $\geq$50 years old, with HFpEF and EF $\geq$ 45%, the majority with symptomatic NYHA class II, with a mean follow-up of 3.3 years. At the end of the study, spironolactone did not significantly reduce the incidence of primary composite end-point compared with placebo. However, when each component was separately analyzed, spironolactone significantly reduced the risk of heart failure hospitalizations with 17% (12% vs. 14.2%, HR 0.83; 95% CI 0.69–0.99; $P = 0.04$). So, despite the neutral result on the main composite outcome, the morbidity in the elderly patients with HFpEF was reduced by spironolactone treatment.

The lack of positive results for the primary composite outcome of TOPCAT trial deserves some considerations. There were marked and unusual regional variation between Russia/Georgia (which contributed to 49% of the total enrollment) and North and South Americas (Americas). The post hoc analysis performed in order to clarify these regional differences, pointed out that the population enrolled in Russia/Georgia had a low risk profile, with a fourfold lower rates of the primary end-point than in Americas (Pfeffer et al. 2015). Also the rates of hospitalizaton for heart failure in the placebo-arm in Russia/Georgia were fivefold lower than in HFpEF patients enrolled in large ARBs trials

(CHARM- PRESERVED and I-PRESERVED) being quite similar with rates reported in some hypertension trials (ALLHAT, VALUE and LIFE, while in Americas the event rates were comparable to those in other HFpEF trials (Yusuf et al. 2003; Massie et al. 2008; ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group 2002; Julius et al. 2006; Dahlöf et al. 2002). Moreover, there was a considerably lower effect of spironolactone compared with placebo on potassium, creatinine and blood pressure in Russia/Georgia than in Americas and, in a sample from the active arm of this population, the spironolactone metabolite was nondetectable. These post hoc analyses, beside the significant limitations, showed the efficacy of spironolactone in HFpEF patients on primary outcome and on its two individual components, cardiovascular death and heart failure hospitalization, only in the Americas (HR = 0.83), but not in Russia/Georgia (HR = 1.10). The result of TOPCAT trial supported the class IIb recommendation in the recent 2017 ACC/AHA/HFSA Focused Update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure (Yancy et al. 2017a). The significant interaction between the TOPCAT recruitment strategy, based either on prior heart failure hospitalization, or natriuretic peptides level, and the efficacy of spironolactone treatment, emphasizes the need for diagnosis accuracy of HFpEF in future studies.

1.3 Beta-blockers

Beta-blocker (BB) therapy reduces mortality and morbidity in HFrEF patients, but their efficacy on the prognosis of patients with HFpEF remains unclear.

Betareceptor blockade has been proven to improve myocardial relaxation and diastolic function and to prolong diastole, promoting diastolic filling and improving myocardial perfusion. Patients with diastolic dysfunction and higher heart rates seem to benefit more from BB treatment by an improvement in early filling in particular. BB could reduce arrhythmias and sudden death in HFPEF patients, having similar effects as in HFrEF patients (Andersson et al. 2002; Wallhaus et al. 2001).

The treatment with carvedilol resulted in a significant improvement in E/A ratio, an echocardiographic marker of LV diastolic dysfunction, in 113 patients with diastolic heart failure enrolled in the double blind multi-center trial Swedish Doppler-echocardiographic study (SWEDIC) (Bergström et al. 2004). However, exercise capacity was not improved by nebivolol compared with placebo in 116 subjects with HFPEF from the trial "Effects of Long-term Administration of Nebivolol on the clinical symptoms, exercise capacity, and LV function of patients with Diastolic Dysfunction (ELANDD)" (Conraads et al. 2012).

The effect of BB therapy on outcome in patients with HFpEF was evaluated in some small clinical studies. Carvedilol had no effect on mortality or hospitalizations neither in the SWEDIC trial, nor in the "Japanese Diastolic Heart Failure" (J-DHF) study on the primary endpoint of cardiovascular death or unplanned HF hospitalization (Yamamoto et al. 2013). The "Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with Heart Failure" (SENIORS) trial enrolled 2128 elderly patients with a history of heart failure or with an EF < 35% (Flather et al. 2005). Treatment with nebivolol was associated with a 14% reduction in the primary composite end-point of all-cause mortality or cardiovascular hospitalizations in elderly patients. However a small number of randomized patients had HFpEF (LVEF>35%), encompassing only one-third of the heart failure population with known EF.

In summary, due to the inconsistent data from these small randomized controlled trials, not adequately powered, considering BB treatment in HFPEF remains questionable.

The effects of BB therapy on outcome in patients with HFpEF were analysed in two recent metaanalysis. The impact of BB treatment on mortality and hospitalization was assessed in HFpEF patients with EF ≥ 40% in the first

metaanalysis comprising 21,206 patients from 12 clinical studies between 2005 to 2013 (Liu et al. 2014). BB treatment was associated with a lower risk of all-cause mortality, but did not reduce the risk of all-cause hospitalization or cardiovascular hospitalization.

In a recent meta-analysis of 25 RCTs from 1996 to 2016 including a number of 18,101 patients patients with HFpEF and EF ≥40%, BB therapy significantly reduces all-cause mortality (RR: 0.78, 95%CI 0.65 to 0.94, p = 0.008) compared with placebo (Zheng et al. 2017).

The prognosis of patients with HFPEF treated with BB was assessed from the Swedish Heart Failure Registry (Lund et al. 2014). In a propensity score-matched cohort for β-blocker use study including 19.083 patients with HFpEF, 4054 patients were treated with BB. The treatment was associated with 8% reduction in all-cause mortality, but did not have a significant effect on combined all-cause mortality or heart failure hospitalization.

In light of the results of these meta analyses and registry which demonstrated the beneficial effect of BB on mortality in HFpEF a prospective large randomized trial is needed in order to clarify the efficiency of BB treatment in HFpEF. According to current evidence, the treatment with BB is not recommended in HFpEF, but patients with HFpEF could benefit from BB use in uncontrolled arterial hypertension treated with other drugs or in atrial fibrillation for symptomatic improvement (Whelton et al. 2017; Kirchhof et al. 2016).

1.4 Ivabradine

Ivabradine, by blocking the "funny channel" ($I_{(f)}$) in the sino-atrial node, slows down the spontaneous depolarization slope of the pacemaker cells, thus reducing heart rate. Current guidelines recommend ivabradine for the treatment of stable, symptomatic patients HFrEF with heart rate > 70 bpm on maximally tolerated BB doses or in those who are BB intolerant, in order to reduce hospitalizations for heart failure (Yancy et al. 2017a; The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology (ESC) 2016).

In HFpEF, ivabradine use might be beneficial by reducing heart rate, leading to prolonged diastolic filling time with improvement in stroke volume, reduced LV filling pressures and decreased wall stress, a stimulus for myocardial fibrosis (Kanwar et al. 2016).

After the promising results from experimental studies in a mouse model of HFpEF suggesting that ivabradine improves vascular stiffness, LV systolic and diastolic function, the clinical efficacy of ivabradine was investigated in EDIFY trial (Effect of ivabradine in patients with heart failure with preserved ejection fraction) (Becher et al. 2012; Komajda et al. 2017). It was a randomised placebo-controlled trial, in which 171 patients with heart failure NYHA class II–III, in sinus rhythm, with heart rate ≥ 70 bpm, NT-proBNP ≥220 ng/mL or BNP ≥ 80 pg/mL, and EF ≥45% were included, being randomized to ivabradine or placebo. Although in patients treated with ivabradine there was a significant reduction in heart rate compared with placebo, there were no significant improvements in diastolic function (assessed by changes in E/e′ ratio), exercise capacity (evaluated by six minute walk test) or NT-proBNP. The lack of positive effect of ivabradine could be explained by the presence of extensive myocardial fibrosis and increased LV stiffness, with severe diastolic restriction to filling and a very limited stroke volume reserve, not significantly influenced by the lengthening of the filling time through heart rate reduction (Komajda et al. 2017). The neutral results of the EDIFY trial does not support the use of ivabradine in HFpEF.

1.5 Digoxin

Digitalis glycosides have the longest history in the treatment of heart failure based on their positive inotropic effect. However, over the last decades, digoxin use has narrowed considerably, as more effective drugs, with fewer side effects have been developed. Digoxin currently has a IIbB class

indication in HFrEF in patients in sinus rhythm who remain symptomatic despite optimal treatment (The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology (ESC) 2016). A potential benefit in HFpEF could be due to neurohormonal effect of digoxin (Massie and Abdalla 1998; Smith et al. 1984). Low dose digoxin improves baroreceptor sensitivity, thus increasing vagal tone and reducing sympatheticactivation (Gheorghiade and Ferguson 1991). Digoxin might also provide antifibrotic effects by interfering with aldosterone and by suppressing the RAAS (Sundaram et al. 2002; Torretti et al. 1972). Digoxin has positive inotropic effect at doses of 0.25 mg/day or higher, whilst at lower doses the neurohormonal effect is dominant (Gheorghiade et al. 2004). Hence, digoxin capacity to modulate the neurohormonal imbalance, major contributor to HFrEF and HFpEF progression, suggests its possible benefits in all patients with heart failure. Another mechanism recently explored is the improvement in early energy-dependent diastolic function of the myocardium, that might support digoxin use in HFpEF (Wang et al. 1990).

The usefulness of digoxin in diastolic heart failure was investigated in DIG (Digitalis Investigation Group) ancillary trial, carried out concomitantly with the primary DIG trial. The objective of DIG trial was to evaluate the effect of digoxin on heart failure hospitalization and death in patients with heart failure in sinus rhythm. Patients with LV ejection fraction $\leq 45\%$ ($n = 6800$) constituted the main study group, whilst patients with LV ejection fraction >45% ($n = 988$) were enrolled in the ancillary study, being randomized to digoxin at a median daily dose of 0.25 mg ($n = 492$) or placebo ($n = 496$). Digoxin had no effect on mortality and all-cause or cardiovascular hospitalizations. Patients treated with digoxin had a nonsignificant 18% lower risk of heart failure hospitalization or mortality, and a nonsignificant 21% reduction in hospitalization for heart failure ($p = 0.094$) (Digitalis Investigation Group 1996, 1997; Ahmed et al. 2006). The favorable effects of digoxin treatment in HFpEF might be due to its neurohormonal effects (Chirinos et al. 2005). However, there is a consensus on the lack of information about the effect of digoxin in patients with HFpEF that does not support its use in these patients (Massie and Abdalla 1998).

2 Treatment with Drugs Targeting Mediator Pathways of Heart Failure with Preserved Ejection Fraction

2.1 Proof of Concept Studies Targeting the Nitric Oxide – Cyclic Guanosine Monophosphate – Protein Kinase G Axis

The recently developed HFpEF paradigm focused on chronic microvascular inflammation which induced an unfavorable molecular cascade in the cardiomyocytes resulting in increased myocardial stiffness, hypertrophy and interstitial fibrosis leading to LV diastolic dysfunction (Paulus and Tschope 2013). The involved pathway is the decreased concentration and impairing signaling of cyclic guanosine monophosphate (cGMP) and reduced activity of protein kinase G (PKG) in the cardiomyocyte, which became therapeutic targets. This observation provides a compelling rationale to pharmacologically modulate this pathway in HFpEF patients. There are two types of guanylate cyclases (GC) enzymes, which convert the guanosine triphosphate to cGMP. The soluble guanylate cyclase (sGC) is functioning as a receptor for nitric oxide (NO) and the transmembrane-associated particulate guanylate cyclase serves as a receptor for natriuretic peptides. The reduced NO bioavailability is associated with decreased NO stimulation and/or the responsiveness of soluble guanylate cyclase. NO donors and nitrates and orally active soluble guanylate cyclase (sGC) stimulators have been developed. The cardiac up-regulation and overexpression of phosphodiesterase-5 (PDE5) with enhanced cGMP degradation represent another mechanism that can be prevented by PDE5 inhibition. The reduced synthesis of the transmembrane-associated particulate guanylate cyclase due to natriuretic peptide activation is a mechanism targeted by neprilysin inhibitors (Greene et al. 2013).

2.2 Exogenous Nitrates

Nitrates decrease the number of anginal attacks in ischemic heart disease and and symptoms in patients with HFrEF, by decreasing the pulmonary congestion and improving exercise tolerance. In HFpEF, nitrates increase peripheral venous capacitance, thus reducing ventricular preload and LV filling pressure and may improve exercise capacity. At the molecular level, exogenous nitrates or NO donors activate soluble guanylyl cyclase increasing cGMP synthesis with subsequent PKG activation, leading to vasodilation.

However, the Nitrate's Effect on Activity Tolerance in Heart Failure With Preserved Ejection Fraction (NEAT-HFpEF) trial failed to demonstrate beneficial effects of isosorbide mononitrate on exercise tolerance in HFpEF patients with limited activity related to symptoms (dyspnea, fatigue, or chest pain) (Zakeri et al. 2015). Although nitrates may improve endothelial function, chronic therapy with long-acting nitrates can paradoxically increase oxidative stress and local endothelin activation, augmenting the endothelial dysfunction (Oelze et al. 2013). Based on NEAT-HFpEF trial, the routine use of nitrates in patients with HFpEF is ineffective and is not recommended in the 2017 update Guideline for the Management of Heart Failure, except for patients with HFpEF and coronary artery disease, for symptoms relief (Yancy et al. 2017a).

2.3 Phosphodiesterase-5 Inhibitors

Phosphodiesterase-5 (PDE5) inhibitors prevent the intracellular catabolism of cGMP by phosphodiesterases, upregulating cGMP activity and hence augmenting the vascular and myocardial effects of nitric oxide. Consequently, there is a decreased stiffness of titin, modulated through PKG, and improvement in LV diastolic function (Oelze et al. 2013; van Heerebeek et al. 2006; Kruger et al. 2009; Bishu et al. 2011).

In a small study, in 44 patients with HFpEF, EF $\geq$ 50%, pulmonary hypertension and recent onset dyspnea, PDE5 inhibitor sildenafil improved LV diastolic function, LV remodeling and reduces pulmonary hypertension compared with placebo after 12 months (Guazzi et al. 2011).

However, the beneficial effects of sildenafil were not confirmed in another trial, PDE5 inhibition to Improve Clinical Status and Exercise Capacity in Diastolic Heart Failure (RELAX) (Redfield et al. 2012). 216 patients with HFpEF, NYHA class II–IV, LVEF $\geq$50 and reduced exercise tolerance, were randomized to sildenafil at different doses or placebo. At baseline, the patients were on stable heart failure therapy and had elevated LV filling pressure and mild increase in pulmonary artery systolic pressure. After 24 weeks, there were no significant differences between the sildenafil and placebo group in the median change in peak VO_2, nor in exercise tolerance or in the LV diastolic function.

The neutral results of the RELAX trial may be explained by the enrollment of HFpEF patients without associated pulmonary hypertension or by the coexistence of cronothropic incompetence as a contributor to the exercise intolerance. Another explanation could be the limited efficacy of PDE5 inhibitors in preventing cGMP breakdown, when the dominant mechanism of low molecular level of cGMP was the deficient generation of cGMP.

Based on RELAX trial, PDE5 inhibitors are not recommended for the treatment of HFpEF in the 2017 update Guideline for the Management of Heart Failure.

2.4 Soluble Guanilate Cyclase Stimulators

In HFpEF, reactive oxygen species (OS) and endothelial dysfunction contribute to the reduction of NO bioavailability, with inadequate stimulation of soluble guanilate cyclase (sGC) and reduced generation of cGMP. Furthermore, OS induces a shift of native sGC to a dysfunctional form at the molecular level, unresponsive to endogenous and exogenous NO (Greene et al. 2013). Evidence shows that cGMP deficiency is rather due to diminished production rather than increased PDE5-mediated degradation in HFpEF.

The attempt to increase cGMP by PDE5 inhibition could be efficient if PDE5 synthesis was up-regulated, such as in pulmonary arterial hypertension (Redfield et al. 2013). The increase in NO bioavailability by nitrates, ACEIs or other molecules may not be sufficient to improve microvascular function in patients with heart failure (Cole et al. 2011). Direct small molecule sGC agonists appear particularly promising, as they might overcome these limitations.

Recently available, the oral treatment with direct sGC stimulators had encouraging results in patients with heart failure before hospital discharge or early post-hospitalization (Stasch et al. 2011; Gheorghiade et al. 2013). The SOluble guanylate Cyclase stimulatoR in heArT failurE Studies (SOCRATES) programme aimed to assess the effects of the novel once-daily oral sGC stimulator vericiguat (BAY 1021189) in patients with HFrEF or HFpEF stabilized after hospitalization or under intravenously diuretic therapy for worsening heart failure. SOCRATES programme was designed as two parallel phase II trials, SOCRATES-REDUCED in HFrEF and SOCRATES-PRESERVED in HFpEF. In SOCRATES-REDUCED trial there was a significant reduction in NTproBNP levels and a trend towards decreased hospitalizations for heart failure in vericiguat arm compared with placebo, a rationale for further Phase 3 trials (Pieske et al. 2014; Gheorghiade et al. 2015). SOCRATES-PRESERVED, a phase 2b dose-finding trial, aimed to evaluate the safety, tolerability, and pharmacodynamic effects of optimal doses of vericiguat in patients with HFpEF (LVEF $\geq$45%) (Pieske et al. 2014). The primary endpoints were changes in NT-proBNP levels and left atrial volume from baseline at 12 weeks. Patients (n = 477) were randomized to vericiguat (n = 384) or placebo (n = 93) within 4 weeks of hospitalization for heart failure (75%) or outpatient treatment with intravenous diuretics for heart failure (25%). Although there was no change in the NT-proBNP level and left atrial volume at 12 weeks in the active arm compared with placebo, patients treated with vericiguat had significant improvements in the quality of life (Pieske et al. 2017). Riociguat currently has no indications in patients with HFpEF, but given the encouraging results of SOCRATES-PRESERVED trial, further research is warranted.

2.5 Angiotensin II Receptor Blocker Neprilysin Inhibitors

Angiotensin II receptor blocker neprilysin inhibitor (ARNI) is a new therapeutic class of agents acting on the RAAS and the neutral endopeptidase system. LCZ696, the first drug in the class, is a combination of valsartan, an angiotensin AT1 receptor blocker, and sacubitril, a neprilysin inhibitor. LCZ696 acts both by suppressing the RAAS system, and by enhancing the protective effects of natriuretic peptide (NP). Sacubitril, by inhibiting neprilysin, the primary enzyme that degrades NP, increases the bioavailability of NP which exerts natriuretic, vasodilator and antiproliferative effects. After the beneficial results on morbi-mortality in the PARADIGM-HF trial, ARNI is strongly indicated (class 1 level of evidence) in patients with chronic symptomatic HFrEF in both European and American heart failure guidelines (Yancy et al. 2017a; The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology(ESC) 2016).

LCZ696, by its mechanism of action, could improve LV diastolic dysfunction, by reducing myocardial hypertrophy and fibrosis and consequently reducing LV diastolic stiffness, important pathophysiologic mechanisms of HFpEF. The efficacy of LCZ696 on NT–proBNP as a marker of LV wall stress (which is not a substrate for neprilysin) was assessed by the phase II trial "Prospective Comparison of ARNI with ARB on Examination of Heart Failure with Preserved Ejection Fraction" (PARAMOUNT) (Solomon et al. 2012). In 301 patients with HFpEF, NYHA class II-III, EF $\geq$45% and elevated NT-proBNP plasma levels, the efficacy and safety of LCZ696 from baseline to 12 weeks were assessed in comparison with valsartan. NT-proBNP was significantly lower at 12 weeks in the LCZ696 group compared with the valsartan group and the drug was well tolerated. Of note,

NYHA functional class and left atrial dimensions, marker of sustained elevations in LV filling pressures, were also significantly reduced in the LCZ696 group after 36 weeks.

2.6 Ranolazine

Ranolazine inhibits late inward sodium current (I_{Na}) in cardiac muscle, thus reducing intracellular calcium levels and therefore decreasing LV wall tension and oxygen requirement. Ranolazine also reduces LV end-diastolic pressure by the improvement in ventricular relaxation and increases the coronary blood flow (Noble and Noble 2006). Currently used as an antianginal agent, ranolazine was thought to provide favourable outcomes in HFpEF based on its effect on LV diastolic function through late sodium current inhibition and possibly through a direct effect on myofilament calcium sensitivity and myofilament cross-bridging (Lovelock et al. 2012).

RALI-DHF (The Ranolazine for the Treatment of Diastolic Heart Failure) trial was designed to evaluate the effect of ranolazine in patients with HFPEF. It was a small, prospective, single-center, randomized, double-blind, placebo-controlled trial, in which 20 patients with heart failure and LVEF $\geq$45% had been included. Patients received ranolazine or placebo in iv bolus followed by 24 h continuous infusion and then ranolazine 1 g twice daily or placebo. Although in patients treated with ranolazine there was an improvement in some hemodynamic parameters, there was no improvement in relaxation parameters (Jacobshagen et al. 2011; Maier et al. 2013).

3 Unsolved Issues Related to HFpEF Syndrome

In the past years, HFpEF became a recognized clinical entity with a steadily increasing prevalence and high morbidity and mortality. In contrast to HFrEF, in which the therapeutic management significantly improved patients' outcome, there is no effective therapy in HFpEF so far, since the drugs used in large clinical trials failed to prove beneficial effects. There are many unsolved issues in this heterogeneous HF syndrome with a variety of phenotypes.

HFpEF pathophysiology is incompletely elucidated. LV diastolic dysfunction, a consequence of myocardial stiffening and relaxation abnormalities, was considered a dominant and constant component. However, it has been demonstrated that HFpEF syndrome is a complex interaction between elevation of LV filling pressures and other concomitant cardiovascular patologies such as abnormal ventriculo-arterial coupling, chronotropic incompetence, intrinsic pulmonary vascular disease associated with pulmonary hypertension and, notably, subclinical systolic dysfunction despite preserved EF.

There are distinctive demographic characteristic of HFpEF patients in contrast with patients with HFrEF. The clinical profile of the HFpEF patient is an elderly, more often woman, with comorbid conditions, in particular arterial hypertension (with the prevalence of hypertension between 60% and 90%), but also with atrial fibrillation, and, less commonly, ischemic heart disease (Mant et al. 2009).

Non-cardiovascular comorbid conditions, such as obesity, diabetes, chronic kidney disease, anemia, chronic obstructive pulmonary disease or obstructive sleep apnea, are common, contributing to the progression of HFpEF and to the higher noncardiac hospitalization and mortality than in patients with HFrEF. In a new paradigm, these comorbidities induce a systemic proinflammatory state, responsible for structural and functional changes in the myocardium and vascular system of HFpEF patients. The low grade inflammation with increased oxidative stress, impaired NO bioavailability, and endothelial dysfunction appear to be the link between comorbidities and HFpEF progression (Paulus and Tschope 2013).

The negative result of major clinical trials testing different drugs classes proved to have favorable effects on outcome in HFrEF could have multiple explanations, relying on disease characteristics, patients selection or trial design.

A lower level of neurohormonal activation in HFpEF compared to HFrEF is suggestive for different pathway of cardiac remodeling, which are less responsive to neurohormonal inhibition with RAAS or sympathetic antagonists. Myocardial fibrosis and excessive extracellular matrix are major determinants of myocardial stiffness and diastolic dysfunction in HFpEF and remains important therapeutic targets in future clinical studies. The differences in the severity of the disease in patients with HFpEF enrolled in differents trials are another confounding factor, as some patients with severe disease could be less responsive to pharmacological treatment.

Another reason for the heterogenous results in different trials is the challenge to select the "true" HFpEF patient. The accurate diagnosis of HFpEF is difficult and relies mostly on the exclusion of other causes of the symptoms. In some trials, patients with non-cardiac dyspnea and with incident LV hypertrophy, but without true HFpEF were enrolled, leading to the negative results.

An important weakness of epidemiological studies and registries in HFpEF was the lack of consensus regarding the definition of preserved EF. While HFrEF or systolic heart failure is defined by an EF $\leq$ 40%, different cut-off of EF were applied for HFpEF definition in the clinical trials ($\geq$ 40% (CHARM) $\geq$ 45% (I-Preserved, PEP-HF, TOPCAT) or $\geq$50% (ALDO-DHF), while HFpEF was defined by an EF $\geq$50% in heart failure guidelines (Yancy et al. 2013).

Retrospective subgroup analyzes from large RCTs (CHARM, TOPCAT) and registry data revealed differences in etiology and in the response to treatment between patients with heart failure and EF between 41 and 49% compared to those with heart failure and EF $\geq$50%. For these reasons, in the recent heart failure guidelines, heart failure and EF between 41 and 49% is recognized as a new entity, heart failure with mid range EF (HFmrEF) or borderline HFpEF (Yancy et al. 2017a; The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology(ESC) 2016). In a recent prospective heart failure long-term European registry, the epidemiological data after 1 year of follow-up revealed that in comparison with HFrEF, HFpEF patients were older, hypertensive, with atrial fibrillation and were less likely to have an ischemic heart disease. The HFmrEF patients had more similarities with the HFrEF being younger, males and more often with ischemic heart failure (Chioncel et al. 2017).

The current heart failure Guidelines recommendations on HFpEF treatment emerged from RCTs, patients with HFmrEF being included in HFpEF patients. The future clinical trials will shed light on this new entity, better defining each heart failure category and as much as new data become available, further Guidelines recommendations would be presumably distinct for each heart failure phenotype.

4 Current Guidelines' Recommendations in Heart Failure with Preserved Ejection Fraction

In the absence of effective treatments to improve the prognosis of HFpEF patients, heart failure guidelines recommend therapies for symptomatic control of the disease (Table 1). Diuretics are by now the only recommended intervention firmly proven to alleviate symptoms in patients with HFpEF and congestion. Patients with stage C HFpEF and persistent arterial hypertension should be treated with ACEIs, ARBs, and BB after the management of volume overload with diuretics in order to reach lower blood pressure (BP) goals. The BP target in HFpEF is lower than 130/80 mmHg, as recommended by the recent American Heart Failure and High Blood Pressure guidelines (Whelton et al. 2017; Yancy et al. 2017b).

Atrial fibrillation, a common comorbidity in patients with HFpEF, should be treated in order to reduce the risk of thromboembolic events and to control either the heart rate, or the cardiac

Table 1 Therapies for stage C HFpEF in clinical trials and the recommendations of ACC/AHA/HFSA guideline for the management of heart failure

Drug	Trial Phase Year	Number of patients	LVEF cut-off	Primary end points	Results	ACC/AHA/HFSA Guideline for the Management of Heart Failure (Yancy et al. 2017b) Class of Recommendation and Level of Evidence for Stage C HFpEF
Therapies proven to be beneficial in HFrEF						
Beta-blockers						
Carvedilol	SWEDIC II 2004	113	≥ 45%	Echocardiographic assessment of LV diastolic function	Only E/A ratio significantly improved	**The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure in patients with HFpEF**
Carvedilol	J-DHF II 2013	245	>40%	CV death/unplanned heart failure hospitalization	No benefit	**IIaC**
Nebivolol	SENIORS III 2005	752 (35% of 2128 patients enrolled)	>35%	All-cause mortality or cardiovascular hospitalizations	Inconsistent data (small number of HFpEF patients)	
Nebivolol	ELANDD II 2012	116	>45%	exercise capacity (6 min walking test)	No benefit	
Renin-angiotensin-aldosterone axis inhibition						
Perindopril	PEP-CHF III 2006	850	>45%	All-cause mortality/heart failure hospitalization	No benefit (underpowered study)	**The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure in patients with HFpEF** **IIaC**
Candesartan	CHARM-Preserved II 2003	3023	>40%	CV death/heart failure hospitalization	No benefit Only modest benefit in reducing heart failure hospitalizations	**The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure in patients with HFpEF**
Irbesartan	I-PRESERVE III 2008	4128	>45%	All-cause death/CV hospitalization	No benefit	**IIaC** **The use of ARBs might be considered to decrease hospitalization for patients with HFpEF** **IIbB**

rhythm, for the improvement of heart failure symptoms (Kirchhof et al. 2016). The treatment of coronary artery disease should be managed according to guidelines, including coronary revascularization strategies, since myocardial ischemia has a detrimental role on outcome and symptoms in HFpEF patients. ARBs and, in selected patients, aldosterone receptor antagonists might be advised to reduce hospitalizations for heart failure. Non-cardiovascular comorbidities, such as obesity, diabetes, chronic kidney disease, anaemia, chronic obstructive pulmonary disease, sleep apnea, are commonly associated with HFpEF and the current guidelines strongly recommend their screening and their proper management (Yancy et al. 2017a; The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology (ESC) 2016).

One of the major challenges is the prevention of HFpEF development. BP control in patients at increased risk for heart failure remains an essential goal. In a large RCT trial in patients at high cardiovascular risk, strict BP control (systolic BP <120 mmHg) was associated not only with a significantly lower incidence of heart failure, but also with a decrease in cardiovascular mortality, leading to a new approach for BP control (The SPRINT Research Group 2015). In the last American Heart Failure and High Blood Pressure guidelines, the recommended optimal BP target measured in the office setting is lower than 130/80 mmHg in patients with increased cardiovascular risk, which is less than the BP target proposed by the latest European Arterial Hypertension Guidelines (systolic BP < 140 mmHg) (Whelton et al. 2017; Yancy et al. 2017b; The Task Force for the management of arterial hypertension of the European Society of Hypertension (ESH) and of the European Society of Cardiology (ESC) 2013). Attaining BP target in patients with increased CV risk, defined as age > 75 years, established vascular disease, chronic renal disease, or a Framingham Risk Score > 15% is a mandatory strategy to prevent heart failure.

5 Emerging Treatment Strategies and Ongoing Clinical Trials in Heart Failure with Preserved Ejection Fraction (Table 2)

5.1 Exercise Training

Some recent studies were designed to evaluate the efficacy of exercise training (ET) as a complementary therapeutic strategy in patients with HFpEF and their results support the beneficial effect of ET on exercise capacity and quality of life (Gary et al. 2010; Edelmann et al. 2011; Alves et al. 2012; Smart et al. 2012; Kitzman et al. 2013). In Ex-DHF (Exercise training in Diastolic Heart Failure) pilot study, the exercise capacity measured as peak oxygen uptake (mL/kg/min) significantly increased in patients undergoing supervised physical training programme in addition to the usual care compaired with patients receiving usual care (Edelmann et al. 2011). The quality of life, estimated using Minnesota living with heart failure score, was also significantly improved in patients undergoing ET.

Although ET improved systolic function in patients with HFrEF it is still debatable if it might improve diastolic function in patients with HFpEF (Haykowsky et al. 2007). However, in clinical studies using more specific diastolic function parameters (E/E′ ratio), there was a significant improvement in diastolic function with ET. ET significantly improves E/e′, (marker of left ventricular filling pressures), and left atrial volume index (Edelmann et al. 2011).

Various mechanisms could explain the positive effect of ET in patients with HFpEF. ET has been shown to improve endothelial function, to reduce systemic inflammation and to diminish age-related stiffening of the heart and LV diastolic dysfunction (Hambrecht et al. 1998, 2000; Linke et al. 2001; Adamopoulos et al. 2001). ET also induces favorable changes within the peripheral arterial blood flow and in the function of metabolically active skeletal muscle leading to an increased oxygen uptake (Sullivan et al. 1988).

Table 2 Emerging therapies for HFpEF – ongoing clinical trials

Drug/intervention	Trial name	n	Primary outcomes	End
Exercise training				
Individually prescribed, supervised, combined endurance/strength training for 12 months (≥3x/week)	Exercise Training in Diastolic Heart Failure (**Ex-DHF**)	320	Composite outcome score: all cause mortality, cardiovascular hospitalizations, NYHA class, global self-assessment, exercise capacity and diastolic function.	?
Aldosterone Antagonists				
Spironolactone	Spironolactone Initiation Registry Randomized Interventional Trial in Heart Failure With Preserved Ejection Fraction (**SPIRRIT**)	3500	Time to death from any cause [Time Frame: Collected at data base lock, 5 years after study start].	2021
			Information on Death from the Swedish Causes of death registry.	
Angiotensin II Receptor Blocker Neprilysin Inhibitor (ARNI)				
Sacubitril/Valsartan; Valsartan	Efficacy and Safety of LCZ696 Compared to Valsartan, on Morbidity and Mortality in Heart Failure Patients With Preserved Ejection Fraction (**PARAGON-HF**)	4822	Cumulative number of primary composite events of cardiovascular death and total (first and recurrent) HF hospitalizations. [Total follow up time (up to 57 months)].	2019
Sacubitril/Valsartan; Enalapril; Valsartan	A Randomized, Double-blind Controlled Study Comparing LCZ696 to Medical Therapy for Comorbidities in HFpEF Patients (**PARALLAX**)	2200	Change from baseline in N-terminal pro-brain natriuretic peptide (NT-proBNP) after 12 weeks.	2019
			To demonstrate that LCZ696 is superior to individualized medical therapy for comorbidities in reducing NT-proBNP from baseline after 12 weeks of treatment in patients with HFpEF.	
Antidiabetic drugs with evidence- based cardiovascular outcomes improvement				
Empagliflozin (Sodium glucose co-transporter-2 (SGLT-2) inhibitor)	EMPagliflozin outcomE tRial in Patients With chrOnic heaRt Failure With Preserved Ejection Fraction (**EMPEROR-Preserved**)	4126	Composite primary endpoint – Time to first event of adjudicated Cardiovascular death or adjudicated hospitalization for Heart Failure in patients with HFpEF [Time Frame: up to 38 months].	2020
Teneligliptin (Dipeptidyl peptidase-4 inhibitors (DPP-4i))	Teneligliptin on the Progressive Left Ventricular Diastolic Dysfunction With Type 2 Diabetes Mellitus Study (**TOPLEVEL**)	936	Change of the ratio of peak velocity of early transmitral diastolic filling by echocardiography (E) to early diastolic mitral annular velocity by tissue Doppler echocardiography (E/e') [Time Frame: Up to 2 years].	2019

Current guidelines recommend combined endurance/resistance training as a safe therapy to improve maximal exercise capacity, LV diastolic function, and quality of life for patients with HFpEF. In patients at high risk for HFpEF (sedentary, overweight or obese women with arterial hypertension), ET has been also proven effective in improving exercise tolerance (Church et al. 2007).

However, the long-term impact of ET on patient-related outcomes in HFpEF is still unclear, since none of the studies published so far have been designed to address hospitalizations and mortality in these patients.

Exercise training in Diastolic Heart Failure (Ex-DHF) trial was designed as the first multicenter RCT to evaluate the effects of physical training on clinical outcomes in patients with HFpEF (Edelmann et al. 2011). The primary objective of Ex-DHF trial is to establish whether a 12 month supervised ET program can improve a composite outcome score in HFpEF patients. The effect of supervised ET in addition to usual care compared to usual care alone on the primary end point (all cause mortality, cardiovascular hospitalizations, NYHA class, global self-assessment, exercise capacity and diastolic function) will be assessed in 320 patients with stable HFpEF. The ET effects on inflammatory, metabolic and collagen turnover biomarkers, as well as on cardiac and vascular function and ventriculo–arterial coupling will also be evaluated in Ex-DHF substudies.

5.2 Aldosterone Antagonist – Spironolactone

Occurring early in the evolution and present in variable degrees in all patients with HFpEF, myocardial and vascular fibrosis, a major contributor to the impairment of LV diastolic function, represents a meaningful therapeutic target. Collagen synthesis within the extracellular matrix, the major mechanism of fibrosis, is increased by RAAS activation (Borlaug and Paulus 2011). Aldosterone stimulates cardiac fibroblasts and also stimulates the expression of profibrotic molecules through inflammation and oxidative stress mediated mechanisms (Marney and Brown 2007). Mineralocorticoid receptor antagonism (MRA) seems reasonable for the improvement of LV diastolic function and data from clinical studies are promising supporting the hypothesis that MRAs may improve outcomes in HFpEF. Uncertainties in the past will probably be elucidated by ongoing trials and new anti-fibrotic therapies would bring important benefits in HFpEF.

The TOPCAT trial, although with neutral results, suggested that the effects of spironolactone varies according to LV EF, having greatest benefit at the lower end of the EF spectrum (Solomon et al. 2016). Based on this data, the "Spironolactone Initiation Registry Randomized Interventional Trial in Heart Failure With Preserved Ejection Fraction" (SPIRRIT) trial was designed as a unique registry-randomized clinical trial including HFPEF patients from the Swedish Heart Failure Registry. The primary objective the trial was the effects of spironolactone on all-cause mortality in symptomatic HFpEF patients with EF > 40% and elevated elevated NTproBNP. The trial will include about 3500 patients during 5 years period and is projected to end by 2021.

5.3 Angiotensin II Receptor Blockerneprilysin Inhibitors

5.3.1 PARAGON – HF Trial

Sacubitril-valsartan (LCZ696), the first in the class of angiotensin receptor neprilysin inhibitors (the primary enzyme that degrades the natriuretic peptides with antriproliferative and natriuretic effects), significantly reduced the composite endpoint of cardiovascular death or heart failure hospitalization in HFrEF in PARADIGM-HF trial and is indicated in HFrEF patients who remain symptomatic as an alternative to ACEi/ARB therapy in the current heart failure guidelines (McMurray et al. 2014).

In PARAMOUNT trial, in patients with HFpEF there was a significant reduction in NT-proBNP at 12 weeks and significant improvement in left atrial size and NYHA class in patients randomized to sacubitril-valsartan compared to valsartan at 36 weeks (Solomon et al. 2012).

After the positive results of sacubitril-valsartan in these trials, the effect of sacubitril-valsartan compared to valsartan on morbidity and mortality

in HFpEF will be assessed in PARAGON-HF (Efficacy and Safety of LCZ696 Compared to Valsartan, on Morbidity and Mortality in Heart Failure Patients With Preserved Ejection Fraction).

5.3.2 PARALLAX – HF Trial

The mechanisms of action of sacubitril-valsartan (LCZ696) suggest that it may have an impact on the pathophysiology of HFpEF, in which excessive fibrosis and myocyte hypertrophy may lead to abnormal LV relaxation and filling, impaired diastolic distensibility and increased vascular stiffness, generating elevated cardiac filling pressures. The purpose of the PARALLAX-HF study is to prove the superiority of sacubitril-valsartan over individualized medical therapy for comorbidities in reducing NT-proBNP and improving heart failure symptoms and functional capacity in patients with HFpEF.

5.4 Antidiabetic Drugs

Heart failure is among the most worrisome complications of diabetes. On the other hand diabetes is a major comorbidity contributing to progression and prognostic in HFpEF. Treating diabetes with optimum metabolic control is an important target, especially in patients with HFpEF. Moreover, recent data also demonstrated the beneficial effect of some classes of antidiabetic drugs on HFpEF prognosis, explained by their mechanism of action interfering heart failure pathogenic pathways. These drugs are currently under investigation in large outcome trials.

5.5 Sodium Glucose Co-transporter-2 Inhibitors

5.5.1 EMPEROR – Preserved Trial

Empagliflozin belongs to glifozins class, being an inhibitor of the sodium glucose co-transporter-2 (SGLT-2), which is found almost exclusively in the proximal tubules in the kidneys. SGLT-2 accounts for about 90% of glucose reabsorption into the blood. Blocking SGLT-2 in patients with type 2 diabetes and high blood sugar levels reduces blood glucose by blocking glucose reabsorption in the kidney and thereby augmenting urinary glucose excretion. Inhibition of SGLT2 with empagliflozin increases excretion of salt (i.e. sodium) from the body and reduces intravascular volume. Excretion of sugar, salt and water after the initiation of treatment with empagliflozin may therefore contribute to the improvement in cardiovascular outcomes. The aim of the EMPEROR – Preserved study is to evaluate efficacy and safety of empagliflozin versus placebo on top of guideline-directed medical therapy in patients with HFpEF.

5.6 Dipeptidyl Peptidase-4 Inhibitors (DPP-4i)

5.6.1 TOPLEVEL Trial

Dipeptidyl peptidase-4 inhibitors (DPP-4i) have recently become widely used to treat type 2 diabetes mellitus. Animal studies report numerous pleiotropic effects of DPP-4i: cardioprotective effects on hypertension, HFrEF, HFpEF, myocardial infarction, and cardiac hypertrophy. Therefore, DPP-4i are expected to inhibit cardiovascular events in clinical trials, by preventing cardiomyocyte hypertrophy and perivascular fibrosis, and improving endothelial function (Yamamoto et al. 2017).

The TOPLEVEL clinical trial is designed to assess the LV diastolic function of long term treatment with teneligliptin in patients with type 2 diabetes mellitus by two arms: one with patients showing E/e′ by echocardiography less than 8, the other including patients with E/e′ higher than 8. The results of the study are expected by 2019.

In conclusion, HFpEF is a heterogeneous form of heart failure, incompletely defined, with multiple pathophysiological mechanisms, numerous phenotypic aspects and many unknowns. To date, no drug treatment has been shown to be effective in lowering the morbidity or mortality

of HFpEF. A deeper understanding of the mechanisms of the disease, which could become therapeutic targets, the elucidation of numerous uncertainties of the epidemiological and clinical studies, as well as the results of ongoing trials with various new classes of drugs could bring therapeutic benefits and improve the prognosis of this highly prevalent form of heart failure.

Circulating Biomarkers in Heart Failure

Alexander E. Berezin

Abstract

Biological markers have served for diagnosis, risk stratification and guided therapy of heart failure (HF). Our knowledge regarding abilities of biomarkers to relate to several pathways of HF pathogenesis and reflect clinical worsening or improvement in the disease is steadily expanding. Although there are numerous clinical guidelines, which clearly diagnosis, prevention and evidence-based treatment of HF, a strategy regarding exclusion of HF, as well as risk stratification of HF, nature evolution of disease is not well established and requires more development. The aim of the chapter is to discuss a role of biomarker-based approaches for more accurate diagnosis, in-depth risk stratification and individual targeting in treatment of patients with HF.

Abbreviations

ADM	adrenomedullin
ANP	atrial natriuretic peptide
ARNI	angiotensin receptor neprilysin inhibitors
BNP	brain natriuretic peptide
BRPs	bone related proteins
cGMP	cyclic guanylyl monophosphate
CITP	carboxy-terminal telopeptide
CNP	C-type natriuretic peptide
CRP	C-reactive protein
CT-proET-1	C-terminal-pro-endothelin-1
CV	cardiovascular
EMPs	endothelial microparticles
EPCs	endothelial progenitor cells
Gal-3	galectin-3
GDF-15	Growth differentiation factor-15
HF	heart failure
hFABP	heart type of fatty acid binding protein
HFpEF	heart failure with preserved ejection fraction
HFrEF	heart failure with reduced ejection fraction
LV	left ventricular
MMP	matrix metalloproteinase
MPs	micro particles
MR-proANP	mid-regional pro-atrial natriuretic peptide

MR-proADM	mid-regional pro-adrenomedullin
NPs	natriuretic peptides
NT-proBNP	NT-pro-brain natriuretic peptide
PICP	carboxy-terminal propeptide
sST2	soluble suppressor of tumorigenicity-2 receptor

1 Introduction

Heart failure (HF) is a leading cause of premature cardiovascular (CV) death in patients with established CV disease (Ponikowski et al. 2016). Prevalence of HF has been exhibiting a tendency to worldwide, despite the scientific progress in the field of the two past decades. HF is also characterized by an elevated rate of primary and secondary hospitalization and increased economic burden for patients and their families. Although there are numerous clinical guidelines, which clearly indicated diagnosis, prevention and evidence-based treatment of HF, a strategy regarding exclusion of HF diagnosis, as well as risk stratification of HF, nature evolution of disease is not well established and requires more development (Wettersten and Maisel 2016). In this context, biological markers reflected several pathophysiological stages of HF have become a powerful and convenient noninvasive tool for diagnosis of HF, a stratification of HF patients at risk of progression, HF severity, and biomarker-guided therapy (Ledwidge et al. 2013). The aim of the chapter is to discuss a role of biomarker-based approaches for more accurate diagnosis, in-depth risk stratification and individual targeting in treatment patients with HF.

2 Conventionally Used Biomarkers of Heart Failure

According to The Biomarkers Definitions Working Group Biomarkers are defined as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention (Biomarkers Definitions Working Group (National Institutes of Health) 2001).There are numerous of biomarkers, which reflect several pathophysiological stages of HF and allow stratifying individuals at risk (Fig. 1). Currently updated clinical recommendations have been reported that the natriuretic peptides (NPs), including brain NP (BNP), mid-regional pro-atrial NP (MR-proANP), NT-pro-brain NP (NT-proBNP), mid-regional pro-brain NP (MR-proBNP), are the most frequently used biomarkers in clinical practice to stratify patients at risk of cardiac dysfunction, a risk of admission/readmission to the hospital due to HF-related reasons, and a risk of death (Pouleur 2015), while galectin-3, high-sensitivity cardiac troponins and soluble suppressor of tumorigenicity-2 (sST2) receptor are thought to be promising biomarkers in this respect (Table 1). Most data on cardiac biomarkers have been derived from chronic HF individuals. In contrast, risk prediction in patients admitted to hospital with acute HF remains a challenge.

2.1 Natriuretic Peptides

First NPs were recommended by the European Society of Cardiology and American Heart Association for exclusion HF, and then they were discussed as a tool for risk stratification, and NPs-guided therapy (Ponikowski et al. 2016; Wettersten and Maisel 2016). The majority of NPs' family members (Atrial NP [ANP] and brain [BNP] apart from C-type of NP [CNP]) are mechanical stress-related markers. They are actively released by cardiomyocytes as a result in fluid overload, cardiac stretching, as well as due to exposure to other causes, e.g. ischemia/ necrosis, metabolic and toxic damage, membrane stability loss, and inflammation (Berezin 2017a). ANP is released from atrial granules upon acute volume overload, whereas BNP is stressed-related peptide that does not accumulate before stimulation. In contrast, CNP is secreted from activated endothelial cells and renal cells in response to cytokine activation and through endothelium-dependent

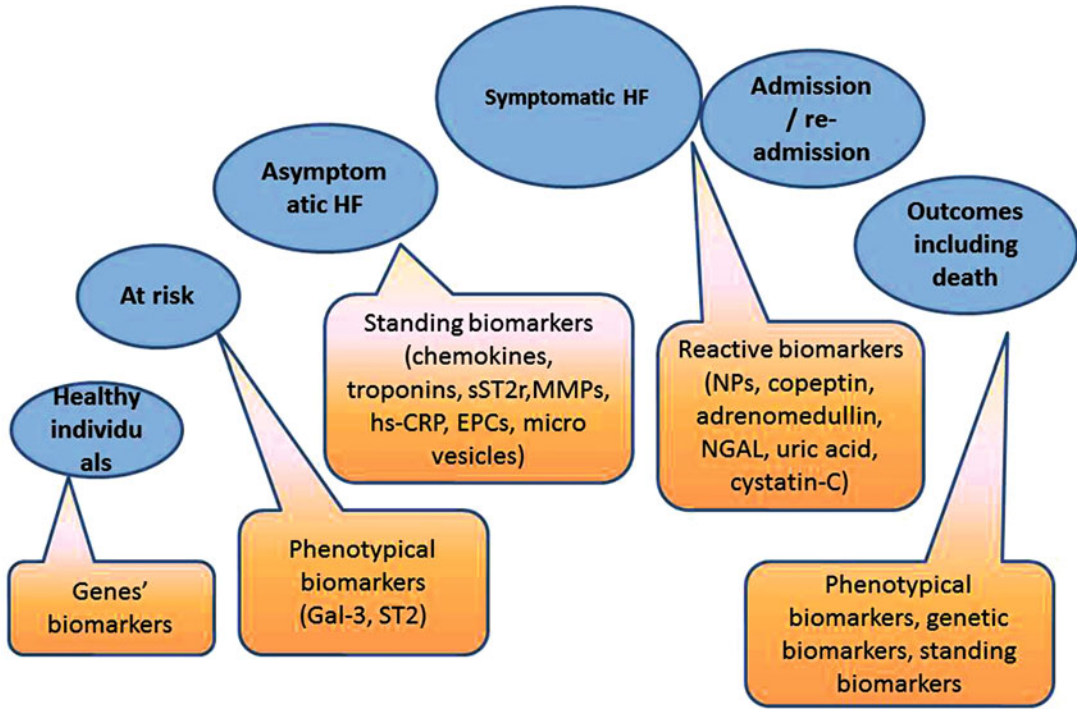

Fig. 1 Schema of practical use of various biomarkers in HF development and progression

agonists, e.g. acetylcholine (Berezin 2017a). The biological effects of ANP and BNP are mediated by binding with appropriate NP receptor type A (NPRA). NPRA are expressed at the surfaces of the target cells and are linked with cGMP mediating water/electrolyte homeostatic effects, i.e. diuresis/natriuresis, increasing glomerular filtration rate, volume of circulating plasma, suppressing systemic sympathetic activities, maintenance of cardiac output and regulation of blood pressure. NPs may demonstrate anti-proliferative activity and anti-mutagenic effect, mediate vascular dilatation and prevent vascular wall hypertrophy (Berezin 2017a). Additionally, NPs show modest anti-aldosterone and endothelin-1 effects.

In patients with HF the plasma levels of BNP and NT-proBNP are typically >100 pg/ml and >250 pg/mL, respectively, while there is high individual biological variability of both biomarkers irrespective of presentation of HFrEF or HFpEF (Felker et al. 2017). Elevated levels of NPs are well correlated with clinical status and severity of HFrEF/HFpEF patients, a risk of developing acute HF regardless etiology of the disease, risk of hospital admission/re-admission, as well as all-cause mortality, CV and HF death in individuals with established HF including at discharge from the hospital after treating HF decompensation (Feng et al. 2017). More recent evidence suggests that NPs along with the next generation of CV biomarkers could provide added predictive value to drug therapy of HF, which could potentially lower HF-related risk of outcomes (Fonarow 2017; Chow et al. 2017).

2.2 Biomarkers of Myocardial Fibrosis

2.2.1 Galectin-3

Galectin-3 is a soluble β-galactoside-binding protein, which is actively secreted by activated mononuclears and macrophages due to inflammatory stimulation. The main biological function

Table 1 Utility of biomarkers in HF management

Suggestions for use	Patients	COR	LOE
NPs (BNP, NT-proBNP or MR-proANP)			
Rule-in or support of initial working diagnosis	Patients with suspected HF in non-acute setting condition with dyspnea	I	A
	Patients with suspected acute and chronic HF, when the etiology of dyspnea is unclear	I	A
	Patients with suspected HF in acute setting condition	IIb	C
Exclusion of important cardiac dysfunction	Outpatients with uncertain signs and symptoms of HF	I	A
Prognosis of HF	Outpatients/inpatients with established HF	I	A
	Patients who were admitted to the hospital with acute HF	I	A
	Postdischarged patients	IIa	B
Prevent development of LV dysfunction or new-onset HF	Patients at risk of HF development	IIa	B
Target therapy	Outpatients with established HF in euvolemic condition	IIa	B
Biomarkers of myocardial injury (cardiac troponins)			
Risk stratification	Patients with established HF	I	A
	Patients who were admitted to the hospital with acute HF	I	A
Biomarkers of myocardial fibrosis (galectin-3)			
Risk stratification	Outpatients with established chronic HF	IIb	B
	Inpatients with established acute and chronic HF	IIb	A
	Post-discharged patients	IIa	B
sST2			
Prognosis of HF	Outpatients/inpatients with established HF	I	A
	Patients who were admitted to the hospital with acute HF	I	A
	Post-discharged patients	IIa	B

Abbreviations: *HF* heart failure, *NPs* natriuretic peptides, *BNP* brain NP, *NT-proBNP* N-terminal fragment of brain NP, *sST2* soluble suppressor of tumorigenicity-2, *MR-proANP* mid-regional pro-atrial NP, *COR* classes of recommendations, *LOE* level of evidence

of galectin-3 is to activate the fibroblasts for further collagen synthesis (Yancy et al. 2017). Recent pre-clinical and clinical studies have revealed the pivotal role of galectin-3 in progressive accumulation of extracellular matrix leading to cardiac fibrosis, cardiac remodeling, and worsening cardiac performances associated with impaired cardiac systolic and diastolic function, dilation of cardiac cavities, and induction of cardiac arrhythmias (Boulogne et al. 2017a; Souza et al. 2017). Galectin-3 in elevated concentrations was measured in a serum of the patients at risk of HF and CV disease (Lala et al. 2017). In patients with acute HF galectin-3 associated with NT-proBNP levels and the estimated glomerular filtration rate but not with age and serum cardiac troponins (Imran et al. 2017). Galectin-3 was not superior to NT-proBNP, sST2 receptor, Growth Differentiation Factor (GDF)-15 or high-sensitive C-reactive protein (hsCRP) in prediction of CV mortality and HF death, while the combination of galectin-3 and NPs was more accurate in predicting HF death compared to either of the biomarkers alone (Besler et al. 2017a).

2.2.2 Soluble Suppressor of Tumorigenicity-2 Receptor

Soluble suppressor of tumorigenicity-2 receptor (sST2) belongs to the interleukin (IL)-1 receptor family members, which has two isoforms, i.e. membrane-bound (ST2L) and soluble (sST2) isoforms. sST2 interacts with its ligand IL-33 and through myocardial mRNA expressions of Th1-related cytokines (tumor necrosis factor-alpha) may directly enhance

cardiac hypertrophy, fibrosis, cavity dilation with impaired cardiac function (Berezin 2017a).

The serum levels of sST2 in acute HF were dramatically increased on admission and appeared to be decreased rapidly depending on clinical improvement. Therefore, sST2 in HF has well correlated with BNP and GDF15 levels (Srivatsan et al. 2015). sST2 levels at discharge were better predictor of HF re-admission than ones at admission (Boulogne et al. 2017b). Although both biomarkers of myocardial fibrosis (sST2 receptor and galectin-3) are predictive of HF-related admission to the hospital and CV death (Billebeau et al. 2017), direct head-to-head comparison of sST2 and galectin-3 revealed superiority of sST2 over galectin-3 in HF risk stratification (Bayes-Genis et al. 2014).

2.3 Biomarkers of Myocardial Injury

Development and progression of HF strongly relates to direct and indirect damages of cardiac cells by effect of etiological factors of cardiac dysfunction (i.e. ischemia/necrosis, inflammation, hypoxia, hypertrophy, fibrosis) as well as by other factors contributing to the pathogenesis of HF (i.e., biomechanical stress due to cardiac remodeling, iron deficiency, oxidative stress/mitochondrial dysfunction). Biomarkers of myocardial injury may be detected in peripheral blood in elevated concentration as a result of leakage through cardiac cell membranes and due to injury of cells. However, regardless of the main cause of cell dysfunction, biomarkers of cardiac cell injury reflect a wide range of pathophysiological process: from instability of lipid layers of membrane due to lipid peroxidation to destroying cell due to necrosis/apoptosis (Berezin 2017a).

There are some biomarkers of myocardial injury and necrosis (cardiac troponins T and I, myoglobin, heart type of fatty acid binding protein, glutathione transferase P1), which are investigated in details as potential predictors of HF onset and HF-related outcomes (Anguita 2017). Since last two decades high-sensitivity cardiac troponins had been suggested to be prognosticators of high risk of CV mortality and combined adverse CV outcomes in HF (Nagarajan et al. 2012; Masson et al. 2010).

3 Biomarker-Guided Therapy of HF

It had been found that NP guided HF therapy improved titration of medications (Feng et al. 2017; Fonarow 2017), but did not lead to better HF clinical outcomes (Wettersten and Maisel 2016; Berezin 2017a). Meanwhile, serial measurements of NPs could be useful for determining the severity of HF for decision about ambulatory and in-hospital medical care. Additionally, NT-proBNP, but not BNP, is better suited during HF therapy based on the new angiotensin-receptor-neprilysin-inhibitor (ARNI) (Malek and Gaikwad 2017). The clinical trials have shown that neprilysin inhibition together with chronic renin-angiotensin system blockage with Sacubitril/Valsartan may increase the bioavailability of NPs and promotes additional cardio-renal benefits and thereby reduce all-cause mortality, CV mortality and HF death (Wong et al. 2017). Because biologically active BNP is degraded by neprilysin, in HF patients treated with ARNI circulating level of BNP sufficiently increases, whereas NT-proBNP concentration declines dramatically. In such situations the principles of NPs-based HF guided therapy are become complicated. Apparently, monitoring of BNP levels is not suitable for risk stratification and HF adjusted medical care, when ARNIs are used, however, NT-proBNP remains useful for risk assessment and HF stratification regardless drug prescriptions (Luchner et al. 2017; Aspromonte et al. 2016; Skaf et al. 2017; Nakanishi et al. 2017). Finally, majority of experts believe that a combination of biomarkers may ultimately prove to be more informative in their predictive ability than single biomarker (Nymo et al. 2017).

4 Limitations in Use of Conventional Biomarkers in HF

Confusingly, the role of NPs in modification of treatment considerably relates to aging, CV disease, metabolic co-morbidities, kidney clearance, metabolism (neprilysin for BNP, glycosylation, methylation, oxidation for other NPs), toxic effect (cardiotoxicity) (Berezin 2016a). Therefore, higher individual biological variability of these biomarkers may impair interpretation of the measured results (Favresse and Gruson 2017). There is a big list of diseases associated with increased level of NPs beyond HF development (Table 2).

Although galectin-3 is an independent predictor of all-cause mortality, CV death and occurrence of HF, there is an inverse relationship

Table 2 The potential causes of changes in circulating NPs' levels

Diseases	Types of changes	Causes for NP evolution	
		Primary	Other
Acute and chronic HF	↑↑↑	Over-production due to myocardial wall stretching/fluid overload	Lowered kidney clearance, cardiac injury
MI/ACS	↑↑	Cardiac injury	Fluid overload, biochemical stress, ischemia/hypoxia
Atrial fibrillation/ atrial flutter	↑↑	Leakage through cardiac myocyte membrane	Cardiac injury
Myocardities/ cardiomyopathy	↑-↑↑↑	Cardiac injury	Leakage through cardiac myocyte membrane due to inflammation, fluid overload, biochemical stress
Cardiac hypertrophy	↑	Leakage through cardiac myocyte membrane	Biochemical stress
Cardioversion	↑	Cardiac injury	Metabolic myocardial damage
Cancer chemotherapy	↑	Toxic-metabolic myocardial insults	Biochemical stress
Valvular and pericardial disease	↑-↑↑	Leakage through cardiac myocyte membrane	Biochemical stress, fluid overload, cardiac injury
Pulmonary hypertension	↑-↑↑	Leakage through cardiac myocyte membrane	Fluid overload, biochemical stress, ischemia/hypoxia
Cardiac surgery	↑	Leakage through cardiac myocyte membrane	Biochemical stress, fluid overload, cardiac injury
Aging	↑	Lowered kidney clearance	Biochemical stress
DM	↑-↑↑	Lowered kidney clearance	Cardiac injury, fluid overload, biochemical stress
COPD	↑↑	Myocardial wall stretching	Fluid overload, cardiac injury
Obesity	↓	Increased degradation by enzymes (glycosylation for NT-poBNP, nephrylisin for BNP)	Increased kidney clearance
Anemia	↑	Leakage through cardiac myocyte membrane	Metabolic myocardial damage, biochemical stress, cardiac injury, ischemia/hypoxia
Renal failure	↑	Lowered kidney clearance	Biochemical stress, metabolic myocardial damage
Critical illness, bacterial sepsis, severe burns	↑-↑↑	Lowered kidney clearance	Metabolic myocardial damage, biochemical stress, cardiac injury, ischemia/hypoxia

Abbreviations: *NP* natriuretic peptide, *HF* heart failure, *ACS* acute coronary syndrome, *MI* myocardial infarction, *COPD* chronic obstructive pulmonary disease, *DM* diabetes mellitus, ↑ mild increase, ↑↑ moderate increase, ↑↑↑ severe increase, ↓ decrease

between serum galectin-3 level and estimated glomerular filtration rate (Besler et al. 2017b). Accordingly, lowered kidney clearance should be taken into consideration, when data of galectin-3 measurement are interpreted. Therefore, older patients contributed to higher galectin-3 concentrations than younger individuals (Krintus et al. 2017). Amongst other biomarkers (NPs, GDF-15, high-sensitivity troponin T, sST2, aldosterone, phosphate, parathyroid hormone, plasma renin, and creatinine), galectin-3 had the lowest individual biological variability, whereas NPs and GDF-15 had the highest ones (Meijers et al. 2017). In contrast to NPs serum galectin-3 levels did not appear to be significantly related to circulating level of cardiac troponins, left ventricular (LV) ejection fraction and LV mass index (Agnello et al. 2017). However, there was a positive correlation between galectin-3 levels and NT-proBNP in HF individuals. Thus, galectin3 and NPs might be considered as the best markers for both short- and long term death prediction in HF regardless kidney function and age. Unfortunately, no biomarker predicted the short-term composite HF endpoints in acute HF (Miró et al. 2017). Additionally, there are controversial findings related to the lack of association of galectin-3 concentration with adverse outcomes in chronic HF (Wojciechowska et al. 2017).

Even sST2 was not associated with age, female sex, LV structure or LV systolic or diastolic function (Maisel and Di Somma 2016; Berezin 2016b; AbouEzzeddine et al. 2017). Thus, these findings confirmed that the sST2 is a marker of systemic inflammation and fibrosis with predictive ability regarding all-cause and CV death in HF (AbouEzzeddine et al. 2017; Aimo et al. 2017).

5 Novel Biomarkers for HF Management

The discovery of new biomarkers is promising, but rarely novel molecules prove to be significantly better in diagnostic and predictive value than the established biomarkers. In addition to the various types of NPs, galectin-3, sST2, high-sensitive cardiac troponins, several other biomarkers have been investigated to be better predictors in HF (Table 3).

5.1 Procalcitonin

Procalcitonin is propeptide of calcitonin, which is normaly produced and actively secreted by the parafollicular C cells of the thyroid gland (Ryu et al. 2015). Procalcitonin/calcitonin axis is essential for regulation of calcium homeostasis and immunity (Berezin 2017a). The preclinical and clinical studies have shown that extrathyroidal production of procalcitonin markedly increases in cases of systemic inflammatory reaction, severe infections (viral, bacterial, fungal and parasitic), and shock (Reiner et al. 2017; Hayashida et al. 2017; Simon et al. 2004). Although serial measurements of procalcitonin are recommended to discriminate of in-hospital mortality in various diseases associated with pro-inflammatory activation (pneumonia, chronic obstructive pulmonary disease, acute respiratory tract infections, sepsis, etc.), there is evidence that the serum procalcitotin levels might be a predictive biomarker for chronic HF (Simon et al. 2004). Large clinical trials are required to obtain evidence for a predictive role of procalcitonin in exacerbated HF individuals.

5.2 Copeptin

Copeptin is C-terminal derivative of the arginine vasopressin that normally acts as regulator of water and electrolyte homeostasis (Morgenthaler 2006). Although plasma levels of copeptin are very variable and tightly relate to blood/urine osmolality, copeptin appears to be in higher concentrations in sever hypertension, stroke, acute and chronic HF, myocardial infarction,

Table 3 The promising novel biomarkers for HF depending on HF phenotypes

Related pathophysiological processes in HF	HF phenotype	Biomarkers	Relevance to clinical outcomes in HF
Myocardial biochemical stress	Any	MR-proANP	All-cause, CV and HF-related mortality, risk of hospital re-admission at discharge, risk of HF deterioration
Neurohumoral activation	HFrEF	Copeptin	All-cause and HF-related death, CV mortality, hospital admission rate
	HFrEF	CT-proET-1	NYHA stage
	HFrEF	ADM/MR-proADM	All-cause mortality, CV mortality and HF-related death in acute HF
Myocardial fibrosis	HFpEF/ HFmrEF	PICP	AF, CV mortality, MI, HF-related death
	HFpEF/ HFmrEF	CITP	AF, CV mortality, MI, HF-related death
	HFpEF/ HFmrEF	PIIINP	All-cause mortality, CV mortality, MI, HF-related death
	HFpEF, HFmrEF	MMPs	All-cause, CV and HF-related mortality in acute HF, ADHF, risk of HF admission in HF
Myocardial necrosis	Any	hFABP	CV and HF-related mortality
	Any	GSTP1	MI mortality, CV events and HF admission
Vascular remodeling	Any	OPN	CV mortality, MI, HF onset
	HFpEF/ HFmrEF	OPG	CV mortality, MI, HF onset
	Any	Signature of miRNAs	All-cause and CV mortality, MI, HF onset, HF progression
Inflammation	HFrEF	hs-CRP	NYHA stage of HF, risk of death in ADHF
	HFrEF	Procalcitonin	ADHF, acute HF, CV death, readmission rate
	HFrEF	GDF-15	CV mortality, HF deterioration
Oxidative stress	HFrEF	Uric acid	All-cause and CV mortality
	HFrEF	Myeloperoxidase	All-cause and CV mortality in ADHF, acute HF, HF-related outcomes in chronic HF
	HFpEF/ HFmrEF	Ceruloplasmin	Risk of HF deterioration, NYHA-stage
	HFpEF/ HFmrEF	8-OHdG	
	HFpEF/ HFmrEF	Trx1	
Renal dysfunction	HFrEF	Cystatin C	All-cause and CV mortality, HF-related death, HF readmission in acute HF
	HFrEF	NGAL	HF-related death in acute HF and ADHF
Metabolomic state	HFrEF	Signature of metabolomics (fatty and amine acids, Krebs cycle components, DNAs, lipids, glucose, variable very-long chain carbons, proteins, hormones, enzymes ets.)	HF-related death, CV mortality, hospital re-admission rate

(continued)

Table 3 (continued)

Related pathophysiological processes in HF	HF phenotype	Biomarkers	Relevance to clinical outcomes in HF
Endothelial dysfunction	HFpEF, HFrEF, HFmrEF (?)	EPCs	All-cause mortality, CV mortality, HF-related death, admission/ readmission rate
	Any	EMPs	

Abbreviations: *ADHF* acutely decompensated heart failure, *AF* atrial fibrillation, *MR-proANP* mid-regional pro atrial natriuretic peptide, *ADM* adrenomedullin, *MR-proADM* mid-regional pro-adrenomedullin, *PICP* carboxy terminal propeptide, *CT-proET-1* C-terminal-pro-endothelin-1, *CITP* carboxy-terminal telopeptide, *PIIINP* amino-terminal peptide of procollagen type III, *HF* heart failure, *hs-CRP* high-sensitive C-reactive protein, *hFABP* high-sensitive fatty acid binding protein, *GDF* growth differentiation factor, *EPCs* endothelial progenitor cells, *EMPs* endothelial cell-derived micro particles, *MI* myocardial infarction, *MMP* matrix metalloproteinase, *NGAL* neutrophil gelatinase-associated lipocalin, *8-OHdG* 8-hydroxy-2′-deoxyguanosine, *Trx1* thioredoxin 1, *GSTP1* glutathione transferase P1

diabetes mellitus, advanced kidney diseases, and in critical conditions. As quantitative biomarker of endogenous biomechanical stress elevated level of copeptin was found in close positive association with increased CV mortality and CV disease in out-patients and all-cause mortality in critical states (Remde et al. 2016). There is a large body of evidence that the serial measurements of copeptin level may be provide an important information for discrimination of a risk of all-cause mortality, HF-related outcomes and CV events and diseases (Moayedi and Ross 2017; Krane et al. 2017; Yan et al. 2017a; Berezin 2015a). Although both increased NT-proBNP levels and copeptin levels were recognized significant independent predictors of adverse clinical outcomes in HF, the role of dual marker contribution in HF risk stratification remains to be clarified (Savic-Radojevic et al. 2017; Smaradottir et al. 2017; Sahin et al. 2017; Herrero-Puente et al. 2017).

5.3 Heart Type of Fatty Acid Binding Protein

The heart type of fatty acid binding protein (hFABP) is normally essential for the long-chain fatty acids re-uptake, regulation of calcium homeostasis in cardiomyocytes and mediating inflammatory reaction (Chmurzynska 2006). Because hFABP is tissue-specific biomarker of myocardial injury and necrosis, it is reserved as predictor of myocardial infarction at the early hours of development of the disease. Recent studies have shown that circulating levels of hFABP are elevated in cardiac dysfunction and closely predicted CV outcomes and HF-related events in in-patients especially in those who had fluid retention and lung congestion (Savic-Radojevic et al. 2017; Chmurzynska 2006; Qian et al. 2016; Kitai et al. 2017). Although elevated serum level of hFABP yielded better prognostic information on survival in individuals with acute and advanced HF when compared to NPs, cardiac troponins and even galectin-3 taken alone, there is confusion about the improved precision of entire predictive model after incorporating hFABP to NPs and/or galectin-3 (Savic-Radojevic et al. 2017; Qian et al. 2016; Kitai et al. 2017).

5.4 Growth Differentiation Factor-15

Growth differentiation factor (GDF)-15 is multifunctional cytokine that belongs to the transforming growth factor-β superfamily (Kempf and Wollert 2009). GDF-15 is normally expressed in various cells including immune cells, fibroblasts, myocardial cells, endothelial cells, and mononuclears. Additionally, GDF-15 is actively secreted into circulation by cardiac myocytes due to stretching and biochemical stress (Berezin 2015a; Kempf and Wollert 2009; Chan et al. 2016).

Serum levels of GDF-15 are associated with increased risk of all-cause death independent of age, clinical signs and symptoms of cardiac dysfunction, LVEF, renal function and NPs in HF (Hage et al. 2017). Interestingly, in in-patients with acute HF the serum levels of GDF-15 were not better to NPs and galectin-3 taken alone in accuracy to predict HF-related outcomes including death and re-admission to the hospital after discharge (Demissei et al. 2017). In contrast, out-patients with chronic HFrHF/HFpEF may be candidates to multiple predictive biomarker strategy based on collective measurement of NPs, GDF-15, and galectin-3 (Berezin et al. 2015a; Berezin 2015b).

5.5 Endothelial Cell-Derived Micro Particles and Endothelial Progenitor Cells

Impaired endothelial function plays a pivotal role in HF development and HF-related complications and also associates with an appearance in the peripheral blood of specific circulating biomarkers, i.e. endothelial microparticles (EMPs) and endothelial progenitor cells (EPCs) (Berezin et al. 2015a; Berezin 2015b; Berezin at al. 2016). Recent clinical studies have shown that an ability of mature endothelial cells and their precursors to release of secretom progressively worse depended on HF stage and severity (Berezin 2015b, c; Berezin et al. 2014a, 2015b, 2016c). There is novel HF risk prediction score created by means of biomarkers, e.g. NPs, galectin-3, high sensitive CRP and estimated ratio between both numbers of apoptotic EMPs and EPCs (Berezin et al. 2015b; Berezin 2015d). However, it is not clear whether new predictive models would be effective in HF treatment. More clinical trials are required to improve our understanding in the field of individualized therapy of HF under biomarker control.

5.6 Biomarkers of Collagen Metabolism

Recent studies have shown that impaired collagen metabolism may alter the myocardial collagen network, enable cardiovascular remodeling, and mediates HF complications, i.e. atrial fibrillation/flutter, sudden death, and decline in LV pump function (Löfsjögård et al. 2014). Interestingly, there is evidence regarding causative role of BNP in alterations in collagen type I metabolism in HFrEF (Berezin 2016c). The OPTIMAL (The Optimizing Congestive Heart Failure Outpatient Clinic trial) revealed that disturbances of collagen type I metabolism are independent predictors of long-term, all-cause mortality and CV mortality in HFrEF individuals (Löfsjögård et al. 2017). Therefore, circulating CITP is probably an independent predictor of survival in patients with HFrEF (Tziakas et al. 2012).

5.7 Matrix Metalloproteinases

Development of HF strongly associates with CV remodeling, biomechanical and oxidative myocardial stress, neurohormonal and inflammatory activation that are modulated by matrix metalloproteinases (MMPs). It has demonstrated that MMPs determine extracellular accumulation of collagen and mediate pro-fibrotic processes (Berezin and Samura 2013). Recent pre-clinical and clinical studies have shown that an impairment of cardiac function may relate to the collagen accumulation due to an imbalance between expression of MMPs, predominantly MMP-1, MMP-3, MMP-6, MMP-9, and suppression of their tissue inhibitors (Collier et al. 2011; Hutchinson et al. 2010; Berezin et al. 2015c). However, the predictive value of these biomarkers was not confirmed and requires more future investigations.

5.8 Biomarkers of Oxidative Stress

5.8.1 Serum Uric Acid

Observational and clinical studies have shown that the elevated level of serum uric acid (SUA) is a common feature in patients with HF, hypertension, atherosclerosis, obesity, diabetes mellitus and chronic renal disease (Grassi et al. 2013; Borghi et al. 2015). The role of SUA in pathogenesis of CV disease is controversial. On the one hand, SUA induces an oxidative stress through over-production of reactive oxygen species. SUA often impairs vascular function via enhancement of inflammatory damage, inducing vascular calcification and directly via cell membranes deterioration effect (Grassi et al. 2013). On the other hand, low-grading inflammation that is frequently found in HF may cause xanthine oxidase over-activity and leads to increased tissue SUA accumulation, which acts as scavenger of free radicals and protects against an damaging effect of oxidative stress (Berezin and Kremzer 2013; Berezin 2014). Additionally, an increase of SUA may be an attribute of lowered kidney clearance in a progress of HF. Therefore, there is evidence regarding the regulatory role of SUA in EPC differentiation that allow discussing uric acid as a mediator of reparation of tissues in HF (Berezin et al. 2014b).

Numerous clinical studies have emphasized the predictive role of baseline SUA for early post-discharge HF outcomes (Amin et al. 2017; Okazaki et al. 2016, 2017). Interestingly, the activity of xanthine oxidoreductase that is a key rate-limiting enzyme of purine degradation may be more accurate predictor of HFrEF severity and HF clinical outcomes than SUA (Otaki et al. 2017; Huerta et al. 2016; Kim et al. 2013). Consequently, SUA remains an established risk factor of clinical outcomes in acute HF (Berezin 2017b), while poor prognosis in patients with chronic HF is not elucidated (Berezin 2017c).

5.8.2 Other Biomarkers of Oxidative Stress

Serum levels of myeloperoxidase, vitamin D3, ceruloplasmin and 8-hydroxy-2-′-deoxyguanosine correlate with staging of chronic HF regardless of LVEF and predict a development of HFrEF, while the role of these biomarkers of oxidative stress remains under discussion (Chan et al. 2016; Mozos et al. 2017). Although there is evidence regarding the close link between vascular remodeling (Berezin 2017d; Mozos and Marginean 2015), endothelial dysfunction and CV disease the predictive role of vitamin signature in serum (i.e., vitamin A, B12, D, K, C and E) in HF individuals is not still clear and requires to be investigated (Berezin 2017c).

5.9 Biomarkers of Renal Dysfunction in HF

5.9.1 Cystatin C

Cystatin C is an endogenous inhibitor of cysteine proteases and this biomarker is discussed as an alternative predictor of CV events in acute and chronic HF patients with any types of cardiorenal syndrome (Kim et al. 2013). The patients with HFrEF demonstrated elevated serum cystatin C, especially in cases with serious risk of CV complications (Kim et al. 2013). Additionally, increased cystatin C level in hypertensive patients with HFpEF was found (Berezin 2017d). It appears to be associated with LV diastolic dysfunction and alterations in collagen metabolism regardless of estimated GFR (Berezin 2017d). Although cystatin C has now validated a powerful predictor of CV outcomes and kidney injury, its sensitivity in patients with chronic HF is inferior to that of hs-CRP and NPs (Berezin 2017c). In contrast, in acute HF Cystatin C provided an incremental value for prognosis more than NT-proBNP and uric acid (Kim et al. 2015; Taub et al. 2012).

5.9.2 Other Biomarkers of Kidney Injury in HF

There are many perspective biomarkers of kidney injury that could be useful for stratification of HF at risk, i.g. stromal cell-derived factor-1, exosomes, MPs, neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1, interleukin-18 and miRNAs (Berezin 2017d; Taub et al. 2012). Although they are at the early stages of renal dysfunction prior to any elevations in serum creatinine, the prognostication of clinical outcomes in acute HF and chronic HF require more investigations.

5.10 Genetic Biomarkers

By now, genetic testing has incorporated as a part of patient evaluation for suspected inherited cardiomyopathies (Teekakirikul et al. 2013; Teo et al. 2015). It turns out the epigenetic modifications through DNA methylation, ATP-dependent chromatin remodeling, histone modifications with an involvement of microRNA-related mechanisms might be sufficient pathophysiological factors contributing to adverse cardiac remodeling and altered cardiac function (Hershberger and Siegfried 2011). In this context, the novel risk scores reflecting variabilities in genetic and epigenetic features in HF development appear to be promising (Berezin 2016d; Yang et al. 2015; Lopes and Elliott 2013). Indeed, some early studies have reported interesting results with respect to genetic precursors of HFpEF and HFrEF (Berezin 2016e; Fazakas et al. 2016; McNamara et al. 2014; Friedrich et al. 2013; Hofman et al. 2010; Sutter et al. 2013; Kolder et al. 2012). There are numerous studies depicted the role of single nucleotide polymorphisms (SNPs) of genes encoding enzymes related to oxidative stress (Berezin 2016e), genotype of guanine nucleotide-binding proteins (G-proteins) beta-3 subunit (GNB3) (Fazakas et al. 2016), transcription factor Islet-1 gene (McNamara et al. 2014), troponin T (Friedrich et al. 2013), CYP2D6 polymorphism (Hofman et al. 2010), cardiac myosin binding protein-C mutations (Sutter et al. 2013), renin-angiotensin-aldosterone system polymorphism (Kolder et al. 2012) etc. in HF development and progression. It is well known that angiotensin-converting enzyme (ACE) I/D gene D allele was associated with higher overall mortality as compared with the I allele in HF patients and that the effect could be modified by ACE inhibitors' given (Wu et al. 2010). Additionally, ACE DD and angiotensin-1-receptor 1166 CC genotypes may synergistically increase the predisposition to HFpEF (Kolder et al. 2012; Wu et al. 2009, 2010).

The ARIC (Atherosclerosis Risk in Communities) study reported that none of the metabolite SNPs including pyroglutamine, dihydroxy docosatrienoic acid were individually associated with incident HF, whereas a genetic risk score created by summing the most significant risk alleles from each metabolite determined 11% greater risk of HF per allele (Yu et al. 2013). (Ganna et al. 2013) have reported that amongst 707 common SNPs associated with 125 diseases including HF it would not be easy to obtain explainable results by common genetic variants related to HF development. Consequently, a close gene-gene interaction may determine an individual's risk of HF through different pathways including epigenetic modifications. All these findings lead to the assumption that genes score might be a powerful tool for prediction of HF development.

More successful genome-wide linkage studies toward genes-related contribution in HF have been done by incorporating SNPs of several genes (i.g. the bradykinin type 1 receptor gene, angiotensin-II type I receptor gene, the β1-adrenoceptor gene and CYP2D6 polymorphism) in predictive score to benefit and suffer harm from HF therapy. Although these pharmacogenetic studies have focused on promised topics, the obtained results have not been absolutely consistent (Ganna et al. 2013; Yip and Pirmohamed 2013; Nelveg-Kristensen et al. 2015). In contrast, there is evidence that the gene expression profiles might be useful rather for risk prediction in HF than for choosing HF treatment regime (Bondar et al. 2014; Berezin

2016f). Thus, the clinical implementation of the HF therapy based on genes scoring remains uncertain and requires more evaluation in the future (Poller et al. 2017).

5.11 Micro-RNAs

It has been established that microRNAs (miRNA) are involved in the development and progression of HF across all pathophysiological stages of the disease (Berezin 2016d). miRNA are epigenetic regulators of myocardial response and fibrosis, growth of cardiac myocytes, cardiac and vasculature reparation, immunity, angiogenesis, and inflammation (Berezin 2016e). The altered miRNA' signature was found in patients with asymptomatic and symptomatic HF (Jin et al. 2017; Vegter et al. 2017; Yan et al. 2017b). It has suggested the signatures of non-coding RNAs would be candidate to improve diagnosis and prognostication of HF (Wong et al. 2014).

5.12 Mid-Regional pro-Adrenomedullin

Mid-regional pro-adrenomedullin (MR-proADM) is the prohormone of the CV protein adrenomedullin and it is well-established neurohumoral marker of cardiac biochemical stress that is raised in patients with infections, acute dyspnea, acute HF, severe chronic HFrEF/HFpEF, unstable angina pectoris/myocardial infarction, and throughout the first week after stroke (Bustamante et al. 2017). There is evidence that the MR-proADM is an early predictor of in-hospital mortality due to various reasons, i.e. respiratory infections, surgical procedure and CV diseases (Odermatt et al. 2017; Dres et al. 2017; Lopes and Menezes Falcão 2017). MR-proADM as a marker of biomechanical stress and fibrosis was not better than NPs and did not exhibit equal predictive value to sST2r and galectin-3 in HFrEF/HFpEF (Lopes and Menezes Falcão 2017). Interestingly, sST2 was better to MR-proADM, because it is more closely related to left ventricular remodeling and cardiac fibrosis. Moreover, MR-proADM did not improve a risk stratification based on NPs in patients with chronic HFrEF and moderate anaemia (Welsh et al. 2017). Thus, the role of MR-proADM as a component of biomarker-based stratification is discussable, may contribute to determine the short-term outcomes of critical ill patients with acute severe dyspnea, respiratory infection and acute HF.

6 Validation of Multiple Biomarker Predictive Scores

Despite several predictive scores based on biomarkers' measurement and approved for chronic HF, predictive scores for acute HF have not been validated (Bayes-Genis and Ordonez-Llanos 2015; Cohen-Solal et al. 2015). Current multiple biomarker scores for prognostication, risk stratification and diagnosis of HF (Fig. 2) are based on NPs in combination with biomarkers of myocardial injury and fibrosis (galectin-3 and sST2 receptor). A new score was validated by the American Heart Association/American College of Cardiology (2017), suitable for patients at risk of HF, with established chronic HF (for both HFrEF and HFpEF), with suspected and documented acute HF (at admission), as well as patients with HF at discharge from the hospital.

Interestingly, there are several attempts regarding use of biomarkers to stratify at risk patients with HFrEF and HFpEF. Whether add-on biomarkers are needed to improve cumulative predictive value for wide spectrum of HF individuals with different HF phenotypes, co-morbidities, ages and sex-related peculiarities is not fully clear. There is no clarity and consistent evidence for multiple biomarker strategy in improvement in CV mortality and CV outcomes. It has been suggested that sST2 and galectin-3 could improve prognosis in HF-related hospitalization and CV death, when added to NPs. This strategy is confirmed by experts of various

medical associations and is the only one that is validated now (Chow et al. 2017).

7 Conclusions

There are many controversies regarding the importance of biomarkers as predictors of survival and in diagnosis of HF. Improvement of clinical guideline recommendations for optimizing HF therapy in routine clinical practice under biomarkers' control is required. Obviously, galectin-3 or sST2r would be optimal for improving NPs- based biomarker strategy in HF individuals, while there is evidence regarding other biomarkers that could individualize stratification of risk and treatment. There is need of larger clinical trials in order to head-to-head compare different biomarkers and clarify their role in diagnosis and guided therapy of HF.

Evolving Role of Natriuretic Peptides from Diagnostic Tool to Therapeutic Modality

Ines Pagel-Langenickel

Abstract

Natriuretic peptides (NP) are widely recognized as key regulators of blood pressure, water and salt homeostasis. In addition, they play a critical role in physiological cardiac growth and mediate a variety of biological effects including antiproliferative and anti-inflammatory effects in other organs and tissues. The cardiac release of NPs ANP and BNP represents an important compensatory mechanism during acute and chronic cardiac overload and during the pathogenesis of heart failure where their actions counteract the sustained activation of renin-angiotensin-aldosterone and other neurohormonal systems. Elevated circulating plasma NP levels correlate with the severity of heart failure and particularly BNP and the pro-peptide, NT-proBNP have been established as biomarkers for the diagnosis of heart failure as well as prognostic markers for cardiovascular risk. Despite activation of the NP system in heart failure it is inadequate to prevent progressive fluid and sodium retention and cardiac remodeling. Therapeutic approaches included administration of synthetic peptide analogs and the inhibition of NP-degrading enzyme neutral endopeptidase (NEP). Of all strategies only the combined NEP/ARB inhibition with sacubitril/valsartan had shown clinical success in reducing cardiovascular mortality and morbidity in patients with heart failure.

Keywords

Natriuretic peptides · ANP · BNP · NT-proBNP · CNP · Heart failure · Biomarker · NP receptors · Neprilysin · ARNI · Sacubitril/valsartan

1 Natriuretic Peptides – Characterization and Biological Effects

The family of natriuretic peptides (NP) comprises genetically distinct but structurally homologous peptides including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP) (Potter et al. 2009). Some publications also attribute Dendroaspis natriuretic peptide (DNP) (Schweitz et al. 1992; Burnett 2006) and urodilatin (Forssmann et al. 1998) to this group which continues to expand with new peptides being discovered (Nobata et al. 2010). The typical 17 amino acid ring structure of the NPs is determined by an intramolecular disulfide bridge and contains several common amino acids. Particularly ANP is well preserved among different

species, suggesting an important phylogenetic role for these peptides in osmoregulation (Vlasuk et al. 1986).

NPs mediate their actions via the activation of membrane-bound guanylyl cyclase-coupled receptors (NPR-A and NPR-B) (Tremblay et al. 2002) and the subsequent formation of cyclic guanosine monophosphate (cGMP) (Hamet and Tremblay 1991) (Fig. 1a). The physiological effects of the NP are terminated by either the cleavage of the peptides by neutral endopeptidase (NEP 24.11, neprilysin) (Charles et al. 1996), or the binding to a transmembrane clearance receptor (NPR-C) (Rademaker et al. 1997) followed by intracellular degradation. Whereas ANP and BNP are synthesized and released from atrial or ventricular cardiomyocytes, CNP is predominantly secreted by endothelial cells upon various stimuli. The main biological function of the NPs along the cardiorenal axis is regulation of electrolyte and water homeostasis in response to changes in intravascular volume and blood pressure. Furthermore, antiproliferative effects involving cardiomyocytes and non-myocytes play an important role in maintaining myocardial structure and function (Burnett 2006). More recently, an important role of NPs in the regulation of metabolic processes such as lipolysis, mitochondrial fatty acid oxidation and glucose homeostasis has been revealed (Schlueter et al. 2014) (Fig. 1b).

1.1 ANP

As the first in this group ANP was discovered in 1981 by *de Bold* and colleagues (1981) who found that the injection of atrial extracts elicited a potent natriuretic effect in rats. Subsequent studies revealed that this peptide hormone is predominantly expressed in atrial cardiomyocytes and stored in preformed granules (Corthorn et al. 1991); only a small percentage is found in ventricles under physiological conditions. In humans, ANP is synthesizes as a 151 amino acid (aa) prohormone (prepro-ANP) and, after cleavage of a signal peptide, 126 aa proANP is stored in the atrial granules. Upon secretion of the C-terminal 28 aa biologically active ANP an equimolar amount of N- terminal peptide, NT-proANP, is released into the blood (Mathisen et al. 1993), the final step being facilitated by the cardiac serine protease corin (Yan et al. 2000).

In response to atrial stretch (Dietz et al. 1995) ANP released into the circulation, binds selectively to the NPRs and promotes natriuresis, diuresis and vasodilation; the same effect could be observed after volume or salt load (Eskay et al. 1986), mineralocorticoid administration (Gardner et al. 1986), rapid atrial pacing (Espiner et al. 1985), angiotensin II or endothelin-1 administration (Ruskoaho et al. 1997), hypoxia (Chen 2005) and adrenergic stimulation (Wong et al. 1988). The renal effects can be attributed to an augmented intrarenal perfusion with increased renal blood flow, increased glomerular filtration rate as well as reduced tubular sodium reabsorption (Weidmann et al. 1986; Marin-Grez et al. 1986). Hemodynamic effects are caused by a direct, endothelium-independent vasorelexation that leads to a reduction of the peripheral resistance, a shift of intravascular fluid to the extracellular space (Lang et al. 1987) in combination with a reduction of cardiac output, and inhibition of the activity of the renin-angiotensin-aldosterone (RAAS) and arginine vasopressin systems (AVP). The net effects include a reduction of intravascular fluid and cardiac filling and a reduction of systemic and pulmonary arterial pressure. This mechanism is particularly relevant in conditions with systemic neurohormonal activation such as heart failure and hypertension. Interestingly, no reflex tachycardia was observed after ANP-induced blood pressure reduction, an effect that is due to the modulatory effect of ANP on cardiac baroreceptors (Volpe 1992).

Adding yet another facet to the spectrum of their properties, NPs are emerging as important regulators of energy consumption and metabolism, pointing towards a "*heart-adipose tissue connection*" (Schlueter et al. 2014; Ramos et al. 2015; Collins 2014). Recent studies demonstrate that NPs are able to promote adipocyte lipolysis (Sengenes et al. 2000), lipid oxidation and mitochondrial respiration via a cGMP-dependent pathway. ANP infusion in humans induced lipolysis systemically and in subcutaneous adipose

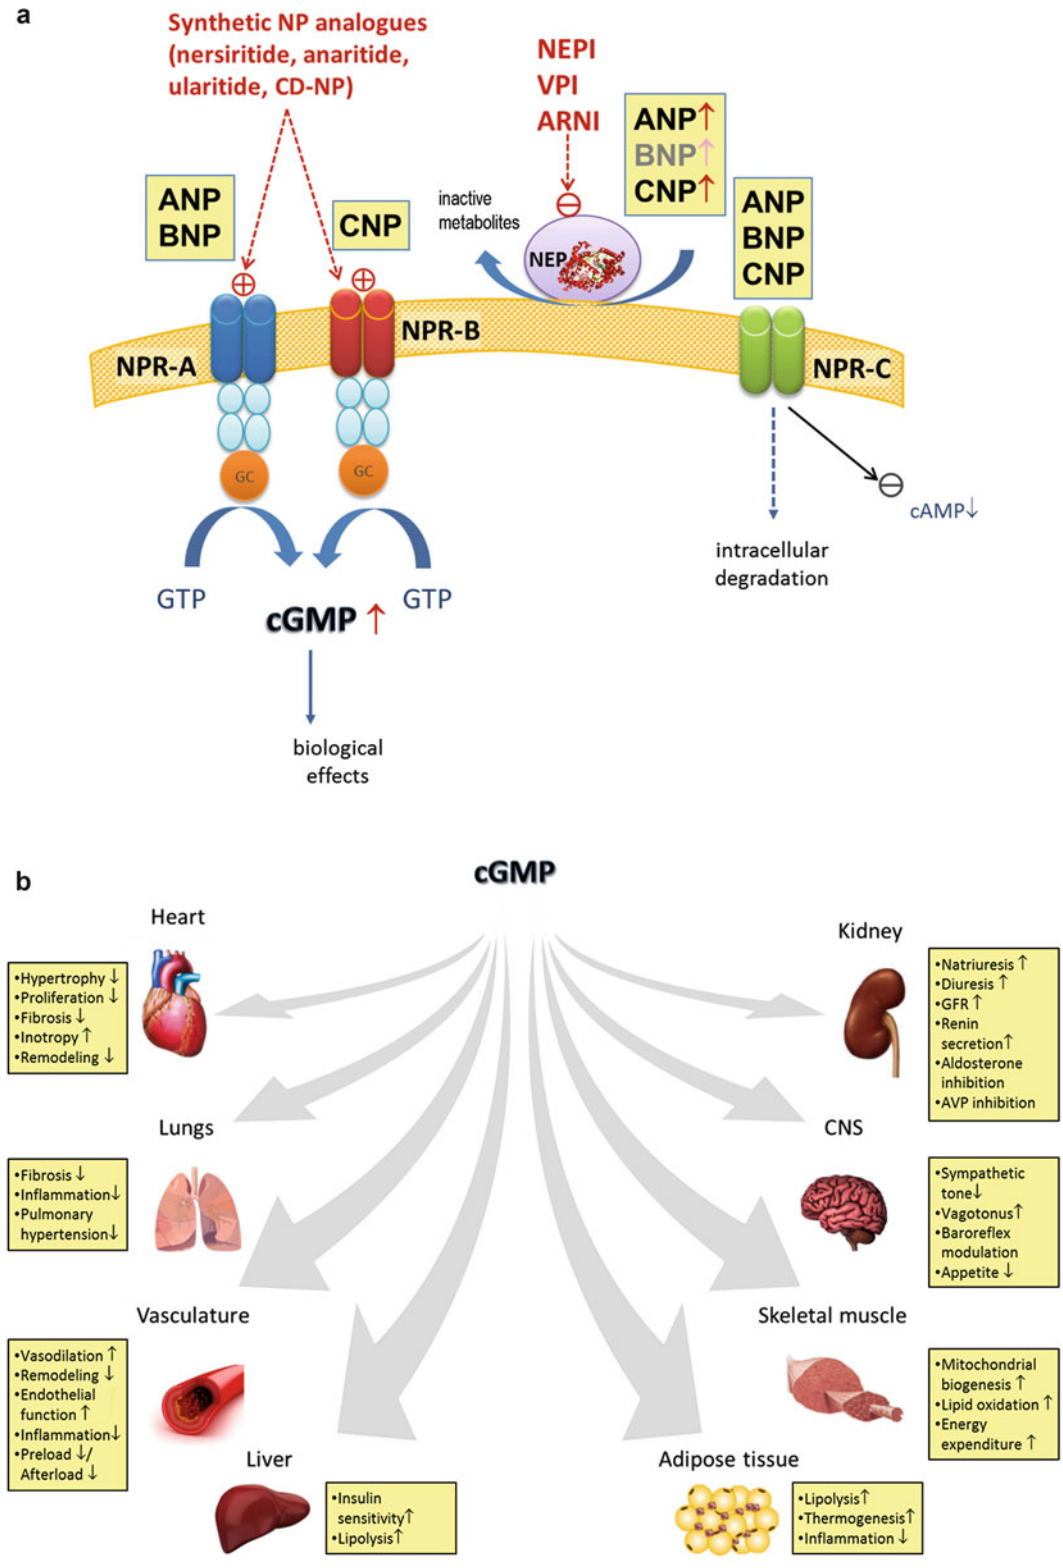

Fig. 1 (**a**) NP signaling and therapeutic modalities (in red), (**b**) physiological effects

tissue. These effects were associated with increased oxidative capacity of skeletal muscle and postprandial energy expenditure (Birkenfeld et al. 2008). The complex regulatory pathway that leads to activation of lipid oxidation and oxidative phosphorylation involves the orchestration of local adipose tissue concentrations of NPs through regulation of their clearance, mitochondrial biogenesis via upregulation of peroxisome proliferator-activated receptor (PPAR)-γ coactivator (PGC)-1α, nuclear receptor PPARδ as well as downstream genes encoding components of the respiratory chain complexes (Engeli et al. 2012). Mitochondrial biogenesis in turn plays a critical role in the pathophysiology of insulin resistance in diabetes (Pagel-Langenickel et al. 2010) and targeting this signaling cascade could represent an attractive therapeutic approach in patients with cardiovascular diseases complicated by metabolic syndrome. Taken together, these metabolic effects could contribute to a relative protection against diet-induced obesity and insulin resistance. This hypothesis is further supported by the observation that mice lacking NPR-A are more susceptible to weight gain and insulin resistance while BNP transgenic mice are relatively resistant when fed on a high-fat diet (Miyashita et al. 2009).

1.2 BNP

Despite being first isolated from porcine brain (Sudoh et al. 1988), BNP is the major NP of the cardiac tissue and is synthesized in both atria and ventricles (Kambayashi et al. 1990; Luchner et al. 1998). In atrial granules BNP is stored together with ANP (Hasegawa et al. 1991) and co-secretion of both peptides has been described (Toth et al. 1994), explaining the close correlation of plasma ANP and BNP levels in healthy individuals. Similar to ANP, the precursor preproBNP is synthesized by cardiomyocytes and processed to proBNP involving the convertases corin and furin (Ichiki et al. 2013). The C-terminal 32 aa fragment is secreted as active BNP together with the inactive N-terminal fragment, NT-proBNP that consists of 76 aa. Ventricular stretch seems to be the main stimulus for BNP release and elevated BNP levels have been found in conditions with elevated left ventricular enddiastolic pressure and pulmonary artery wedge pressure (Richards et al. 1993). The physiological effects of BNP are comparable to ANP although the biological half-life of BNP is longer: in humans it is 19 min for BNP compared to 4.5 min for ANP (Florkowski et al. 1994; Biollaz et al. 1987) which results from slower degradation by neprilysin. Similar to ANP, BNP has been identified as a potential regulator of metabolic pathways. An inverse relationship between plasma BNP levels and those of the anorexigenic peptide leptin has been found in patients with heart failure (Melenovsky et al. 2013). BNP infusion reduced plasma glucose level and, similarly, BNP overexpression has been associated with improved glucose tolerance and lower blood glucose levels. Conversely, low BNP levels were correlated with insulin resistance and type 2 diabetes in an epidemiological study (Kroon et al. 2012).

1.3 CNP

As the third member of the NP family the 22 aa peptide CNP has been identified by Sudoh et al. in 1990. In contrast to ANP and BNP, the heart is not the main source of CNP synthesis. It is abundant in the brain, particularly in the cerebellum and hypothalamus, chondrocytes and cardiac tissue. CNP shows high expression levels in the kidney (Mattingly et al. 1994) involving proximal, distal and medullary collecting duct tubular cells and has been detected in urine samples. Similar to the other NPs, mature CNP is generated after several cleavage steps from a 126 aa pre-pro peptide. Important stimulators of CNP secretion are cytokines and growth factors including TNF-α, interleukins, TGF β, and shear stress. In addition, ANP and BNP directly stimulate the endothelial synthesis and secretion of CNP. CNP is thought to mediate its action in a paracrine fashion predominantly in the vasculature (Ueno et al. 1997) and can be detected at very low levels in the blood. The different spectrum of activity

(Clavell et al. 1993) with almost no effect on sodium and water balance can be explained by higher affinity for the NPR-B compared to the NPR-A. Important effects of CNP are the potent arterial and venous vasodilation as well as antiproliferative effects due to inhibition of mitogenesis in the fibroblasts (Horio et al. 2003; Cao and Gardner 1995), endothelial and smooth muscle cells (Furuya et al. 1995). In addition, CNP ameliorates pulmonary hypertension along with a reduction of fibrosis and inflammation in animal models (Itoh et al. 2004; Kimura et al. 2016).

1.4 DNP

Dendroaspis natriuretic peptide (DNP) has been first described in snake venom (Schweitz et al. 1992) but has also been detected in human plasma (Schirger et al. 1999). The peptide shows a high structural homology to ANP and causes comparable diuretic and natriuretic effects when given as infusion in dogs (Lisy et al. 1999). This was accompanied by a significant reduction in mean arterial pressure and increase in circulating levels of the second messenger cGMP, indicating that the GC activation after binding to the NPR plays a role for its biological effect. DNP binds with high affinity to the NPR-A and does not seem to be susceptible to degradation by neprilysin (Dickey and Potter 2011).

1.5 Urodilatin

Lacking a circulating form in the blood, urodilatin was first detected in urine and found to be synthesized in the kidney where it is secreted into the lumen of the distal tubules. In contrast to the other NPs there is also no storage of an urodilatin precursor in the renal tissue. The high homology to ANP with only a 4 aa extension at the N-terminus gave rise to the perception that urodilatin may represent a tissue-specific splice variant of the ANP gene (Feller et al. 1989).

Urodilatin induces a potent diuretic and natriuretic response that even exceeds the efficacy of ANP. The longer duration of action of urodilatin compared to ANP is a result of a relative resistance of urodilatin to enzymatic degradation by neprilysin. Despite the systemic hemodynamic effect, including a reduction of arterial blood pressure, increase of cardiac output and reduction of pulmonary pressure that is seen after IV administration (Kentsch et al. 1992) it is thought that urodilatin exerts its physiological actions predominantly in the kidney where it is involved in the regulation of renal perfusion and electrolyte homeostasis.

2 NP Receptors

The presence of natriuretic peptide receptors has been described in a variety of tissues and cells, including endothelial and smooth muscle cells, cardiomyocytes, adrenals, lungs, brain, neurons (Kuhn 2016). First insights into the distribution came from autoradiography studies and showed a high abundance of the receptors in the kidney (Chai et al. 1986) with localization in renal arteries, afferent and efferent arterioles, glomerular epithelial and mesangial cells, tubular epithelium, papillae and renal cortex.

Currently, four receptor subtypes have been characterized of which two, NPR-A and NPR-B, mediate the NP actions via GC activation and cGMP production. The structure of these receptors is characterized by an extracellular ligand-binding domain, a short transmembrane region and an intracellular portion consisting of the GC, a hinge region and the regulatory kinase homology domain (KHD). Phosphorylation of the KHD is required for ligand-dependent receptor activation and subsequent production of cGMP (Pandey et al. 1988; Potter and Hunter 1998).

ANP has the highest affinity to NPR-A but also binds to NPR-B and NPR-C. By contrast, BNP and DNP bind only NPR-A and C while CNP seems to be the exclusive ligand for NPR-B (Koller et al. 1991). NPR-A is expressed in the kidney, vascular smooth muscle cells, endothelial cells, adipose tissue, adrenal gland, liver, brain, and – at lower levels – in the heart (Potter 2011).

NPR-B is highly expressed in vascular endothelial cells and smooth muscle cells (Hutchinson et al. 1997), implying its role in the regulation of vascular tone and blood pressure. NPR-C lacks the intracellular guanylyl cyclase and is considered a NP clearance receptor (Nussenzveig et al. 1990). Upon binding of its ligands, the NPR-C-ligand complex is internalized resulting in lysosomal hydrolysis of the ligand and recycling of NPR-C to the cell surface. However, an intrinsic effect of NPR-C activation involving the inhibition of adenylate cyclase has been discussed (Anand-Srivastava and Trachte 1993). Another receptor, NPR-D, has been cloned and its ligand binding properties have been characterized (Kashiwagi et al. 1995). It is abundant in the brain but its physiological relevance in mammals remains unclear.

3 Transgenic Models Illustrating the Function of the NP system

While the exogenous administration of NPs provided valuable information on their main actions, the observed effects were typically of short duration and the receptor-selectivity was lost when supra-physiological doses were given. To overcome these constraints, genetic models of either overexpression or targeted deletion have been employed to facilitate the understanding of the physiological functions of NP and their receptors thereby providing additional insights into their role in health and disease states.

The transgenic overexpression of the ANP gene in mice that resulted in a fivefold increase in plasma ANP levels was associated with a significantly lower blood pressure compared to their littermates reflecting a reduction in vascular resistance (Barbee et al. 1994). These mice also showed a 27% reduction in heart weight while cardiac output, stroke volume and heart rate remained unaltered. Conversely, ANP deficiency by targeted deletion of the proANP gene resulted in salt-sensitive hypertension and cardiac hypertrophy that seemed to be independent of blood pressure (John et al. 1995; Feng et al. 2003).

The genetic modification of BNP showed a similar pattern: overexpression of human BNP in mice was associated with arterial hypotension while BNP deficiency through disruption of the preproBNP gene led to cardiac fibrosis (Ogawa et al. 1994; Tamura et al. 2000).

Mice lacking NPR-A were characterized by cardiac hypertrophy and fibrosis along with a reduced survival (Oliver et al. 1997). These mice had elevated blood pressure and died prematurely due to the development of congestive heart failure or aortic dissection.

Mice with targeted deletion of either CNP (Chusho et al. 2001) or NPR-B were not viable as their intrauterine growth was significantly impaired, highlighting the role of NPR-B in normal development (Tamura et al. 2004). However, a rat model overexpressing a dominant-negative NPR-B mutant that was associated with blunted NPR-B signaling had a normal phenotype at birth but developed progressive myocardial hypertrophy primarily due to increased cardiomyocyte size in the absence of marked fibrosis (Langenickel et al. 2006). The important role of NPR-C in clearing NPs from the circulation became evident in mice lacking NPR-C that showed a prolonged ANP half-life associated with hypotension, mild diuresis and volume contraction (Matsukawa et al. 1999).

Taken together, these animal models revealed the importance of the NP system in the regulation of blood pressure, water and electrolyte balance as well as cardiac growth.

4 Regulation of Natriuretic Peptides in Heart Failure

Heart failure is a complex clinical syndrome that is characterized by impaired left ventricular function and typically manifests with fluid retention leading to pulmonary congestion and dyspnea, peripheral edema and decreased exercise tolerance (Yancy et al. 2013). These maladaptive changes can be attributed to systemic neurohormonal activation involving RAAS, endothelin, vasopressin and the sympathetic nervous system, which, initially acting as compensatory

mechanism to maintain systemic circulation, lead to a vicious cycle of sustained activation.

Under physiological conditions, both ANP and BNP are predominantly stored in the atria and continuously secreted, the resulting plasma levels ranging between 3–20 and 1.4–12 pM, respectively (Rademaker and Richards 2005). In heart failure, plasma ANP and BNP levels increase primarily in response to cardiac filling in the presence of cardiac congestion. Initially, acute volume load leading to atrial distention triggers the release of pre-formed ANP while at a later stage increased atrial and ventricular synthesis of both ANP and BNP contribute to a persistent elevation of their plasma concentrations. According to immunohistological studies, the peptide concentrations of ANP, BNP and CNP are significantly increased in ventricles of human failing hearts (Wei et al. 1993a). In recent studies, ANP has been shown to positively correlate with the pulmonary capillary wedge pressure, left ventricular end-diastolic pressure and left ventricular hypertrophy thereby representing an indicator for the severity of heart failure (Raine et al. 1986; Dietz et al. 1986; Tsutamoto et al. 1989). These observations initiated the utilization of NPs as diagnostic and prognostic markers in the management of heart failure.

The activation of NP system in heart failure represents an important compensatory mechanism which ultimately fails to effectively prevent fluid retention and to maintain water and electrolyte homeostasis. Several underlying mechanisms have been discussed: (1) an inadequate NP release in response to stimuli, (2) downregulation of NPRs (Matsumoto et al. 1999; Tsutamoto et al. 1992; Cabiati et al. 2010), (3) impaired NP signaling due to desensitization of NPRs leading to relative peripheral NP resistance (Schroter et al. 2010), (4) upregulation of NP degrading enzyme neprilysin (Knecht et al. 2002), (5) upregulation of cGMP-degrading enzyme phosphodiesterase-5 (Nagendran et al. 2007; Pokreisz et al. 2009). Nevertheless, the NP system has been recognized as an important regulatory system in CHF and therapeutic strategies promoting the effectiveness of NPs in individuals with heart failure have shown beneficial effects.

5 Use of NPs As Biomarkers in Heart Failure

Based on the observations that heart failure is associated with elevated plasma levels of ANP and BNP, these peptides became an attractive tool aiding in the diagnosis and management of HF (Omland et al. 1996). As the N-terminal fragments of the ANP and BNP prohormones are secreted in equimolar amounts but do not undergo the same fast enzymatic degradation except renal excretion, they have a longer half-life resulting in higher plasma levels. Plasma NP levels can be measured using commercial assays, including point of care devices, making them suitable biomarkers for rapid diagnosis (Weber and Hamm 2006; Nayer et al. 2014). While ANP is the dominant circulating peptide in healthy individuals, the rise of BNP levels is more pronounced in the presence of heart failure or other conditions that are associated with increased ventricular wall stress. Today, NPs play an important role as biomarkers in three different aspects of heart failure and also in the more general context of cardiovascular diseases: (1) primary prevention: assessment of cardiovascular risk in an apparently "healthy" individuals, (2) diagnosis of heart failure in acute care setting of patients presenting with dyspnea, (3) stratification and management of patients with chronic heart failure.

5.1 Biomarkers Predicting CV Risk in the General Population

Large epidemiological studies have established the use of NPs as predictors for heart failure and cardiovascular events in healthy subjects or patients with preexisting CV diseases (Agarwal et al. 2012; Wang et al. 2006; Chahal et al. 2015). In the context of the Framingham Heart Study, the use of CV biomarkers was assessed in more than 3000 participants and it was found that BNP

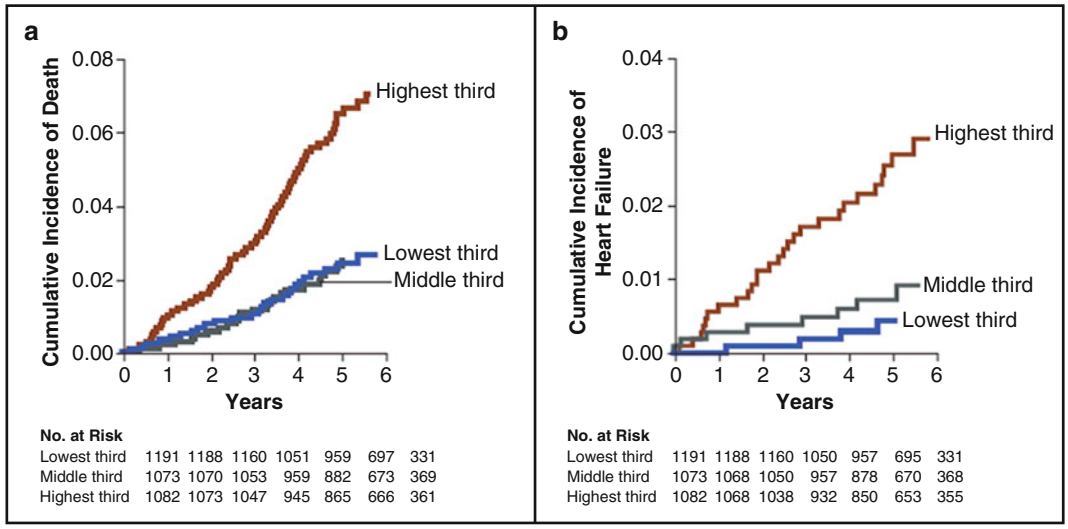

Fig. 2 The use of plasma BNP levels in predicting the incidence of death and heart failure in the general population (Data from the Framingham Heart Study, Wang et al. 2006)

was the most informative predictor for future major cardiovascular events and death (Fig. 2). Similarly, elevated plasma BNP levels were found to be a key risk factor for the incidence of heart failure (Velagaleti et al. 2010). The value of adding the measurement of NT-BNP to the risk stratification beyond conventional clinical risk factors has also been demonstrated in several trials (Kistorp et al. 2005). McKie et al. compared the potential of ANP, NT-pro ANP and pro-BNP as predictive markers for heart failure in a large community-based cohort that was followed over 9 years (McKie et al. 2011). While ANP was found to correlate with the onset HF, it did not predict mortality or the risk for MI. By contrast, NT-proBNP was associated with increased mortality, HF and MI. Overall, NT-pro BNP was identified as the most robust marker to predict mortality and CV risk in the general population. Another study in patients with chronic heart failure found that mid-regional proANP (MR-proANP) showed a better correlation with poor survival than NT-pro BNP, thus adding prognostic information in these patients (von Haehling et al. 2007).

Based on cumulative evidence showing BNP and NT-BNP as strong predictors for the new onset of heart failure in the general population, these biomarkers are currently recommended for clinical use by the AHA (Chow et al. 2017).

5.2 Diagnosis of HF in Acute Settings

The measurement of plasma NP levels has been proven extremely useful in addressing a common problem in clinical cardiology, which is the accurate diagnosis of heart failure in patients presenting with dyspnea in the emergency room or outpatient clinic. Early studies indicated that both plasma ANP and BNP levels increase with the extent of hemodynamic load and left ventricular dysfunction (Schrier and Abraham 1999). More recent studies found that BNP and NT-proBNP were superior to ANP in establishing the diagnosis of heart failure (Maeda et al. 1998). In the **B**reathing **N**ot **P**roperly study, plasma BNP levels correlated well with the symptoms according to the New York Heart Association class (Maisel et al. 2002). Furthermore, when 100 pg/ml was used as a cut-off, the sensitivity of BNP to diagnose heart failure in patients presenting with dyspnea was 90% while the specificity was 76% (Fig. 3). A similar

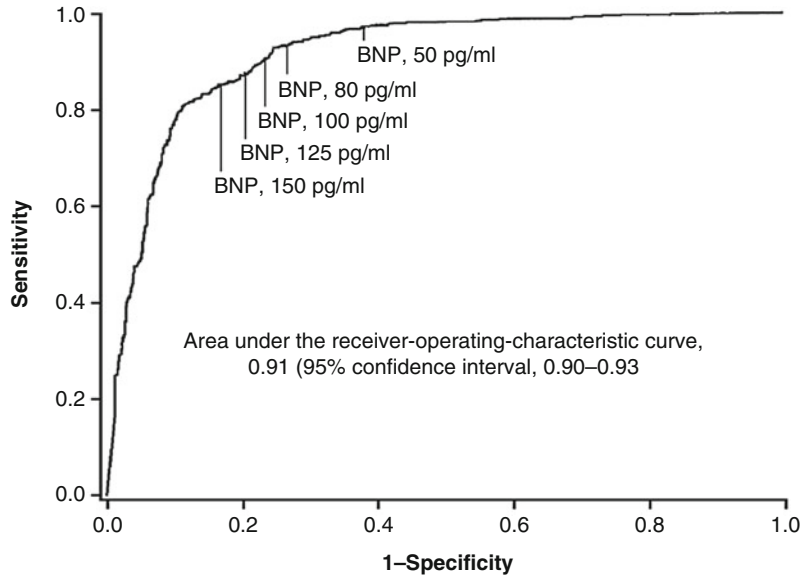

Fig. 3 Diagnostic sensitivity and specificity of plasma BNP levels in patients presenting with dyspnea (Data from the Breathing Not Properly trial, Maisel et al. 2002)

BNP pg/ml	Sensitivity	Specificity	Positive Predictive Value	Negative Predictive Value	Accuracy
	(95 percent confidence interval)				
50	97 (96–98)	62 (59–66)	71 (68–74)	96 (94–97)	79
80	93 (91–95)	74 (70–77)	77 (75–80)	92 (89–94)	83
100	90 (88–92)	76 (73–79)	79 (76–81)	89 (87–91)	83
125	87 (85–90)	79 (76–82)	80 (78–83)	87 (84–89)	83
150	85 (82–88)	83 (80–85)	83 (80–85)	85 (83–88)	84

accuracy was found for NT-proBNP (Roberts et al. 2015). Defining the threshold of NT-proBNP at 300 pg/ml resulted in a 99% accuracy to rule out heart failure according to the PRIDE study (Januzzi et al. 2005).

Based on these data, the concept of utilizing NPs in the differential diagnosis of heart failure has now been adapted by ESC, AHA and ACC guidelines that recommend the use of BNP and NT-proBNP for decision making as well as assessment of severity and prognosis (Ponikowski et al. 2016; Yancy et al. 2016). Accordingly, FDA approved BNP and NT-proBNP immunoassays to aid the diagnosis of heart failure (FDA 2001).

When interpreting the results of NP testing, medical conditions that have an impact on circulating plasma NP levels need to be taken into account. Such confounding factors that lead to increased plasma levels include: higher age, impaired renal function, anemia, atrial fibrillation, pulmonary hypertension or embolism, right ventricular dysfunction and sepsis (Chow et al. 2017; Collins et al. 2015; Richards et al. 2013). Conversely, NP levels were found to be lower in patients with obesity, pericarditis and end-stage cardiomyopathy. For the clinical practice, the use of different cut-off points for different age groups, kidney function parameters and BMI have been discussed (Hill et al. 2014).

5.3 NPs for Guidance in HF Management

The therapeutic management of patients with heart failure is complex despite the availability of drugs including beta blockers (BB), ACE

inhibitors (ACEi), angiotensin receptor blockers (ARBs), and mineralocorticoid receptor antagonists (MRA) that have a proven benefit for long-term survival. Nevertheless, the individual treatment regimen is often chosen based on symptoms rather than on objective criteria. As BNP and NT-proBNP are excellent marker for CV mortality and have shown to improve with treatment of chronic heart failure (Anand et al. 2003; Fruhwald et al. 2007; Tsutamoto et al. 2001), it is reasonable to assume that changes in plasma NP levels reflect the progression or prognosis of heart failure. Therefore, their role in guiding the management of patients with existing heart failure has been evaluated.

One of the first clinical studies to demonstrate a significant benefit of NP-guided therapy was published in 2000 and showed a reduction in 6-month mortality in patients hospitalized with decompensated heart failure and impaired left ventricular function (Troughton et al. 2000). Here, patients whose therapy was modified based on periodic plasma NT-proBNP level measurement had a reduced risk to experience a cardiovascular event including death, hospital admission or outpatient heart failure. Conversely, the intensified medical treatment in the NP-guided treatment was associated with a reduction in plasma NT-proBNP levels.

A recent meta-analysis that pooled data of 11 studies enrolling 2000 patients with heart failure compared the outcome of patients undergoing NP-guided versus clinically guided treatment showed that utilizing BNP or NT-proBNP in the management of heart failure reduced all-cause mortality (Troughton et al. 2014). In this treatment group the prescription of ACEi/ARB, BB and MRA was also higher. However, the benefit seemed to depend on the age and was limited to patients younger than 75 years as the survival benefit was abolished in patients above 75. In the TIME-CHF study that compared intensified (based on NT-proBNP levels) and standard therapy in elderly heart failure patients and used a target of 400 pg/ml in patients <75 years or 800 pg/ml in patients >75, no difference was seen with respect to heart failure symptoms or hospital admission-free survival (Pfisterer et al. 2009). While NT-proBNP guided treatment reduced the number of hospitalizations for heart failure, this effect was again limited to those patients less than 75 years. When selecting a threshold of 1000 pg/ml NT-proBNP for the outpatient management of individuals with chronic left ventricular function (PROTECT), the effect was striking showing a 42% reduction in total cardiovascular events after an average of 10 months follow-up (Januzzi et al. 2011). By contrast, a recently published study that based the intensified treatment on NT-proBNP levels at discharge from hospital did not show any difference from the control group (Carubelli et al. 2016). Furthermore, when comparing the value of (NT-pro)BNP guided treatment in patients with heart failure and reduced (HFrEF) versus preserved (HFpEF) ejection fraction, it was noted that the beneficial effect is limited to the HFrEF population (Brunner-La Rocca et al. 2015).

Taken together, the evidence for the benefit of NPs in heart failure management remains ambiguous and this can be in part attributed to the heterogeneity in the design of the heart failure trials, enrolling different patient populations and defining different cut-off points and criteria for therapy adjustment. Reflecting the controversy resulting from recent studies, the use of BNP/NT-proBNP in guiding the therapy in patients with decompensated heart failure is currently not recommended (Ponikowski et al. 2016; Yancy et al. 2016).

6 Therapeutic Implications for NPs in Heart Failure

6.1 Synthetic NPs

Based on the observation that NPs elicit profound natriuretic and vasodilatory effects, several synthetic NPs were explored as a potential therapeutic strategy in heart failure to counteract progressive sodium and water retention.

6.1.1 Anaritide and Carperitide (ANP)

The synthetic human ANP-analog anaritide, which corresponds to the 25 aa carboxy terminus of the mature peptide had been investigated in healthy subjects and shown to have the expected renal effects and also reduced systemic and pulmonary blood pressure along with a suppression of plasma renin and aldosterone levels. When administered in patients with congestive heart failure, however, some of the hemodynamic effects were comparable while the renal effects were blunted (Cody et al. 1986). A similar renal hyporesponsiveness was observed by other groups upon infusion of the full-length peptide in patients with heart failure (Saito et al. 1987) while others were able to demonstrate beneficial renal effects in these patients (Fifer et al. 1990). As a result, carperitide, a synthetic full-length peptide was approved for the treatment of acute decompensated heart failure in Japan but is not approved in other countries.

6.1.2 Neseritide (BNP)

Despite its approval for the treatment of acute decompensated heart failure in the US in 2001 the data on the use of nesiritide has sparked a lot of controversy, which ultimately led to a decline in its clinical application (Hauptman et al. 2006). Initial trials demonstrated natriuretic and mild hypotensive responses to the infusion of human BNP in healthy volunteers that could be reproduced in patients with congestive heart failure (Yoshimura et al. 1991; Marcus et al. 1996).

The largest early study in 432 patients hospitalized with symptomatic heart failure that received incremental doses of nesiritide in comparison to intravenous standard therapy showed a sustained hemodynamic and clinical improvement over 1 week (Colucci et al. 2000). Similarly, the VMAC trial published in 2002 showed that nesiritide administration was more effective in improving hemodynamic function and reducing heart failure symptoms than placebo or nitroglycerin (VMAC 2002), although the latter effect was modest.

However, a meta-analysis of five subsequent studies including more than 1200 patients suggested that the administration of nesiritide in heart failure could be associated with a risk of worsening renal function at least at higher doses (Sackner-Bernstein et al. 2005). The ASCEND-HF trial enrolling over 7000 patients was conducted to alleviate these concerns and it did not show any differences between nesiritide and placebo with respect to deterioration of renal function in patients with heart failure. Surprisingly, no benefit on symptomatic improvement, cardiovascular mortality or hospitalization rate was found (O'Connor et al. 2011). The latest metaanalysis assessing data of 38,000 patients from 22 randomized trials provided the final confirmation that, while the concerns about negative effects on renal function could be ruled out, there is no lasting cardiovascular benefit associated with the use of nesiritide. Instead, the risk of symptomatic hypotension was significantly increased (Gong et al. 2016). As a consequence, nesiritide has not been approved in Europe with the exception of Switzerland, and is not recommended for treatment of symptomatic heart failure by the current guidelines.

6.1.3 Ularitide (Urodilatin)

The latest in the group of synthetic NPs that advanced into late stage clinical development for heart failure is ularitide, a 32 aa urodilatin analogue. The peptide combines the renal properties of ANP while presenting with a relative resistance to the degradation by neprilysin. Administered in patients with decompensated heart failure, ularitide increased cardiac output and preserved renal function without affecting systemic blood pressure (Luss et al. 2008).

Despite promising effects and a favorable safety profile in the recently published outcomes study TRUE-AHF that enrolled more than 2000 patients the short-term hemodynamic effects did

not translate into a reduction of long-term cardiovascular mortality (Packer et al. 2017).

6.1.4 Cenderitide (CD-NP)

The dual chimeric NP receptor activator was created by Lisy et al. adding the carboxyl terminus of DNP to human CNP (Lisy et al. 2008). The resulting 37 aa peptide targets NPR-A and NPR-B, is resistant to enzymatic degradation by neprilysin (Dickey and Potter 2011) and combines renal and antifibrotic properties (Lee et al. 2016).

Chronic infusion of cenderitide in a rat model of left ventricular hypertrophy showed a significant reduction of cardiac hypertrophy and fibrosis along with improved left ventricular diastolic function (Martin et al. 2012). This effect was observed in the absence of any blood pressure reduction or change in heart rate.

Similarly, in the first trial in healthy volunteers cenderitide infusion over 4 h resulted in a significantly increased diuresis and natriuresis along with suppression of plasma aldosterone levels while the blood pressure response was minimal (Lee et al. 2009). Recognizing the therapeutic potential of the predominant antiproliferative actions of cenderitide in restenosis prevention after vascular interventions a cenderitide-eluting stent (CES) was developed and implanted in porcine coronary arteries. Despite the detection of CD-NP in the systemic circulation, indicating a sustained release of the peptide after stent implantation, CES was not superior in reducing neointima formation than control stents (Huang et al. 2016). Clinical trials in heart failure and other cardiovascular indications are still ongoing and a clinical benefit has yet to be demonstrated.

6.1.5 Others

Synthetic DNP has been investigated in animal models of heart failure and was found to improve cardiac and renal function by reducing cardiac filling pressure, right atrial and pulmonary wedge pressure and to increase diuresis and natriuresis along with glomerular filtration rate (GFR) (Lisy et al. 2001; Chen et al. 2002). Despite these favorable effects, no clinical development has been reported to date.

Vasonatrin (VNP), a synthetic peptide combining CNP with the 5 C-terminal aa of ANP, has potent arterial and venous vasodilating properties in combination with natriuretic effects (Wei et al. 1993b). This peptide was also shown to be superior to ANP and CNP with respect to its antiproliferative effect in smooth muscle cells (SY et al. 2005).

Finally, a new method of NP delivery has been explored with conjugated oral human BNP that was successfully tested in dogs where it led to blood pressure reduction and increased sodium excretion (Cataliotti et al. 2005, 2008).

6.2 Neprilysin Inhibition

Known for more than 40 years when it was first isolated from renal brush border (George and Kenny 1973), the zinc-dependent endopeptidase NEP 24.11 (neprilysin) has only recently moved to the focus of attention in heart failure therapy.

Enzymatic degradation of NPs by neprilysin is the final step that terminates the action of circulating NPs (Bayes-Genis et al. 2016; Stephenson and Kenny 1987a). Since its discovery neprilysin has been found in various organs and tissues including brain, heart (in cardiomyocytes and fibroblasts), peripheral vasculature, adrenal gland, lungs, gastrointestinal secretory epithelial brush borders, thyroid, epithelia, fibroblasts, and neutrophils. Its soluble form has been detected in urine and cerebrospinal fluid. While NPs, particularly ANP and CNP, have high affinity for this enzyme, they are not specific substrates but share this degradation pathway with other vasoactive peptides such as angiotensins, bradykinin, adrenomedullin, endothelin and arginine vasopressin (Stephenson and Kenny 1987b).

Despite elevated NP levels in patients with heart failure it has been postulated that the increased NP secretion is inadequate to compensate the progressive fluid retention and vasoconstriction caused by systemic neurohormonal activation. Thus, preventing NP degradation

could be a viable strategy to restore the functionality of the NP system under these conditions.

6.2.1 First Generation Neprilysin Inhibitors

Early studies by Wilkins et al. (1992) already showed that specific neprilysin inhibition by candoxatrilat enhanced the natriuretic effect of acute ANP infusion in rats while the neprilysin inhibition alone did not have a renal effect. Interestingly, in a rat model of experimental heart failure characterized by elevated plasma ANP levels and cardiac hypertrophy candoxatrilat alone was able to induce natriuresis and attenuate cardiac hypertrophy (Abassi et al. 2005). However, when candoxatril was administered in patients with mild chronic heart failure, the hemodynamic improvement was comparable to the effect seen with furosemide (Westheim et al. 1999). Similarly, the improvement in exercise tolerance was comparable to the effect seen in the captopril- treated group (Northridge et al. 1999).

6.2.2 Dual Neprilysin/ACE Inhibitors

Given the lack of clinical or hemodynamic benefit of candoxatrilat in patients with heart failure, (Westheim et al. 1999) the development of the dual neprilysin/ACE inhibitor omapatrilat seemed to be promising as it resulted in augmenting NP effects while avoiding stimulation of angiontensin II. Indeed, treatment with this vasopeptidase inhibitor in the OCTAVE study led to a more potent blood pressure reduction in patients with hypertension than ACEI alone (Kostis et al. 2004). However, the concomitant inhibition of bradykinin was associated with an increased incidence of angioedema. The OVERTURE trial that enrolled more than 5000 patients with chronic heart failure and assessed cardiovascular mortality and morbidity revealed that omapatrilat was not superior to enalapril (Packer et al. 2002). Instead, the incidence of angioedema was 60% higher in the omapatrilat treated group (0.8% vs. 0.5%) and safety concerns ultimately led to the termination of the clinical development.

6.2.3 Dual ECE/Neprilysin and Triple ACE/Neprilysin/ECE Inhibitors

A different approach that also targets the neurohormonal activation in heart failure is the simultaneous inhibition of neprilysin and endothelin-1, with or without concurrent ACE inhibition (von Lueder et al. 2013). Dual ECE/neprilysin inhibition lowered blood pressure and left-ventricular enddiastolic pressure without affecting heart rate or left ventricular contractility (Mulder et al. 2004). As echocardiographic studies revealed, the dual inhibitor reduced left ventricular end-diastolic and systolic diameters indicating improved cardiac remodeling after experimental myocardial infarction. Another dual inhibitor, daglutril (SLV306), had been evaluated in patients with congestive heart failure that underwent invasive hemodynamic assessment. Compared to placebo, daglutril lowered pulmonary artery pressure, right atrial pressure and PCWP in a dose-dependent fashion but did not affect systemic blood pressure or heart rate (Dickstein et al. 2004). Although initially promising in this indication, daglutril was not further developed for treatment of heart failure.

Analyzing the effects of triple inhibitor in an experimental model of heart failure, it was demonstrated that triple inhibition for 4 weeks reduced blood pressure more than ACEI or dual ECE/neprilysin inhibition while the increase in cardiac output was comparable among the three groups. However, the triple inhibitor was superior in reducing left ventricular remodeling (Mellin et al. 2005).

Given the controversial results (Xiong et al. 2017) on endothelin antagonism in heart failure trials, the development of combined inhibitors with neprilysin is not likely to move forward.

6.2.4 Angiotensin Receptor/Neprilysin Inhibitors (ARNI)

A new drug class of ARNI combining ARB and neprilysin inhibition has recently been introduced, and with sacubitril/valsartan (also known as LCZ696) the first drug in this class has been approved for treatment in heart failure. Avoiding the bradykinin-related adverse events

seen with omapatrilat and using an ARB instead of an ACEI, the concept of blocking RAAS while augmenting NP system has proven to be beneficial on heart failure symptoms as well as cardiovascular outcome.

In the PARADIGM-HF study more than 8000 patients with heart failure and reduced ejection fraction (<40%) showing mild to moderate symptoms were randomized to receive either sacubitril/valsartan or enalapril (McMurray et al. 2014). The study was stopped early after a median follow-up of 27 months due to overwhelming benefit in the sacubitril/valsartan group (Fig. 4a). In these patients, the rate of hospitalizations for heart failure was reduced by 23% compared to enalapril and this effect became already evident after 30 days (Fig. 4c). Post-hoc analysis of the study data confirmed that the beneficial effect of sacubitril/valsartan exists irrespective of the baseline left ventricular ejection fraction (Solomon et al. 2016). A strong correlation between NT-proBNP levels and CV risk after treatment with sacubitril/valsartan or enalapril was seen in PARADIGM further affirming the role of NT-proBNP as prognostic marker in patients with heart failure (Zile et al.

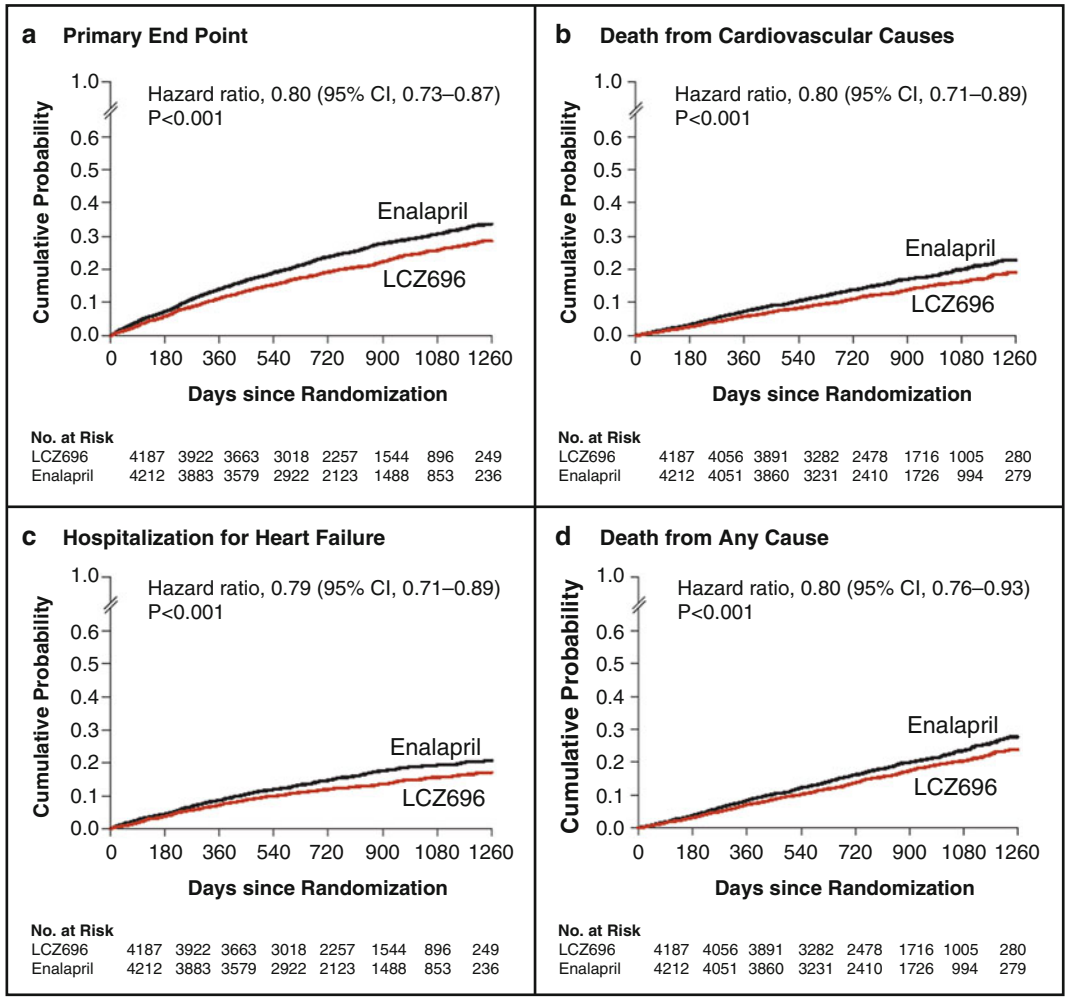

Fig. 4 Effect of sacubitril/valsartan on cardiovascular mortality and morbidity in patients with heart failure and reduced left ventricular function. Primary endpoint was the composite endpoint of death from cardiovascular causes or hospitalization for heart failure (Data from the PARADIGM study, McMurray et al 2014)

2016). Current ESC and AHA guidelines recommend the replacement of ACEIs in ambulatory patients with heart failure and reduced ejection fraction (HFrEF) who remain symptomatic despite optimal treatment (Ponikowski et al. 2016; Yancy et al. 2016).

After establishing the therapeutic value of ARNI in patients with HFrEF, additional trials have been design to investigate the beneficial effect in the HFpEF population. Using NT-proBNP as a surrogate marker for long-term outcome in patients with heart failure, the PARAMOUNT study was able to demonstrate that treatment with sacubitril/valsartan reduced NT-proBNP levels to a greater extent than valsartan (Solomon et al. 2012). The ongoing PARAGON (Prospective Comparison of ARNI with ARB Global Outcomes in HF With Preserved Ejection Fraction) study will determine if these promising results translate into improved outcomes and if treatment with sacubitril/valsartan is more potent in reducing cardiovascular mortality and morbidity in patients with in symptomatic HFpEF than the comparator valsartan (Solomon et al. 2017).

Finally, the concept of NP system playing a pivotal role in the crosstalk between cardiac function and metabolic regulation was further supported by a recent mechanistic study that demonstrated improved insulin sensitivity and subcutaneous lipolysis in patients with obesity and hypertension treated with sacubitril/valsartan (Jordan et al. 2017). Further studies are required to evaluate if the favorable metabolic effects have additional therapeutic potential in other indications such as metabolic syndrome.

7 Conclusion

The important role of NP in the maintenance of fluid and salt homeostasis and blood pressure regulation has been known for several decades. As revealed more recently, the physiological properties extend beyond the cardio-renal axis and include favorable metabolic effects.

Despite promoting vasodilation, diuresis and natriuresis which effectively counteracts renin-angiotensin-system, vasopressin, endothelin and sympathetic activation in healthy individuals, the system ultimately fails under conditions of sustained neurohormonal activation such as heart failure. Here, maladaptive changes lead to progressive water and sodium retention, increased cardiac preload and afterload leading to cardiac hypertrophy.

Cardiac synthesis and secretion of NPs have been demonstrated to increase with cardiac load and plasma NP levels correlate closely with the severity of heart failure. Hence, they are being employed as prognostic markers and are now established as analytical tools in the diagnosis of heart failure.

Due to the described physiological effects the NP system has become an attractive therapeutic target to counteract the unfavorable hemodynamic changes, neurohormonal activation and pathological cardiac remodeling typically found in heart failure. To date the most successful treatment strategy in heart failure patients has been the dual neprilysin/ARB inhibition with sacubitril/valsartan which showed a mortality benefit in these patient as first drug in its class.

In addition, there is potential for improvement of insulin resistance and obesity and manipulating the NP system is a promising strategy to simultaneously address cardiovascular and metabolic disorders.

The Role of Cardiologists in the Management of Patients with Heart Failure

Vera Maria Avaldi and Jacopo Lenzi

Abstract

Heart failure is a complex clinical syndrome with a remarkable impact on health care systems in terms of patients' morbidity and mortality, as well as direct and indirect costs. It is essential to redesign models of care for patients with heart failure that are tailored on personalized health care needs and carried out in the most appropriate setting. There is some debate about the role of cardiologists in the management of patients with heart failure. Indeed, results regarding the inclination of cardiologists' patients to achieve better outcomes are controversial, given the heterogeneity of studies in terms of study design, population, setting and variables considered. The aim of this chapter is to describe and synthesize the current state of knowledge about the role of specialists in the management of patient with heart failure, and to assess whether there is a type of patients for which cardiologists demonstrate the greatest value or a setting of care where they add more benefit.

Keywords

Heart failure · Cardiologist care · Mortality · Readmissions

1 Introduction

Heart failure (HF) is a complex clinical syndrome that affects 1–2% of the adult population in Western countries and whose prevalence increases up to 10% among people older than 70 years of age (Mosterd and Hoes 2007; Dunlay and Roger 2014). HF is considered a major public health issue given its leading role in affecting morbidity, mortality and hospital admissions, which represent the majority of HF-related costs (Ponikowski et al. 2016; Lloyd-Jones et al. 2009). Over the last decades, advances in treatments and management have improved survival, but readmission rates after an index hospitalization for HF remain high (Jhund et al. 2009;

V.M. Avaldi and J. Lenzi (✉)
Department of Biomedical and Neuromotor Sciences, Alma Mater Studiorum – University of Bologna, Bologna, Italy
e-mail: jacopo.lenzi2@unibo.it

Bueno et al. 2010; Maggioni et al. 2013). It is thus urgent to redesign health care systems to develop evidence-based practices and create seamless pathways of care that join community and hospital settings in order to improve quality of care and outcomes for patients with HF (Driscoll et al. 2016).

In light of this, in the last years there has been some debate about the most appropriate role of specialists in the management of HF and other chronic conditions as well. It is possible to imagine that cardiologists have more experience in caring HF patients and provide a more accurate risk-benefit assessment of diagnostic procedures and treatments. Nevertheless, it is unthinkable that all patients with HF will receive specialty care from cardiologists. In the last two decades some articles have compared, with controversial results, cardiologist care with care provided by generalists or other physicians in relation to mortality and readmissions (Lowe et al. 2000; Auerbach et al. 2000; Bellotti et al. 2001; Di Lenarda et al. 2003; Jong et al. 2003; Ansari et al. 2003; Ahmed et al. 2003; Indridason et al. 2003; Ezekowitz et al. 2005; Foody et al. 2005; Lee et al. 2010; Boom et al. 2012; Uthamalingam et al. 2015; Selim et al. 2015; Masters et al. 2017). These studies differ in setting, length of follow-up, outcomes and variables considered in statistical adjustment. However, the approach of "either- or" in comparison of generalists and specialists was limited, and generally the key question was not whether specialists provide more value in HF care, but for what type of patients cardiologists demonstrate the greatest value or in which setting they might add more benefit (Ayanian 2000).

In this chapter we are going to describe and synthesize the current state of knowledge about the role of cardiologists in the management of patient with HF, hoping that it can serve to stimulate thought among readers and suggest policy strategies to improve health care services. The complete list of studies reviewed in this chapter is provided in Table 1.

2 What Is the Effect of Cardiologist Management on HF Patients' Outcomes?

One of the first studies on this topic was published in 2000, and is a prospective cohort study (Lowe et al. 2000) evaluating 257 over 60-year patients with HF managed in-hospital by cardiologists (40.1%) or generalists (59.9%) and followed up to 1 year after hospital discharge. Patients admitted to a cardiology department presented predominantly cardiovascular diseases and less comorbidities. No differences were found in all-cause readmissions between the two groups at 28 and 365 days. On the contrary, mortality at 30 days was higher among patients seen by cardiologists and stayed higher at 3, 6 and 12 months, although this gap diminished over time and was no more significant at 1 year. Authors explained that these findings were mostly due to different baseline characteristics rather than to differences in the quality of care provided. It is also worth noticing that this study was carried out in Australia, where general physicians and cardiologists are trained in specialty care and general medicine respectively, and this training could minimize differences in patterns of care between physicians.

Another study (Auerbach et al. 2000) found no survival advantage attributable to specialty care in the short term after discharge. In particular, Auerbach et al. analyzed the survival of 1298 patients up to 1 year after admission to 5 teaching hospitals for congestive HF between 1989 and 1994. After adjusting for severity of illness and other variables, compared to patients managed by generalists, cardiologists' patients had a lower mortality hazard ratio only at 180 days after admission with a weak statistical significance (0.72; 95% CI 0.54 to 0.96). This result suggests that different outcomes for HF patient may be more likely due to patients' characteristics than to differences in the management or in the type of care provided.

Table 1 Summary of studies comparing cardiologist care with care provided by generalists or other physicians for patients with heart failure

	Country	Study design	Study population	Comparison groups	Population size	Duration of follow-up, days	Main results
Lowe et al. (2000)	Australia	Cohort study	Patients aged ≥60 years hospitalized with HF	Cardiologists vs. Generalists	257	365	No differences were found in all-cause readmissions between the two groups at 28 and 365 days. On the contrary, mortality at 28 days was higher among patients seen by cardiologists and stayed higher at 90, 180 and 365 days, although this gap diminished over time and was no more significant at 1 year.
Auerbach et al. (2000)	United States of America	Cohort study	Patients hospitalized with an exacerbation of HF	Cardiologists vs. Generalists	1298	365	Cardiologists' patients had a significant lower mortality rate at 180 days after admission.
Di Lenarda et al. (2003)	Italy	Prospective, cross-sectional survey	Patients with HF admitted to hospital	Cardiology Department vs. Internal Medicine Department	2127	180	No differences in in-hospital and 6-month mortality or readmissions between the two groups.
Uthamalingam et al. (2015)	United States of America	Cohort study	Patients discharged with acute decompensated HF	Cardiologists vs. Hospitalists/Non-hospitalists	496	180	Mortality at 6 months did not differ between groups; cardiologists' patients were less likely to be readmitted at 6 months; the composite outcome was favorable for cardiologists' patients.
Selim et al. (2015)	United States of America	Cohort study	Patients hospitalized with acute decompensated HF	Cardiologists vs. Generalists	7516	60	The cardiologist group had a lower mortality rate at 60 days; no difference in in-hospital mortality; the cardiologists' patients had a lower readmission rate at 30 and 60 days for both all and the systolic HF subgroup.

(continued)

Table 1 (continued)

	Country	Study design	Study population	Comparison groups	Population size	Duration of follow-up, days	Main results
Boom et al. (2012)	Canada	Cohort study	Patients newly hospitalized for HF	Cardiologists vs. Generalists alone vs. Generalists with cardiologist consultation	7634	365	Patients managed by generalists alone had a higher risk of 30-day and 1-year mortality, as well as of 1-year death and/or all-cause readmission. The beneficial effect of cardiologists was stronger for the elderly and for patients in the highest mortality risk score categories.
Jong et al. (2003)	Canada	Cohort study	Patients with first-time hospitalization for HF	Cardiologists vs. General internists vs. Family practitioners vs. Other physicians	38702	365	The risk-adjusted mortality was favorable for patients treated by cardiologists from 72 hours after admissions until 1 year of follow-up. The effect of cardiologist care was beneficial for patients at medium to high risk (defined as a function of age or comorbidities), but did not emerge for patients at low risk. Readmissions for HF at 1 month were similar between patients seen by different physicians, but higher at 1 year for cardiologists' patients than for other groups. The composite outcome of death and/or readmission for HF at 1 month was lower for cardiologists' patients than for those seen by all the other physicians, but at 1 year cardiologists lost the advantage over general internists.
Ansari et al. (2003)	United States of America	Cohort study	Patients with new-onset HF	Cardiologists vs. Primary care physicians	403	730	Patients managed by cardiologists had a reduction in the risk of composite outcome of death and/or hospital admission for cardiovascular diseases at 24 months after adjusting for potential confounders.

Ezekowitz et al. (2005)	Canada	Cohort study	Patients with first-time hospitalization for congestive HF	Specialists (Cardiologists or General internists) vs. Family physicians vs. both Specialists and Family physicians	3136	365	Patients with specialists follow-up visits had improved survival at 30 days and 1 year compared to patients seen by FP alone. Patients with a high disease burden seen by both a specialist and a FP had a lower mortality rate
Ahmed et al. (2003)	United States of America	Cohort study	Patients aged ≥65 years hospitalized with HF	Cardiologists vs. Generalists	1075	90	Patients receiving consultative care had lower adjusted rates of 90-day all-cause readmission compared to those who received generalist care.
Indridason et al. (2003)	United States of America	Cohort study	Patients hospitalized with chronic HF	Follow-up visits by: only Cardiologists (CARD-only) vs. only Generalists (GM-only) vs. Cardiologist and Generalist (MIXED) vs. no follow-up visits (no-GM-CARD)	11661	365	Using MIXED group as reference, both the GM-only group and the no-GM-CARD group had significant increase in risk of death. There was no significant difference in survival between the MIXED and CARD groups.
Lee et al. (2010)	Canada	Cohort study	Patients with an Emergency Department visit for HF	30-days follow-up visits by: Primary Care physicians (PCPs) alone vs. Cardiologists alone vs. both PCPs and Cardiologists vs. neither PCPs nor Cardiologists	10599	365	Collaborative care, compared with PCP alone, was associated with a significant reduction in 1-year mortality and 1-year death and/or readmission and/or repeated emergency department visits for HF.
Masters et al. (2017)	United Kingdom	Retrospective service evaluation	Patients with a primary diagnosis of HF	Patients with HF managed by a multidisciplinary inpatient heart failure team (HFT) vs. Patients with HF with usual care before the implementation of HFT	407	365	Patients cared for by HFT had significantly lower in-hospital and 1-year mortality compared to patients managed with usual care before the introduction of the HFT.

HF Heart failure

Consistent with this argument are the results of the study by Di Lenarda et al. (2003) that compared characteristics, treatment and outcomes of 2127 patients admitted for HF to 167 cardiology departments and 250 internal medicine departments. Cardiology patients were younger, had more severe HF-related symptoms and underwent more often both invasive and non-invasive procedures; conversely internal medicine patients were older and more often women, and had more frequently a preserved left ventricular (LV) function. Also, cardiologists prescribed more β-blockers than generalists. Nevertheless, after adjusting for patients' characteristics and drug use, there were no differences in in-hospital mortality and 6-month mortality or readmissions between the two groups.

These studies clearly suggest that multivariate analyses are critical, and that the effect of specialist management might be related to selection bias of patients.

There is evidence that patients managed by cardiologists are more frequently male, younger, have more cardiovascular comorbidities than other diseases and are at lower risk of contraindications or intolerance to treatments, (Lowe et al. 2000; Auerbach et al. 2000; Bellotti et al. 2001; Jong et al. 2003; Boom et al. 2012; Selim et al. 2015) and probably for this reason receive more evidence-based drug prescriptions and invasive procedures (Di Lenarda et al. 2003; Jong et al. 2003; Ansari et al. 2003; Foody et al. 2005; Boom et al. 2012; Uthamalingam et al. 2015; Selim et al. 2015). On the contrary, patients cared by non-specialists tend to be older and with more severe comorbidities, and might have more contraindications to evidence-based treatments. In particular, the pattern of drug prescriptions has been shown to be a key element to improve outcomes and reduce mortality and the hospitalization burden for HF patients, (Al-Gobari et al. 2013; Vaduganathan et al. 2013; Sakata et al. 2013; Corrao et al. 2015; Fischer et al. 2015; Chowdhury et al. 2013; Yancy et al. 2017) and could be a process of care strictly related to the performance of cardiologists. Therefore, it is essential to take into consideration and control for differences in the patient case mix, when comparing the performance of different physicians.

Still, results are not fully consistent across studies. More recent articles underlined the beneficial effect of hospital specialist management on HF patients' outcomes even after adjusting for potential confounders. Uthamalingam et al. (2015) studied the outcomes of 496 patients discharged with acute decompensated HF, comparing the management of cardiologists with the management of hospitalists and non-hospitalists. After adjustment for patients' characteristics, comorbidities and clinical variables, mortality rates at 6 months did not differ between groups, while patients treated by cardiologists were less likely to be readmitted at 6 months for HF; also the composite outcome of mortality and/or readmissions for HF at 6 months was favorable for specialists. Still, the authors stated that patients treated by non-cardiologists were different for HF clinical manifestation, age or comorbidities, less adherent to evidence-based drugs and less likely to undergo a LV systolic dysfunction evaluation—all elements that might have a strong impact on outcomes.

Also Selim et al. (2015) highlighted the favorable effect of specialist management. They evaluated the impact of in-hospital cardiologist management on 30 and 60-day mortality and all-cause readmissions. The study population comprised of 7516 patients, 19% treated by cardiologists and 81% by generalists, and authors compared the outcomes of the two groups adjusting for patients' characteristics, comorbidities and clinical variables; they also reran analysis for a subgroup of patients with systolic HF. The cardiologist group received more evidence-based drug prescriptions and presented a lower mortality rate at 60 days compared with the generalist group, but there was no difference at 30 days and for in-hospital mortality. Concerning HF and all-cause readmissions at 30 and 60 days, results were favorable for patients managed by cardiologists for both all and the systolic HF subgroup. The authors concluded that the potential benefit of cardiologist- vs. generalist-centered care should be acknowledged, although cardiologist care was

not associated with a strong improvement in short-term outcomes. These results suggest that involvement of cardiologists could improve outcomes especially for HF patients with specific characteristics of clinical severity. This is confirmed by Boom et al. (2012) that analyzed 7634 patients newly hospitalized for HF in 81 hospitals of Ontario and evaluated the specialty-related differences in processes of care and outcomes. The authors distinguished the in-hospital care provided by cardiologists, generalists alone, and generalists with cardiologist consultation. The involvement of cardiologists had impact on prescriptions of evidence-based drugs and on execution of both invasive and non-invasive procedures. Patients managed by generalists alone had a higher risk of 30-day and 1-year mortality, as well as of 1-year death and/or all-cause readmission. The beneficial effect of cardiologists was stronger for the elderly and for patients in the highest mortality risk score categories, suggesting that specialty care could be most advantageous for high-risk patients, who typically benefit most from evidence-based therapies.

All of these studies evaluated the general survival and readmission of hospitalized patients, given the assumption that the in-hospital management is a primary determinant of post-discharge outcomes. Anyway, these results were also confirmed in studies evaluating the outpatient and primary care setting.

A Canadian study (Jong et al. 2003) analyzed a cohort of 38,702 subjects hospitalized for the first time between 1994 and 1996 and compared processes of care and outcomes of patients managed by cardiologists in hospital (14.2%) vs. those managed by general internists (35%), family practitioners (41%) and physicians of other disciplines (9.9%). Patients seen by cardiologists were more likely to be younger, male and with a history of cardiovascular diseases, and more likely to undergo invasive procedures. The risk-adjusted mortality was favorable for patients treated by cardiologists from 72 h after admissions until 1 year of follow-up. In particular, the effect of cardiologist care was beneficial for patients at medium to high risk (defined as a function of age or comorbidities), but did not emerge for patients at low risk. Moreover, readmissions for HF at 1 month were similar between patients seen by different physicians, but higher at 1 year for cardiologists' patients than for other groups. The composite outcome of death and/or readmission for HF at 1 month was lower for cardiologists' patients than for those seen by all the other physicians, but at 1 year cardiologists lost the advantage over general internists. We think that these results are noteworthy, as they caught the heterogeneity that characterizes the setting of hospital and community care.

Given these evidences, the involvement of cardiologists seems to be advantageous especially for the most complex and impaired HF patients. In addition, as highlighted by the studies described above, there is proof that specialty management affects the outcomes of patients with a new onset of HF.

This is also confirmed by a retrospective cohort study, (Ansari et al. 2003) in which Ansari et al. evaluated characteristics, treatment and outcomes of patients with HF at early stage managed in outpatient setting by primary care physicians and cardiologists. They compared 198 patients managed by cardiologists with 205 patients managed by primary care physicians. Patients treated by cardiologists tended to be men, younger and with more cardiovascular comorbidities. In addition, cardiologist care was associated with a higher adherence to guidelines recommendations as far as prescriptions of evidence-based drugs for HF and related comorbidities. Cardiologists prescribed more ejection fraction evaluations and their patients had a reduction in the risk of composite outcome of death and/or hospital admission for cardiovascular diseases at 24 months after adjusting for potential confounders.

Another study (Ezekowitz et al. 2005) evaluated the impact of specialist follow-up on outcomes of patients with new-onset congestive HF. Of 3136 study patient, 34% received no follow-up cardiovascular visits, 24% were seen only by family physician (FP), 1% only by specialist (cardiologists or general internists), 42%

by both specialist and FP. Patients who received combined care had higher Charlson Index comorbidity scores, more outpatient visits and accesses to emergency department, and were more frequently readmitted for cardiovascular care at 30 days and 1 year compared to those seen solely by FPs. However, after adjusting with a Cox proportional hazards time-dependent covariate model for different follow-up periods, frequency of visits, days spent in hospital during the follow-up, age and some comorbidities, patients seen by specialists had improved survival at 30 days and 1 year compared to patients seen by FP alone. In this study, patients with a high disease burden seen by both a specialist and a FP had a lower mortality rate, and a possible interpretation is that they had more access to health services and more opportunities to detect a worsening health status or to adjust their medical treatment.

That being said, despite the heterogeneity and the substantial differences between the studies until now considered, we can argue that the involvement of cardiologists could influence and improve the management of HF. This is evident in any setting of care and especially for patients with a more severe clinical impairment, who receive more benefit from appropriate diagnostic assessment and pharmacological treatments—all interventions mostly carried out by cardiologists rather than by other physicians.

3 Are Cardiologists Able to Respond to Any Needs of Care of Patients with HF?

It is essential to consider that for chronic conditions, including HF, the more patients seek care from specialists, the higher are medical costs related to procedures, interventions and types of medication prescribed that are not necessarily useful to achieve an improved quality of care (Starfield et al. 2009). In addition, given that patients with HF are elderly and generally affected by other comorbidities, it is necessary to adopt an approach that takes into consideration all of the care needs of these patients.

HF guidelines (Ponikowski et al. 2016; Yancy et al. 2013) recommend a collaborative model in which generalists, cardiologists and other professionals provide care together to optimize outcomes and quality of life. Although there is evidence that multidisciplinary approach improves quality and outcomes of care of HF, (Rich et al. 1995; McAlister et al. 2004; Hansen et al. 2011; Metra and Teerlink 2017) such models of care do not always delineate the specific role of specialists nor preferential settings where cardiologists should be involved with generalists for a better care of patients.

Some studies in this field have compared HF treatments and outcomes based on the specialty of admitting or attending physicians, and assessed whether cardiologists collaborated as consultants in the care of patients directly managed by non-specialists.

A retrospective cohort study (Ahmed et al. 2003) compared the management of 1075 patients with HF, 65 years and older, provided by cardiologists (13%), generalists (55%) or both in consultative care (32%). Patients receiving consultative care were more likely to undergo an LV ejection fraction evaluation and to receive ACE inhibitors compared to those managed in solo care. In addition, they had lower adjusted rates of 90-day all-cause readmission compared to those who received generalist care.

Another study (Indridason et al. 2003) evaluated the 1-year survival of a cohort of almost 12 000 patients with chronic HF discharged from the Department of Veterans Affairs hospitals in 1991 and 1992. Patients were subdivided in 4 groups in relation to the outpatient specialist care received: only cardiologists (CARD-only, 7%), only generalists (GM-only, 56%), cardiologist and generalist (MIXED, 29%), and no follow-up visits (no-GM-CARD, 8%). After a Cox proportional hazards analysis, using MIXED group as reference the GM-only group and the no-GM-CARD group had a 26% and 48% significant increase in

risk of death, respectively. There was no significant difference in survival between the MIXED and CARD groups. These results were compared with analyses carried out in a second cohort observed between 1994 and 1995, and no differences emerged. Authors suggested that the patterns of outpatient care had impact on survival and that the involvement of cardiologists, when in collaboration with generalists, improved survival. A limitation of the study was the use of administrative data and the lack of some important patients' characteristics, including LV function. In addition, patients in the MIXED group had on average more visits compared to others, and it is possible that the intensity of follow-up contributed to better outcomes.

Another Canadian study (Lee et al. 2010) evaluated the impact of outpatient care after an emergency department visit for HF. The study population comprised 10 599 patients seen within 30 days of discharge by primary care physicians (PCPs) alone (62.2%), cardiologists alone (5.1%), both PCPs and cardiologists (13.9%), or neither PCPs nor cardiologists (18.8%). Patients managed in collaborative care received more evidence-based drug prescriptions and were more likely to undergo an assessment of LV function or both invasive and non-invasive procedures compared to those visited only by a PCP. In addition, collaborative care, compared with PCP alone, was associated with a significant reduction in 1-year mortality (HR 0.79; 95% CI 0.63 to 1.00) and 1-year death and/or readmission and/or repeated emergency department visits for HF (HR 0.86; 95% CI 0.78 to 0.94).

Lastly, we want to mention the presence of some specific models of HF management, implemented especially in the UK, based on collaborative care with a multidisciplinary HF specialist team. A very recent study (Masters et al. 2017) evaluated in a UK University Hospital the impact on HF patients' outcomes of a multidisciplinary inpatient heart failure team (HFT), composed by a cardiologist, two nurses specialist in HF, a pharmacist and a clinical fellow. The goal of the HFT was to review and improve patient care and to manage the early follow-up after discharge. Compared to patients admitted 6 months before the introduction of the HFT, patients cared for by HFT had significantly lower in-hospital and 1-year mortality and were more likely to be discharged with evidence-based treatments. No difference between the 2 groups was found in all-cause and HF readmission rates.

These evidences suggest that patients with HF could benefit from collaborative care between specialists and non-specialists—indeed, a multidisciplinary approach is intended to guarantee the management of complex needs related not only to HF, but also to other comorbidities.

4 From Evidence to Practice: Should Cardiologists Be Routinely Involved in the Management of Patients with HF?

Although there is no clear answer to this question, specialty care seems to be associated with improved outcomes for patients with HF. In particular, patients at high risk or with a new onset of HF could benefit the most from specialist care because of the cardiologists' inclination to appropriately manage diagnostic procedures and prescribe evidence-based treatments. In general, specialty approach should be required whenever the clinical conditions are worsening or there is a transition between the inpatient and outpatient setting and vice versa. The collaboration between specialists and non-specialists is also crucial, and might lead to a patient-centered care, rather than a professionally centered care, to achieve patients' health and equity in access to health care.

Nevertheless, the current state of knowledge does not allow to identify specific clinical characteristics of HF patients that require the involvement of specialists as main professionals or consultants. In particular, there is a lack of studies investigating the different impact of cardiologist care for HF patients with preserved ejection fraction (HFpEF) and reduced ejection fraction (HFrEF)—two groups of patients whose clinical characteristics and prognosis require a tailored approach to treatment. Probably EF is

not routinely collected, especially in non-specialist wards, so it is difficult to distinguish these patients. In addition, the diagnosis of HFpEF is more challenging than the diagnosis of HFrEF, (Ponikowski et al. 2016) and is largely based on exclusion criteria (Ferrari et al. 2015). However, on the basis of clinical practice, it might be argued that cardiologists could improve management of patients with HFrEF, for which there are indications for evidence-based treatments, and patients with de-novo HF, for which cardiologists probably could have more experience and training in recognizing underlying cardiovascular etiology of HF.

In addition, there is lack of evidence about the specific impact of cardiologists in post-discharge period. While it is relatively easy to compare specialist and non-specialist management of HF in hospital, in the primary care setting several multidisciplinary strategies for HF management (Rich et al. 1995; McAlister et al. 2004; Takeda et al. 2012; Garin et al. 2012; Jackevicius et al. 2015) have been implemented to take into account the complex needs of patients not only related to HF, and it is difficult to recognize the competing role of different physicians. Further research is needed to identify if there are some "critical changes in care" (e.g., changes in pharmacological treatments, first signs of decompensation) for which cardiologists could add more benefit in comparison to other professionals.

Available literature does not even clarify if cardiologist care has more impact on mortality or readmissions, because of the heterogeneity of study designs and timeframes that makes results difficult to compare. It is worth noticing that differences across studies also subtend other substantial differences in health care organization that are specific to each context. Some of these could be related to: professionals' capabilities, specialized or not, to manage the patients; local procedures, after an emergency department access, for the referral of HF patients to a cardiology ward instead of a generalist or internal medicine ward; local procedures for the request of specialists' consultation when HF patients are admitted in a non-specialist ward. It should also be noted that in some settings there is a lack of standardized referral processes, and the choice of directing patients with HF to a cardiologist is at complete discretion of each professional. All these issues should be taken into consideration when analyzing the literature on this topic and discussing which professional could guarantee the best quality of care.

We can thus argue that each evidence or evaluation on this topic is significant for the context from which it is derived, but only suggestive for other contexts that have different systems of care with specific characteristics in terms of socio-economic background, population or integration between different specialists. A process of care effective in one setting might indeed be less effective or not effective at all in other settings. In conclusion, it is necessary to study and implement management strategies, specific to each context, that identify the best way to deliver cardiologist care and favor the interactions between different health professionals for patients with HF. Further research should assess the impact of cardiologist management by focusing on HF clinical manifestation, in order to identify specific clusters of patients that could benefit more from specialist care. It is also worth considering death as a competing risk for hospital readmission, and evaluating differences between outcomes in the short- long-term period.

Optimizing Management of Heart Failure by Using Echo and Natriuretic Peptides in the Outpatient Unit

Frank Lloyd Dini, Gani Bajraktari, Cornelia Zara, Nicola Mumoli, and Gian Marco Rosa

Abstract

Chronic heart failure (HF) is an important public health problem and is associated with high morbidity, high mortality, and considerable healthcare costs. More than 90% of hospitalizations due to worsening HF result from elevations of left ventricular (LV) filling pressures and fluid overload, which are often accompanied by the increased synthesis and secretion of natriuretic peptides (NPs). Furthermore, persistently abnormal LV filling pressures and a rise in NP circulating levels are well known indicators of poor prognosis. Frequent office visits with the resulting evaluation and management are most often needed. The growing pressure from hospital readmissions in HF patients is shifting the focus of interest from traditionally symptom-guided care to a more specific patient-centered follow-up care based on clinical findings, BNP and echo. Recent studies supported the value of serial NP measurements and Doppler echocardiographic biomarkers of elevated LV filling pressures as tools to scrutinize patients with impending clinically overt HF. Therefore, combination of echo and pulsed-wave blood-flow and tissue Doppler with NPs appears valuable in guiding ambulatory HF management, since they are potentially useful to distinguish stable patients from those at high risk of decompensation.

Heart failure (HF) is a complex clinical syndrome characterized by recurrent episodes of acute decompensation, requiring frequent hospitalizations and readmissions. The prognosis of HF has improved markedly in the past 30 years as a result of many advances in the diagnosis and treatment of this condition (Ponikowski et al. 2016). However, the rate of adverse outcome remains high, underscoring the need for additional disease specific monitoring and treatment strategies (Krumholtz et al. 2000). It has been estimated that 1–2% of the healthcare expenditure is devoted to HF and that most of these costs are related to hospitalization (Heidenreich et al. 2013). The highest risk period for re-hospitalization is in the first weeks to months after discharge (Ross et al. 2010; Desai and Stevenson 2012).

Over the years, it has become apparent that ambulatory patients who receive a regular follow-up have fewer exacerbations and readmissions and that a personalized and tailored management is a fundamental step to achieve a better quality of care and to improve the outcome. Therefore, a number of strategies have recently been implemented to reach these targets (Shah et al. 1998; Fonarow et al. 1997). This evidence strongly supports the thought that HF patients, after discharge from hospital, should be followed-up by cardiologists or internists with particular expertise in HF. Nowadays, new evidences have supported the concept that better optimization of cardiovascular drugs and device therapies can be achieved by combining echo and natriuretic peptides (NPs), i.e., B-type natriuretic peptide (BNP) or N-terminal pro-B-type natriuretic peptide (NT-proBNP), in the follow-up evaluation of outpatients with chronic HF (Fig. 1).

1 Biomarker-Guided Management

BNP is a 32-aminoacid polypeptide synthetized by the ventricular myocytes in response to excessive stretching of the heart muscle and correlated with LV filling pressures (LVFP) (Maisel et al. 2002, 2008). This molecule is secreted attached to 76-aminoacid N-terminal fragment called NT-proBNP. BNP and NT-proBNP are measured immunogically and their elevated levels are strong indicators of HF. However, these assays may measure multiple forms of these peptides. These altered molecules, nicknamed as "junk NPs", are immunoreactive, but minimally hormonally active (Hobbs and Mills 2008).

A modern way of managing HF patients is to apply biomarker-guided therapy. Plasma levels of NPs reflect heart condition, since NPs are known to be overloaded in HF patients, and may supplement clinical findings and can be used to titrate HF medications (Fig. 2).

The use of NP levels to guide HF therapy has been studied extensively in the last decade (Troughton et al. 2014). Elevated BNP (above approximately 125 pg/mL) or NT-proBNP (above approximately 1000 pg/mL) values are prognostically meaningful in chronic HF, and a rising pattern is predictive of impending adverse outcome, irrespective of other subjective and objective prognostic metrics. The results of several studies support the use of serial NP testing to monitor the response to therapy and improve outcome in patients with chronic HF and reduced EF (Table 1) (Jourdain et al. 2007; Januzzi et al. 2011; Eurlings et al. 2010; Shah et al. 2011; Pfisterer et al. 2009). However, not all studies in which therapy has been guided by NPs have shown superiority over the standard strategy (Lainchbury et al. 2010; Gaggin et al. 2012). An important limitation of all these prospective trials was that fixed cut-points for NPs were established *a priori*, independently from patients' characteristics (e.g., age, LV EF, LVFP, renal function etc.). Since the clinical stability of individual patients may be expressed by different NP values, attempting to lower NP levels below a fixed threshold may be impracticable or even counterproductive. It is, therefore, important to individualize NP targets by means of so-called "dry" NP levels, which can be defined as the NP value that corresponds to clinical

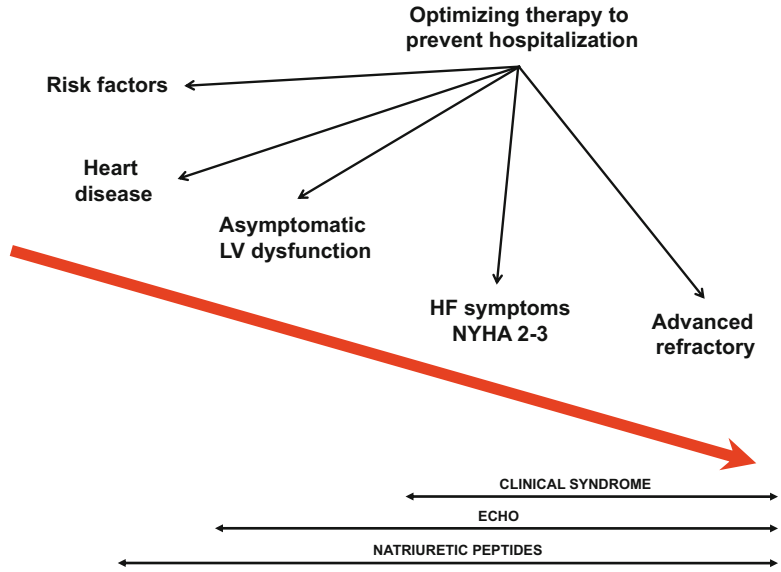

Fig. 1 Optimization of cardiovascular drugs and device therapies can be achieved by combining echo and natriuretic peptides

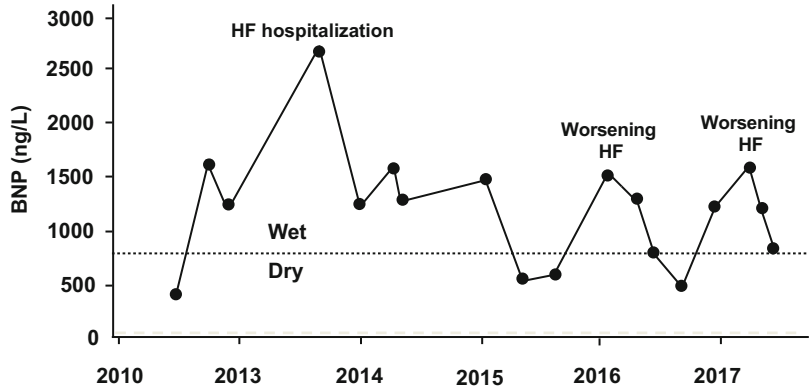

Fig. 2 Time-course of B-type natriuretic peptide levels in a patient with heart failure with reduced left ventricular ejection fraction

stability with no signs of fluid overload. Reaching low BNP or NT-proBNP, bringing the patient as close as possible to his "dry" level, can reduce the rate of both events and re-hospitalizations (Maisel et al. 2002; 2008). Relative changes of 40% in BNP values and of 25% in NT-proBNP values have been suggested as meaningful thresholds for detecting whether a significant variation has occurred (Stienen et al. 2015). With the introduction of neprilysin inhibitors, guided therapy with NT-proBNP should be recommended to prevent disease progression, optimize treatments and improve quality of life and prognosis (Zile et al. 2016).

2 Assessing Left Ventricular Filling Pressures by Echo

Several pressure measurements at cardiac catheterization has been referred to LV diastolic filling pressures. They include mean left atrial pressure, pulmonary capillary wedge pressure (PCWP) and LV end-diastolic pressure. Assessing LVFP in HF patients is of outmost importance inasmuch as more than 90% of hospitalizations due to worsening HF result from elevations of LVFP and fluid overload. Specifically, it has been recognized that PCWP is the ideal

Table 1 Strategies to lower circulating natriuretic peptide levels and reduce left ventricular filling pressures

Uptitrate or add ACEI, ARB or ARNI
Uptitrate or add beta-blockers (if not unstable)
Increase loop diuretic dosage, especially if BNP >500 pg/ml or NT-proBNP >2000 pg/ml
Add oral thiazide diuretic agents (including metolazone)
Add digoxin
Uptitrate or add MRA if tolerated by renal function and potassium
If in AF, maximize rate control or consider more aggressive attempts to restore sinusrhythm
Intensified or repeated HF education regarding sodium restriction and water intake
Consider potential indication for CRT
Consider optimization of CRT (if CRT device implanted)
Consider rehabilitation and exercise training

candidate to reflect the hemodynamic goal (Stevenson 2006).

LV diastolic filling pressures can be estimated reliably by echocardiography (Nishimura and Tajik 1997). Echocardiography offers a unique opportunity to identify the presence of increased LVFP (Table 2). Since the backward transmission of elevated mean left atrial and LV end-diastolic pressures is a prerequisite to cardiogenic pulmonary congestion, echo-derived assessment of filling pressures may be considered a surrogate marker of impending decompensation (Fig. 3) (Lester et al. 2008).

In recent years, knowledge and interpretation of echo Doppler measures have provided a non-invasive means for evaluating LVFP. A number of indices have been used, including: LV pulsed-wave transmitral filling velocities (E:A ratio, E wave deceleration time [EDT]), pulmonary venous flow (ratio of systolic wave velocity and diastolic wave velocity and the difference in duration between pulmonary venous flow and transmitral flow at atrial contraction), Doppler tissue imaging (DTI) and left atrial volume index (Table 2).

In patients with LV dysfunction, diastolic filling abnormalities as assessed by pulsed Doppler include three different transmitral flow velocity patterns: the impaired relaxation (stage I), characterized by a prolonged EDT with an E:A ratio $\leq$0.8, the pseudonormal (stage II), characterized by an EDT $\geq$150 ms and an E:A ratio >0.8, and the restrictive (stage III) (Fig. 4) (Nagueh et al. 2016).

An EDT <150 ms, i.e., restrictive transmitral flow pattern, has been shown to correlate well with a PCWP >15 mmHg, symptoms and advanced NYHA functional class (Nishimura and Tajik 1997). The restrictive pattern has been documented to be an important predictor of cardiac morbidity and mortality (The MeRGE Heart Failure Collaborators 2008). In patients with depressed LVEF (<40%), the presence of a stage I pattern usually reflects normal PCWP (Giannuzzi et al. 1994).

The classification based on transmitral flow velocity patterns is especially useful in patients with depressed LV EF, but in mildly reduced or preserved LV EF a prolonged EDT with an E:A ratio <1 (impaired relaxation pattern) may be sometimes associated with increased LVFP (Yamamoto et al. 1997). Therefore, in the presence of near normal (>40%) or normal EF (>50%), transmitral velocity should be considered an insensitive marker of diastolic dysfunction and combination of several variables, including the ratio of transmitral blood flow to myocardial early diastolic velocities (E/e′), left atrial size and pulmonary artery pressures, are often necessary for reliably estimating filling pressures. In these patients, a comprehensive approach that combines several echocardiographic and Doppler findings was found to be superior of any estimation of the filling pressures

Table 2 Echocardiographic and Doppler criteria to assess elevated left ventricular filling pressures

Measurement	Modality	Variable
Major criteria of elevated left ventricular filling pressures		
Transmitral velocities	Pulsed-wave blood flow Doppler	E wave deceleration time <150 ms
Transmitral and annular velocities	Pulsed-wave tissue and blood flow Doppler	Ratio of transmitral to myocardial early velocities (E/e′): medial >15, lateral ≥13, average ≥13
Pulmonary vein flow	Pulsed-wave blood flow Doppler	Difference in duration between pulmonary venous flow and transmitral flow at atrial contraction ≥30 ms
Pulmonary vein flow	Pulsed-wave blood flow Doppler	Ratio of systolic wave velocity and diastolic wave velocity ≤40%
Minor criteria of elevated left ventricular filling pressures		
Left atrial size	2D echocardiography	Left atrial volume index ≥40 ml/m^2
End-diastolic pulmonary regurgitant velocity	Continuous-wave blood flow Doppler	Estimated pulmonary artery diastolic pressure >13 mmHg
Systolic tricuspid regurgitant velocity	Continuous-wave blood flow Doppler	Estimated pulmonary artery systolic pressure ≥40 mmHg

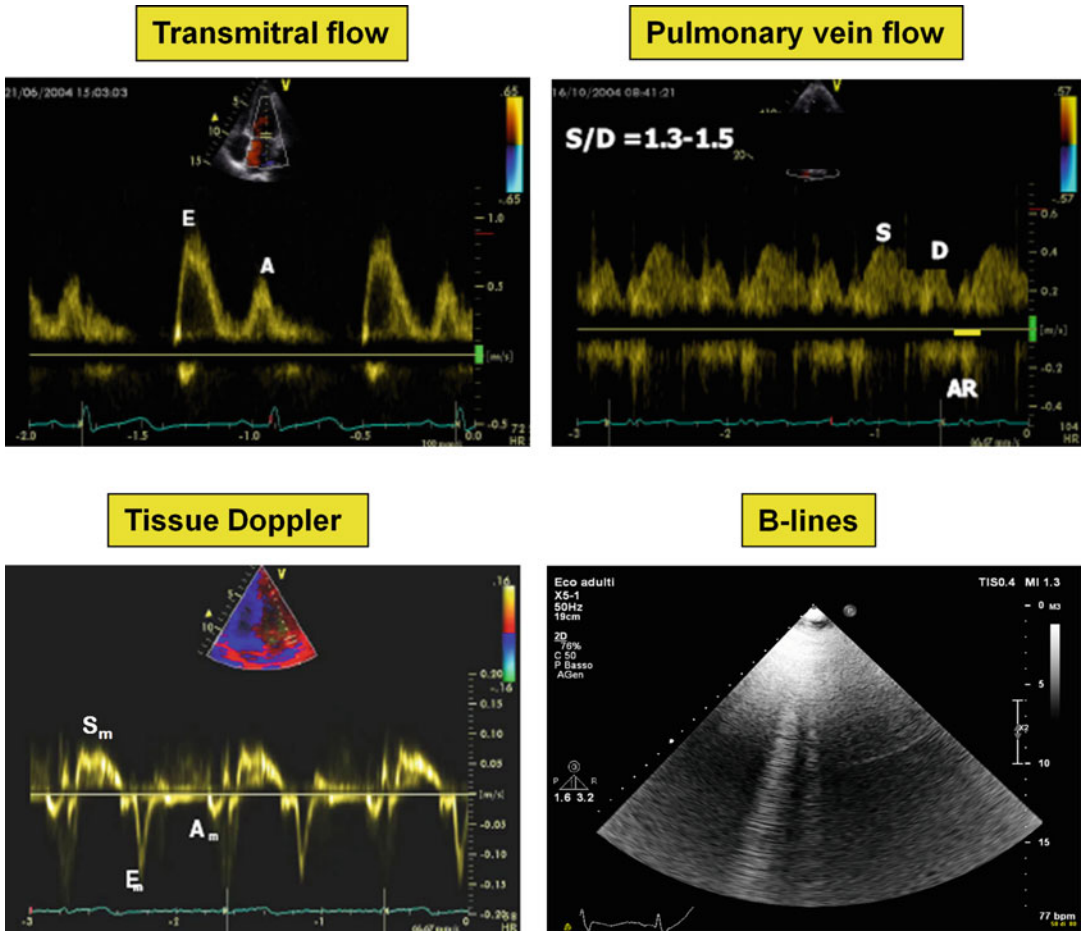

Fig. 3 Assessing left ventricular filling pressure by echo Doppler (transmitral flow, pulmonary vein flow and tissue Doppler) and pulmonary congestion by lung ultrasound

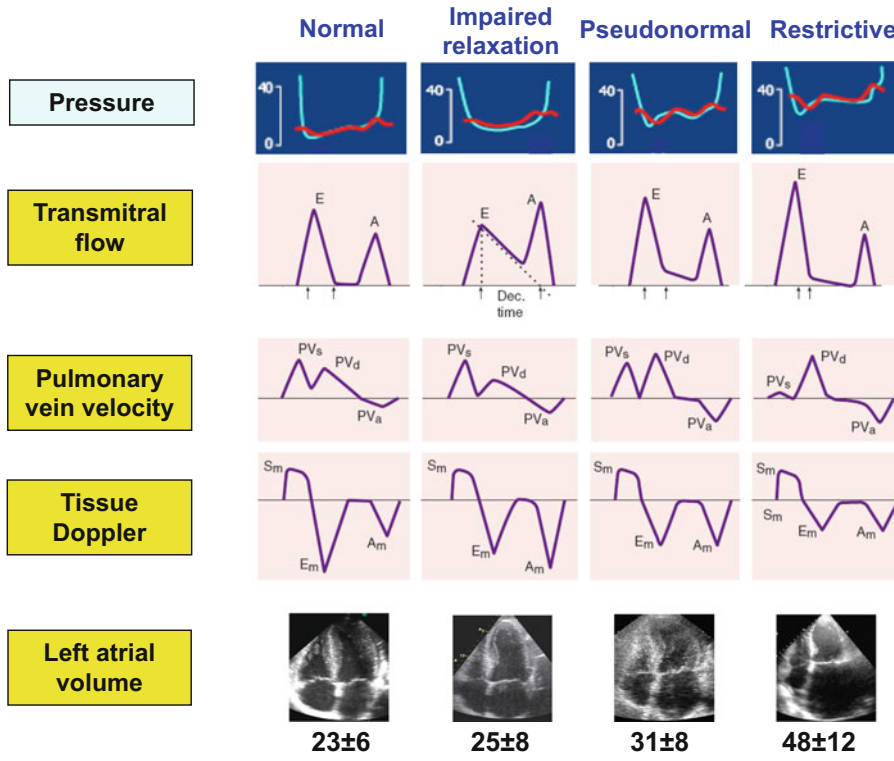

Fig. 4 Progression of the disease from normal to restriction. Note that there are four transmitral flow velocity patterns that corresponds to changes in pulmonary vein and tissue Doppler profiles as well as increases in left atrial volumes

provided by a single parameter (Dini et al. 2010). The use of echocardiographic HF risk scores has been proposed to stratify ambulatory HF patients with preserved or mildly reduced or reduced LV EF (Carluccio et al. 2013).

A clinically useful noninvasive measurement of PCWP should be able to detect meaningful changes in PCWP with therapy. Over the years, several authors have emphasized the value of reversible restrictive diastolic filling, that reflects the transition to more stabilized hemodynamic conditions. A restrictive LV filling pattern that becomes nonrestrictive after treatment or Valsalva maneuver has been associated with improved survival (Temporelli et al. 1998; Whalley et al. 2002). Patients with HF and depressed LV EF who had a restrictive flow and who did not reverse this alteration after unloading therapy had the worst prognosis.

Pulmonary venous flow patterns have provided an additional contribution to the assessment of the filling pressures (Appleton et al. 1993; Dini et al. 2000a). Analysis of the difference in duration of pulmonary venous and transmitral flow at atrial contraction has been shown to identify patients with increased LV end-diastolic pressure irrespectively of patients' LV EF. A valuable categorization has been accomplished using a cut-off value of 30 ms. Pulmonary venous A duration minus transmitral A duration >30 ms was found to be a powerful predictor of cardiac death or hospitalization for worsening HF (Dini et al. 2000b).

Diastolic dysfunction that brings about increases in LVFP very often leads to left atrial enlargement. Left atrial dilation can indicate the presence of longstanding structural heart disease and has a prognostic meaning (Rossi et al. 2002; Dini et al. 2002). The left atrium is considered to be a marker of long-term increased filling pressure analogous to the role of HbA1c as a measure of average glucose level in diabetes.

More recently, Doppler tissue imaging – particularly E/e′ – has entered the clinical scenario, thus providing additional prognostic information. Studies that have evaluated E/e′ in order to monitor PCWP in an outpatient setting have demonstrated that a ratio of E/averaged myocardial early velocity (averaged E/e′) ≥13 reliably reflects increased LVFP (Nagueh et al. 1997). In patients with near normal (>40%) LV EF, E/e′ is recommended for the estimation of LVFP, but adequate assessment of diastolic dysfunction often requires the combined use of transmitral and DTI parameters integrated with left atrial size and pulmonary artery pressures.

3 Lung Ultrasound

Lung ultrasound (LUS) is a novel technique that may detect and quantify pulmonary congestion. B-lines (previously known as lung comets) are sonographic reverberations artifacts, which originate from water-thickened pulmonary interlobular septa. Bilateral multiple B-lines are present in pulmonary congestion and are also helpful in outpatients with chronic HF failure to recognize impending signs of decompensation. B-line assessment has the advantage of being rapid, quick to learn, easy to perform and inexpensive (Frassi et al. 2007).

It has been clearly demonstrated that the presence of B-lines significantly correlated with E/e′ and NP levels, suggesting that assessing lung ultrasound can be feasible and accurate in detecting decompensation (Miglioranza et al. 2013; Gargani et al. 2015). In studies performed in patients admitted for acute HF, persistent pulmonary congestion at LUS before hospital discharge was associated with adverse outcomes of mortality and hospitalization for worsening HF (Gargani et al. 2015; Coiro et al. 2015).

Even though a number of studies have shown that LUS evaluation of pulmonary congestion is useful in the risk stratification of patients with chronic HF, the prognostic value of extravascular lung water in HF outpatients is less certain. In addition, lung comets tend to appear late during the course of the disease, and have low specificity in distinguishing between patients with pulmonary congestion and those with fibrosis. Hence, since the appearance of B-lines is a late evidence it is more reasonable to rely on echocardiographic modalities to assess elevated LVFP, which are a prerequisite to LV decompensation, rather than to depend on markers of increased pulmonary tissue water, which are obviously later findings.

4 Combining Echo and Natriuretic Peptides During Follow-Up

Early diagnosis of nonacute HF is crucial because prompt initiation of evidence-based treatment can prevent or slow down further progression. To diagnose new-onset HF in primary care is challenging and, when based on presenting clinical features alone, there may remain considerable diagnostic uncertainty. Therefore, additional testing, particularly measurements of NPs, may be of great value to refine diagnosis and improve management (Kelder et al. 2011).

In hospitalized patients with symptomatic acute HF, knowledge of LVFP is important for clinical decision making, and physical examination can provide important insight for treatment decision with very little contribution of NPs and echocardiographic findings (From et al. 2011).

In contrast with the acute setting, the clinical utility of integrated use of echocardiography and circulating NP levels has become increasingly apparent in the outpatient unit. Worsening of diastolic dysfunction and increasing NP levels often precede the development of signs and symptoms of HF, suggesting the role for preventing interventions (Fig. 1).

In chronic HF, health societies recommend the use of echocardiography for initial diagnosis when a change in the patient's clinical status occurs and when new data from an echocardiogram would result in the physician changing the patient's care. Health societies do not recommend routine testing when the patient has no change in clinical status or when a physician is

unlikely to change care for the patient based on the results of the exam (Douglas et al. 2007). However, assessment of clinical status is generally conducted with the use of the subjective NYHA classification and this measure is based on expert opinion of the presence of HF symptoms rather than objective evidence. Assessing patients with only NYHA classification may miss an objective measure that gives complimentary information and superior prognostication (Stevenson and Perloff 1989).

In recent years, the idea that a change in clinical status was the only prerequisite to performing echocardiography during follow-up of HF outpatients has been challenged (Tavazzi et al. 2013). It has become apparent that most symptoms and signs of HF have little sensitivity with regard to the detection of elevated PCWP, despite good specificity (Gheorghiade et al. 2010). The ADHERE registry data highlighted the limited reliability of clinician interpretation, as evidenced by incomplete symptom relief, in many patients with HF after hospital discharge (Adams et al. 2005).

Patients with HF are at high risk of death, but perhaps equally burdensome is the high rate of readmission. Recently, the prevention of hospital readmissions has been recognized as a primary goal for asymptomatic or mildly asymptomatic outpatients with HF has given important momentum to the role of follow-up echocardiography. With the introduction of more portable devices and focused cardiac ultrasound, a new window of opportunity has emerged for the more widespread use of echocardiography for serial evaluations of patients (Spencer et al. 2013). The value of repeated echocardiograms during follow-up visits has been supported by the ESC Guidelines on HF. Echocardiographic assessment was recommended not only to assess cardiac structure and function, including LV diastolic function, but also to plan and monitor treatment and to obtain prognostic information.

In HF outpatients, increasing the frequency of follow-up visits with the optimization of medical therapy, particular after hospital discharge, has been associated with improved outcomes, less hospitalizations and reduction of costs. To date, new evidences have supported the concept that better management and tailoring of cardiovascular therapies can be achieved by combining echo and NPs (Yin et al. 2012; Scali et al. 2014). This strategy may be proficiently combined with the standard components of the patient follow-up visit. Indeed, NPs and Doppler echocardiography, when utilized serially in an integrative and personalized manner, can be valuable in monitoring patients who are high risk of clinical exacerbation, with a significant benefit for the outcome. Patients whose BNP levels and echo-derived assessment of LVFP decrease in response to therapy had a better survival during follow-up (Fig. 5a).

The complimentary use of NP and echo-guided strategies can balance their intrinsic limitations, with crucial benefits for the patient. The limitations of the NP-based approach (including biological variability, slow time-course, poor specificity and lack of conclusive scientific evidence) may be overcome by this strategy. By contrast, assessment of NP concentrations seems especially useful in patients in whom Doppler echocardiographic parameters are inconclusive in the determination of LVFP.

The value of integrated circulating NP levels and echo-guided management of outpatients with chronic HF can be established when this strategy is compared with the standard of care. In a recent retrospective study, we observed a greater survival benefit in patients in the echo- and BNP-guided group than in a clinically-guided group (Simioniuc et al. 2016).

In echo-BNP-guided group, patients were first clinically evaluated (history, clinical examination, up-titration of therapy, measure of renal

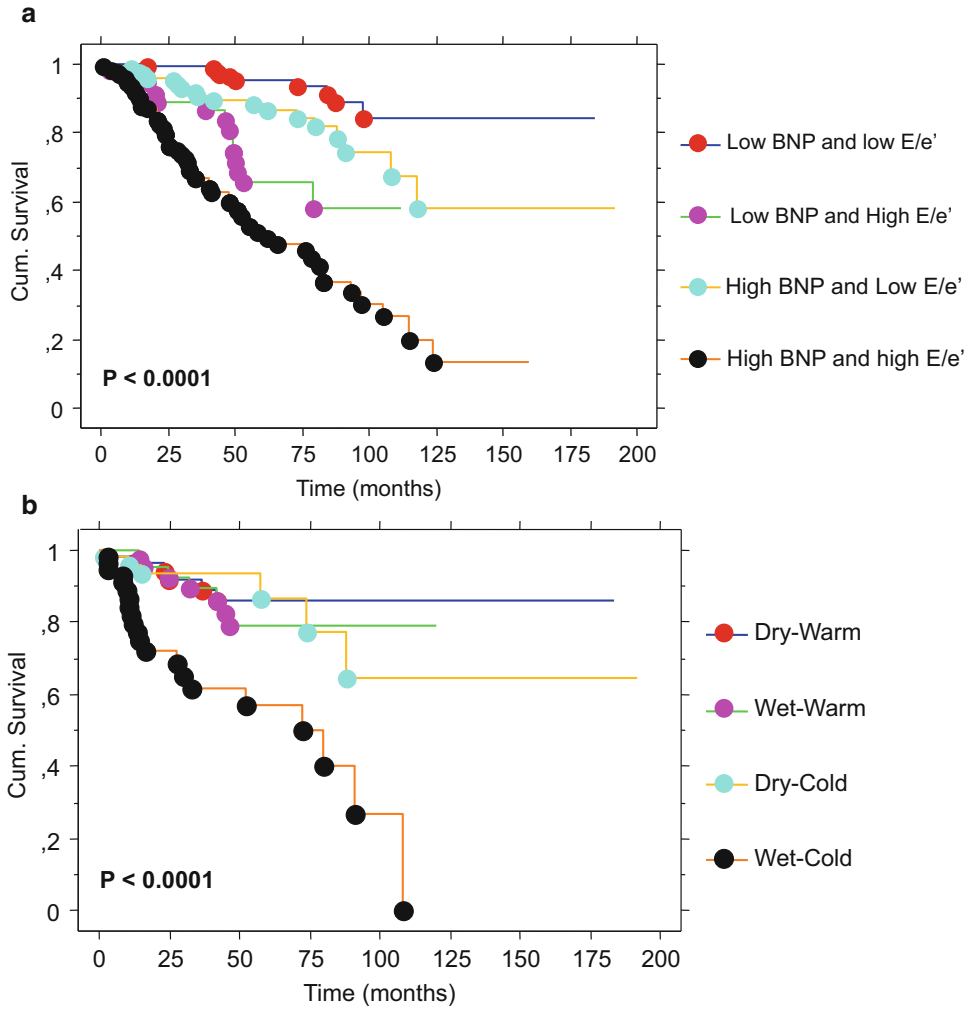

Fig. 5 (**a**) All-cause mortality in patients with chronic heart failure categorized according to B-type natriuretic peptide (BNP) levels and the ratio of transmitral blood flow to myocardial early diastolic velocities (E/e′). (**b**) All-cause mortality in patients categorized according to echo-assessed hemodynamic profiles (Simioniuc et al. 2016)

function) and BNP levels were assessed. If patients fulfilled the Framingham criteria for symptomatic HF or exhibited BNP levels at or above 125 pg/ml, echocardiography was performed as an adjunct to the physical examination, focused on the evaluation of echocardiographic signs of elevated LV filling pressures. Therapeutic decisions, including clinical interventions to lower BNP and/or elevated LV filling pressures, were made, thereafter, based on physical, biochemical and echo findings. A closer follow-up (2–4 weeks) was planned in symptomatic and asymptomatic patients exhibiting echo-Doppler signs of elevated LV

filling pressures and/or a clinically relevant rise in BNP concentration, while the frequencies of visits were extended out to 4–6 months in patients who were doing well.

The survival gain observed in the latter study was associated with a better management of renal function. Patients whose follow-up was based on standard of care had a significantly higher prevalence of worsening renal function, which was likely related to higher diuretic dosages. Patients in whom diuretic requirements were guided by NPs and echo had an advantage. In fact, diuretics were temporarily increased in those with elevated BNP concentrations and/or restrictive mitral flow with or without clinical signs of decompensation, whereas they were cautiously reduced when patients improved, especially if stabilized BNP levels and nonrestrictive mitral flow had been reached. As a result, increased necessity of diuretics or their excessive dosing were more easily identified or prevented by the echo-BNP guided care. A plausible reason behind these observations is that the early recognition of the euvolaemic state, i.e., normal tissue water content, by the echo and BNP guided strategy helps to prevent excessive dosing of loop diuretics, that may predispose patients to renal dysfunction and adverse prognosis (Harjai et al. 1999; Ahmed et al. 2006; Dini et al. 2013; Damman et al. 2016; McKie et al. 2014). We can, therefore, assume that clinical findings are of limited value to assess diuretic requirements during follow-up, whereas the echo and BNP driven approach is important to overcome this limitation and to optimize HF treatment, including loop diuretic regimen. Since renal dysfunction is known to be one of the most predictive markers for adverse outcomes in chronic HF, guiding HF care with echo and NPs seems valuable to reduce patients' risk in the outpatient setting Eliminate and substiture with (Dini et al. 2017).

In another study that compared ambulatory HF patients submitted to an echo and BNP guided follow-up versus patients who underwent a symptom-guided follow-up and those receiving no organized follow-up, management directed by echo and BNP was associated with a better survival. In the echo and BNP-guided group, raised LV filling pressure, as assessed by E/e′, and BNP levels were the best predictors of all-cause mortality, whereas presence of B-lines at LUS were independently associated with the combined end-point of death and HF hospitalization. We can, therefore, assume that clinical findings are of limited value in optimizing HF therapy during follow-up, whereas the echo- and BNP-driven approach is important in order to overcome this limitation and provide the patients with a more tailored therapy (Dini et al. 2017).

5 Hemodynamic Profiles in Patients with Chronic Heart Failure

Management of HF, improvement of survival and avoidance of HF hospitalization depend largely on correct assessment of systolic function and pulmonary congestion (Nohria et al. 2003). Classifying patients with advanced HF by baseline measures of perfusion and pulmonary congestion has been used to estimate hemodynamic status and to select and titrate therapy (Stevenson et al. 1990).

In 1976, Forrester et al. (1977) demonstrated that among patients who had an acute myocardial infarction, Swan-Ganz catheterization identified four hemodynamic profiles. These profiles were based on the presence or absence of congestion (PCWP $>$ or $\leq$18 mm Hg) and adequacy of perfusion (cardiac index [CI] $>$2.2 l/min/m^2). Profile A (dry-warm) represented no congestion or hypoperfusion; profile B (wet-warm), congestion without hypoperfusion; profile C (dry-cold), hypoperfusion without congestion; and profile D (wet-cold), both congestion and hypoperfusion. Furthermore, invasive hemodynamic profiles predicted survival, with increased mortality when congestion was present (profile B) and even worse outcomes when both congestion and hypoperfusion were evident (profile D). Conversely, profile A (dry-warm)

describes a group of well-compensated patients with a good overall prognosis.

The hemodynamic assessment of HF patients is a fundamental strength of echocardiography (Nagueh et al. 2016). According to international guidelines, echocardiography is the single most useful diagnostic test in the evaluation of patients with HF because of its ability to accurately and noninvasively provide measures of LV function and assess causes of structural heart disease. It can also detect and define the hemodynamic and morphologic changes in HF over time and might be equivalent to invasive measures in guiding therapy.

Doppler echocardiography is not only useful for noninvasive determination of LVFP, it can provide reliable and repeatable measures of cardiac output and stroke volume, which can be evaluated across any cardiac orifice, such as the LV outflow tract (Quiñones et al. 2002). The estimation of stroke volume depends on accurate assessment of LV outflow tract, errors of which are squared in the course of cross-sectional area calculations. Luckily, this measurement is facilitated by the dimensions of the LV outflow tract that are highly correlated with body surface area (Shiran et al. 2009; Leye et al. 2009). Like the Forrester hemodynamic classification, echo-directed categorization of HF patients according to hemodynamic profiles can provide information that reflects the patient's fluid status and tissue perfusion. This strategy can also be used in outpatients since it based upon noninvasive variables and does not require the presence of symptoms of decompensation for diagnosis. The value of echo-directed hemodynamic profiles is well depicted in Fig. 5b, where outpatients with HF who manifested low output and increased LVFP had the worst outcome.

Another prospective development is to integrate measures of NPs and echo markers of increased LVFP with parameters that indicate low cardiac output or depressed stroke volume (Fig. 6). The significance of this approach is that it facilitates the early recognition of the high risk patient (B, C and D), on the basis of changes in NP levels from "dry" to "wet" and modifications of echo-Doppler variables, which reflect the evolution toward congestion or low perfusion (Dini et al. 2017). The inclusion of patients in subsets A, B, C, or D may be used not only to better interpret the patient's hemodynamic status but also for prognostic stratification. Our preliminary results show that when high-risk patients do not revert to a lower risk profile on therapy, the event-rate tends to increase substantially. Finally, echo-directed hemodynamic profiling may help guide titration of medical therapy. Patients with profile A may tolerate initiation and up-titration of beta-blockers with the success observed in major trials, whereas profile B might represent a population where chronic beta-blocker therapy could be maintained but initiation or up-titration deferred until restoration of profile A. Conversely, determination of profile C might lead to a decrease or withdrawal of recently initiated beta-blockers until better compensation is achieved. The greater use of beta-blockers on admission in patients with profile A relative to those with profiles B and C is consistent with this management strategy.

6 Conclusions

There are a number of reasons to use echo and NPs in combination to optimize management during follow-up of HF outpatients. Echo parameters, including LUS, have been correlated with LVFP and are useful to identify patients with a higher than normal PCWP and incipient pulmonary congestion. However, echo variables have a significant "gray zone" in which they are often inconclusive in the assessment of LVFP. Integration of echocardiographic estimates of LVFP with the determination of NP circulating levels and measures of LV pumping capacity, such as cardiac output and cardiac index, can be used to reach a comprehensive understanding of patients' hemodynamic status. This findings can be proficiently used to distinguish stable patients form those who at high risk of clinical decompensation and may be utilized to better titrate cardiovascular medications and interventions, with clinical benefit and the reduction of costs of hospitalization.

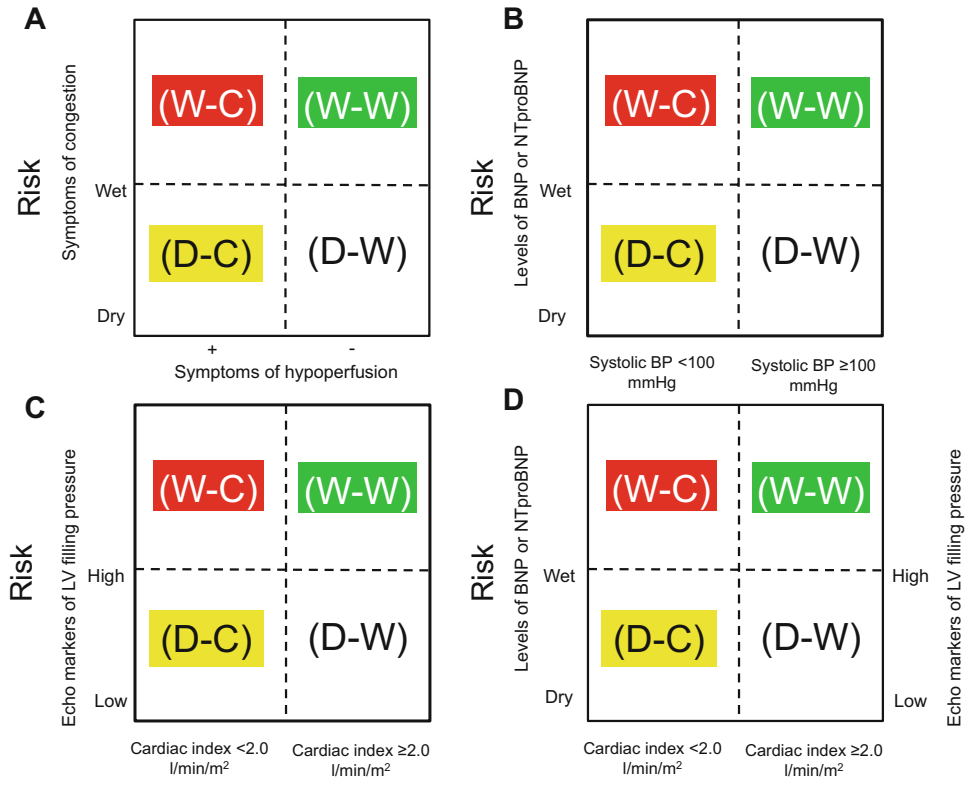

Fig. 6 (**a**) Assessment of clinical profiles. Congestion is assessed by presence of orthopnea, jugular venous distension, rales, hepatojugular reflux, ascites, peripheral edema. Physical Training and Cardiac Rehabilitation in Heart Failure Patients

Cesare de Gregorio

Abstract

Regardless of advances in medical and interventional treatment of cardiovascular disease (CVD), a limited number of patients attend a cardiac rehabilitation (CR) programme on a regular basis. Due to modern therapies more individuals will be surviving an acute cardiovascular event, but the expected burden of chronic heart failure will be increasing worldwide.

However, both in high- and low-income countries, secondary prevention after an acute myocardial infarction or stroke has been implemented in less than a half of eligible patients.

Combined interventions are still needed to reduce decompensations, hospitalizations and mortality in heart failure patients from any origin. In addition to medical treatments, regular exercise has been demonstrated to improve metabolic and hemodynamic conditions in both asymptomatic risk factor carriers and cardiac patients. Risk factor control and exercise should gather together for an effective management of patients.

Exercise-based training is a core component of primary and secondary prevention. It should involve healthy carriers of cardiovascular risk factors, and patients with cardiomyopathy as well. The supposed attenuated effect of CR in the era of advanced revascularization and structural interventions is due to the heterogeneity of training models and physical training in the literature. Moreover, lifestyle modification, psycho-social challenges and patient's compliance are potential confounders.

In this chapter the most recent evidences about training modalities and potential benefit of CR in heart failure patients are discussed.

1 Introduction

Cardiac rehabilitation (CR) is the sum of interventions needed to ensure the best physical, psychological and social conditions to the patient with chronic heart failure (CHF) or post-acute cardiovascular (CV) event (Wenger et al. 1995; Fletcher et al. 2001) [Table 1].

Despite advances in medical and interventional treatment of cardiovascular diseases (CVDs), there are only a few patients attending at CR programme on a regular basis. Therefore, more individuals are expected to survive an acute CV event, but the occurrence of CHF as a chronic complication will be increasing worldwide. Though secondary prevention with medical drugs is habitually promoted after an acute event, CR programmes following an acute myocardial infarction or stroke have been implemented in less than a half of eligible patients. Due to limited access resources to healthcare systems, especially in low-income countries, coverage for primary and/or secondary prevention is less than expected (Piepoli et al. 2014; Rauch et al. 2016; Piepoli et al. 2017).

Table 1 Essential features in cardiac rehabilitation programmes

People's needs centred
Refining patient's ability and skills for daily routines
Encouraging social activities and return to work
Enabling patient's psychological course
Improving people's relationship with relatives
Responding to changes in people's needs
Taking patients part of their therapy
Helping patients in order to change lifestyle
Providing interdisciplinary team counselling
Reducing re-hospitalization and clinical outcomes

However, combined interventions are still needed in order to reduce decompensations, hospitalizations and mortality in CHF patients from any origin. Above drug use, regular exercise has been demonstrated to improve metabolic balance and cardiovascular condition in both cardiac patients and asymptomatic carriers of CV risk factors. Risk factor control, combined exercise and medical therapy should be patient-tailored for a better management of CHF, regardless of nationwide healthcare organization difficulties (Stephens 2009; Pulignano et al. 2016).

Exercise-based CR programmes have been recognized to be as cost-effective as medical treatment. Decreased hospital admissions and benefits in both clinical condition and quality of life have been reported by the majority of studies, and such a low mortality rate has been observed during CR time frame. The underutilization of CR is a crucial issue when successful return to work has to be warranted after an acute CV event in people of working age (Taylor et al. 2014; Ambrosetti et al. 2017).

In these clinical settings, exercise training should be encountered as a core component of secondary prevention, but also of primary prevention in healthy carriers of risk factors. The supposed attenuated effect of CR in the era of advanced revascularization and structural interventions may be linked to the heterogeneity of patients from the available studies. Also, different training models, factual lifestyle modification, psycho-social challenges, and patient's compliance are unforeseen factors (Taylor et al. 2004, 2014; Rauch et al. 2016; Piepoli et al. 2017).

2 From Risk Factor Control to Post-acute Cardiac Event

The mainstream approach to CHF patients necessarily encompasses major risk factors control. For instance, the straightforward management of systemic hypertension is class IA and tobacco smoking cessation class IC level of recommendation.

According to the ESC/ACC guidelines, counselling is strongly encouraged, especially in CHF patients routinely consuming alcohol drinks. Naturally, each patient shows individual characteristics that should be considered on the basis of their specific aetiology and pathophysiology (Arena et al. 2007; Balady et al. 2007; James et al. 2014; Ponikowski et al. 2016; Piepoli et al. 2017).

A substantial number of deaths have been likely demonstrated as a consequence of continued cigarette smoking after an acute CV event. Smokers, in fact, were shown to have 2–4 fold higher risk of new coronary and/or ischemic brain events than non-smokers. Continuing to smoke after an acute myocardial infarction or coronary revascularization leads to high probability of re-infarction and increased mortality in the mid- and long-term follow-up (Suskin et al. 2001).

Diabetes and hypercholesterolemia are very common risk factors among CHF patients, and their presence can lead to myocardial and muscle functional deterioration. Nonetheless, the benefits of rigorous glucose control have been widely debated, because deleterious effects of repeated hypoglycaemic crisis have been demonstrated in comparison with patients keeping moderately, but steady, hyperglycaemia (Aguilar et al. 2009; MacDonald et al. 2010).

However, higher HbA1c is associated with a greater risk of CV events in untreated diabetic patients with CHF (Goode et al. 2009).

Regarding obesity, in a large population-based study on 120,813 nondiabetic obese individuals (aged 51 $\pm$ 4 years), the risk of CV events was related to overweight. During a mean follow-up of 10 $\pm$ 7 years, the risk of developing cardio-metabolic multi-morbidity was 5 times higher in class I obesity individuals (OR 4.5, 3.5–5.8; $p < 0.0001$). It was almost 15 times higher in those from classes II and III combined (14.5, 10.1–21.0; $p < 0.0001$), irrespective of gender, age and race. In view of the risk of death related to cardio-metabolic decompensation, this study likely confirmed that obesity must be carefully managed in order to reduce the risk of diabetes and CVD. Thus, regular exercise should be mandatory for lifestyle to change (Kivimäki et al. 2017).

However, the most important conditions in which CR takes the greatest advantage are post-acute cardiac events. Despite important benefits of CR in combination with stringent risk factors control in patients with first coronary event (Steca et al. 2017), a recent Norwegian study reported low participation rates (20–30%) to a CR pathway among patients undergoing a first percutaneous coronary intervention. Their participation was also dependent on the geographical location. The typical participants were young, overweight and well-educated patients (Olsen et al. 2017).

Another prospective cohort study of patients with a first myocardial infarction referred to 3 different tertiary care teaching hospitals in Switzerland, Poland and Ukraine demonstrated substantial differences in treatment and secondary prevention measures according to their socioeconomic condition (Kämpfer et al. 2017).

More than 7 million people worldwide experience a myocardial infarction every year. Twelve-month mortality rates are now in the range of 10%, and the consequence is that 20% of the survivors suffer a second event. Approximately 50% of major coronary events occur in patients previously hospitalized for ischaemic heart disease (Piepoli et al. 2017).

A call for much stronger secondary prevention is nowadays crucial in order to reduce population risk and recurrences (Fig. 1).

Beyond CV risk factors control and appropriate lifestyle changes, the European Society of Cardiology is determined to embrace current challenges by updated documents aimed at covering present gaps for secondary prevention strategies, which include physical activity and exercise on a regular basis (Piepoli et al. 2014, 2017).

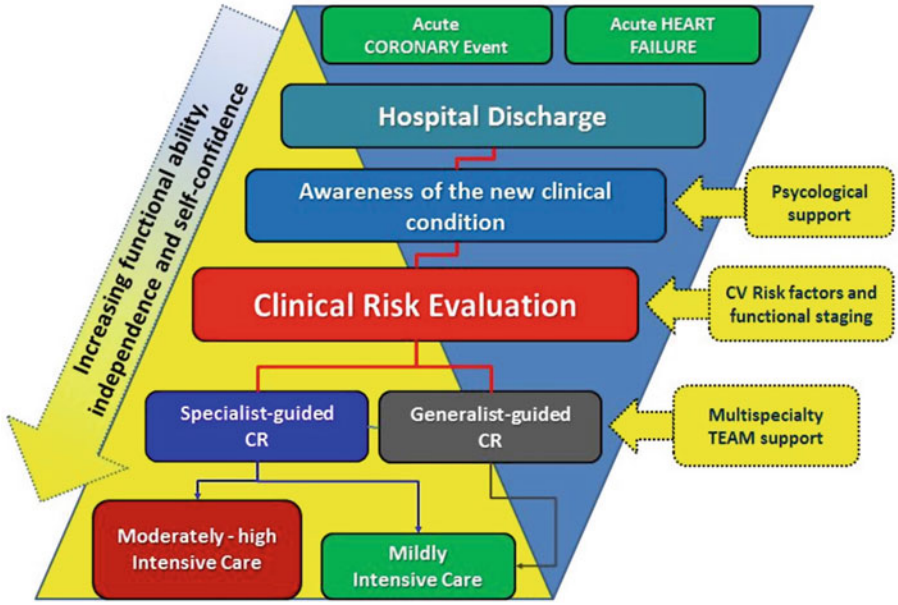

Fig. 1 Cardiac rehabilitation pathway for patients experiencing first cardiac event. Training is aimed at improving functional capability, independence and self-confidence

3 Physical Training in CHF Patients

Diagnosis of CHF is based on established criteria by the international guidelines (Ponikowski et al. 2016). Major causes of CHF with and without LV dilatation are summarized in Table 2.

Several modalities and intensity of training exercise have been tested in CHF patients. Both, progressively rising or steady intensity levels, up to 95% of peak heart rate (HR), have been shown to be beneficial on their hemodynamic status (O'Connor et al. 2009; Taylor et al. 2004). However, training protocols are still debated because of a large methodological heterogeneity (Pollock et al. 2000; Taylor et al. 2014; Cornelis et al. 2016; Ambrosetti et al. 2017).

The *Francais Groupe pour exercice réadaptation et sport (National Society of Cardiology)* has demonstrated such a variability in the management of CR protocols from various Cardiac Centres. For instance, cardiopulmonary exercise test (CET) was performed in 86% of the individuals before a CR programme. Training intensity was established on the basis of gas exchanges and peak VO_2, when available. Alternatively, patients were trained on symptoms (Borg scale), or a combination of both these latter. The amount of daily exercise sessions varied from 2 to 4 (Tabet et al. 2009).

In most cases, intensity of daily activities and exercise refers to the metabolic equivalent (MET), which is the resting metabolic rate (the amount of O_2 consumption at rest) approximately corresponding to 3.5 ml O_2/kg/min (1.2 kcal/min for a person weighing 75 kg). Working at 4 METS improves the metabolism up to 14.0 ml O_2/kg/min (Jetté et al. 1990).

Tables 3 and 4 show various activities and related METS to be applied for a CR programme in either healthy carriers of risk factors or CHF patients.

4 Exercise Modalities

Exercise involves skeletal and cardiac muscles in both mechanical (static or isometric, and dynamic or isotonic) and ventilatory-metabolic properties (aerobic and anaerobic).

Table 2 Main causes of chronic left heart failure

With left ventricular dilatation
Ischemic heart disease and previous myocardial infarction
Primary or secondary dilated cardiomyopathy
Previous myocarditis
End-stage hypertensive heart disease
End-stage hypertrophic cardiomyopathy
Aortic regurgitation
Without left ventricular dilatation
Hypertensive heart disease
Ischemic heart disease
Hypertrophic cardiomyopathy
Left ventricular (pseudo)hypertrophy from storage/infiltrative/systemic disease
Restrictive cardiomyopathy

Table 3 Range definitions of exercise intensity levels for CR

Intensity	effort	METS	Peak VO_2[a]	Peak VO_2 (%)	HR max (%)	Borg scale	Aerobic	Anaeobic	Lactate prod[b]
Low	Light	≤3	≤10.0	<40	<55	≤11/20	√		<2.0
Moderate	Intermediate	3.5–5	11.0–18.0	40–60	55–69	≤13/20	√	√	2.0–3.0
High	Vigourous	5.5–8.5	18.0–25.0	61–79	70–90	≤16/20	√	√	>3.0
Maximal	Very hard	>9	>25.0	>80	>90	≤19/20		√	>4.0

HR heart rate (bpm), *PVO_2* peak oxygen upload
[a](ml/kg/min)
[b]Lactate production (mmol/L)

Isometric exercise results in a static muscular strain, with minimal or absent limb movement. On the contrary, **isotonic exercise** leads to more or less extensive movement of the limb or body, and thus to muscle fibres changes in lengthening. This latter can also be classified as concentric (shortening of the myofibrils against gravity or a weight) or eccentric (lengthening of the muscle fibres, as a weight is lowered against gravity). Alternatively, *metabolic classification* refers to O_2 consumption, available for the muscle contraction. Exercise can be aerobic (in O_2 environment, without lactate production) or anaerobic. Both metabolic and mechanic components are usually present in a variable proportion in all exercises, as well as varying with intensity during the same exercise. Likewise, testing the response to exercise can be challenging in function of the frameworks chosen (Arena et al. 2007; Tabet et al. 2009; Fletcher et al. 2013; Hollings et al. 2017).

Endurance exercise has a predominant *dynamic–aerobic* component, but at a higher intensity it can move into a *dynamic-anaerobic* feature, related to the increased O_2 demand, primarily from the most involved muscles.

Resistance (strength) exercise refers to activities using low-mid-repetition movements against resistance, thus with a prevalent *isometric/static/eccentric* component. For these characteristics, resistance exercise should not be encouraged in patients with high peripheral resistances or systemic hypertension, although it could yield modest reduction in blood pressure.

Endurance-strength exercise is a delicate compendium of the aforementioned modalities. Though challenging, it can improve athletic performance in healthy individuals and shortening the workout time in cardiac patients. From a physiological point of view, muscles dedicate to endurance exercise are different from those involved in strength exercise. There is a

Table 4 Metabolic costs of various physical activities

Exercise	METS	O_2 uptake (ml/Kg/min)
Writing	1.7	5.9

Swimming pool (mid-heavy)	11–14	28–33

documented reciprocal interference phenomenon, because endurance muscle (red) fibres are chiefly devoted at improving aerobic metabolic capacity and facilitating body weight loss, whereas muscle mass and potency are due to strength (white) fibres, with only minor changes in aerobic capacity. Sports science has been working hard to find the best combination of both these components, but not a single solution is available to each patient yet. In cardiac patients, this is a suitable combination of exercises to improve their working ability and wellness, but the proportion of strength exercise should not exceed 30–40% of the whole training programme (Fletcher et al. 2013; Hollings et al. 2017).

5 Training Modalities

Among CR training modalities, the following have been chiefly tested in CHF patients: continuous training; interval training; inspiratory muscle training; strength exercise; and a combination of these (Fletcher et al. 2013; Mezzani et al. 2013; Cornelis et al. 2016; McGregor et al. 2016; Hollings et al. 2017).

Continuous training (CT), basically known as ***endurance training***, is characterized by a low-mid intensity, steady exercise. Usually submaximal and aerobic, it has to be performed for considerable time (eg. sauntering or jogging). It improves respiratory gas exchanges, heart rate (HR) reserve, peripheral vascular resistances and blood pressure. It also facilitates body weight loss, but needs long-term training. If a cardiopulmonary testing (CET) has been performed, training intensity should be started at 30–40% of peak VO_2, rising up to 50–60% over time.

During CT, the cardiac output increases due to the Frank-Starling mechanism and the rise in HR (cardiac output = systolic output × HR). At moderately-high intensity exercise, the cardiac output is chiefly due to HR, because the stroke volume typically reaches a plateau at 50–60% of the maximal VO_2 (Balady et al. 2007; Arena et al. 2007; Fletcher et al. 2013; Hollings et al. 2017).

Interval training (IT) is characterized by short sessions of aerobic high-load (strength) exercise alternating with resting periods (Fig. 2). Apparently more risky than CT, it has been reported as safe as the low-intensity CT. It was demonstrated to get good cardiac improvement even in populations of elderly patients with stable post-infarction CHF (WislØff et al. 2007; Mezzani et al. 2013).

In the study of Wisloff et al. (2007), CT protocol consisted of a combination of exercise at 70% (for CT) and 95% (for aerobic IT) of peak HR, for 12 weeks. Based on available literature, both European and American guidelines committees have endorsed IT as a safe modality of CR (Balady et al. 2007; Mezzani et al. 2013). More recently, high-intensity IT was proven to be beneficial as well, and individualized models of high-intensity training have been proposed according to clinical condition (McGregor et al. 2016; Ribeiro et al. 2017).

Moreover, functional capacity and atrial fibrillation recurrences were demonstrated to ameliorate in CHF patients with non-permanent atrial fibrillation after 12-month aerobic IT in comparison with CT (Malmo et al. 2016).

Inspiratory muscle training (IMT) is a modality of exercise aimed at improving respiratory functional capacity. Mechanisms of dyspnoea are multifactorial and interacting each other in CHF patients. Dominant catabolic processes, caused by LV impairment and low cardiac output, lead to respiratory and skeletal muscle myopathy which weakens exercise tolerance in the advanced stages of CHF. It has been demonstrated that abnormal increase in work of breathing due to the imbalanced ventilatory rate probably contributes to exercise intolerance and symptoms. Also, the central nervous system's perception of huge inspiratory output increases dyspnoea as well (Borghi-Silva et al. 2008).

Bosnak-Guclu et al. (2011) demonstrated that 6-week IMT (after 1-week familiarization with the method) can improve functional capacity, respiratory and peripheral muscle strength in patients with CHF. Likewise, fatigue perception, mood disorders and depression ameliorate.

More recently, IMT was also tested in intensively treated patients with prolonged use of mechanical ventilation. In this group, inspiratory training with the help of an electronic device (the manual mode consisted of 3 series of 10 repetitions with 1-min break between each series, twice a day) increased muscular inspiratory performance and shortened their weaning time significantly (Tonella et al. 2017).

Strength-exercise training (SET)**,** also defined ***resistance training*****,** is a relatively recent modality of training that was unlikely to be applied in CHF patients until a few years ago. Power exercise has been demonstrated to be feasible in a wide number of patients, when tailored to their initial functional capacity, muscle mass and muscular tone. Studies have demonstrated that intensity can be progressively increased

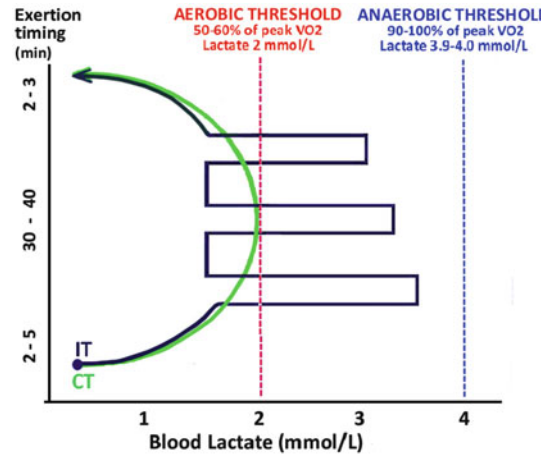

Fig. 2 Comparison of continuous training (CT) with interval training (IT) modality in a cardiac rehabilitation session, according to lactate production (Modified from Tabet et al. 2009)

from low (2–4 sets of exercises at less than 60% of pVO_2) to high-intensity level (8–10 sets, at 80–90% of pVO_2) at no clinical risk (Seguin and Nelson 2003).

Moderate to high intensity resistance training performed 2–3 days per week (for 3–6 months) was really effective in both men and women with heart disease (Pollock et al. 2000; Seguin and Nelson 2003; Ribeiro et al. 2017).

6 Eligibility for Cardiac Rehabilitation

Patients experiencing an acute CV event can be eligible for a CR programme early after hospital discharge. However, the best timing for training to be started cannot be established without considering at least the following factors: (1) magnitude of cardiac damage and persistent ventricular dysfunction; (2) residual myocardial ischemia; (3) electrical instability; (4) clinical deterioration and comorbidities; (5) pulmonary function. As expected, uncomplicated patients can be eligible for physical training earlier than those remaining symptomatic despite intensive therapy and interventional procedures, as well as when complicated by severe cardiac dysfunction, electrical instability and/or advanced kidney disease (Taylor et al. 2004; Balady et al. 2007; Taylor et al. 2014). A three-level risk classification for establishing eligibility to CR is displayed in Fig. 3. Stages A to D refer to the ACC heart failure classification reported by Hunt (2006), still valid.

Fortunately, less severe dysfunctional outcomes are expected in cardiac patients undergoing modern treatments and procedures than in the past (Piepoli et al. 2011; Piepoli et al. 2014; Ponikowski et al. 2016). For instance, a growing number of elderly patients is undergoing transcatheter aortic valve implantation (TAVI) for aortic stenosis. They represent a new class of CR candidates, whose risk level has not been established yet. Although early experimental studies demonstrated no benefit of training in mice with LV hypertrophy from aortic stenosis (exercise induced LV impairment, increased collagen expression, pulmonary congestion and worsening biomarkers) (van Deel et al. 2011), nowadays CR is recommended to patients receiving surgical aortic valve replacement (Hansen et al. 2015; Lund et al. 2016).

Better survival rate and functional capacity, but controversial mental health outcomes, have been reported by Sibilitz et al. (2016).

A recent pilot study on combined SET after TAVI demonstrated a significant improvement in exercise capacity, muscular strength, and quality of life in comparison with the usual care, without new cardiac events or prosthetic valve dysfunction (Pressler et al. 2016).

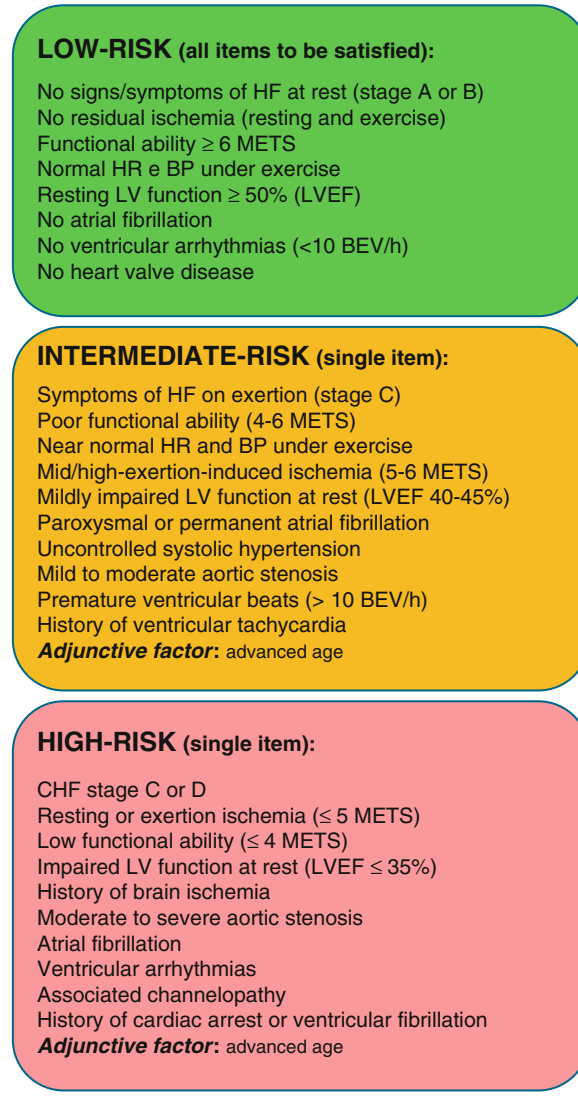

Fig. 3 Assessment of cardiac risk in CHF patients and eligibility requirements for CR. Based on the ACC guidelines, asymptomatic or sporadically symptomatic patients, thus at risk of HF (NYHA class I) can be classified as **stage A** (risk factor carriers) or **B** (presence of cardiac damage, like hypertensive heart disease, LV hypertrophy or dilatation, valve disease, previous myocardial infarction). As they become symptomatic, **stage C** refers to patients with treatable heart failure (NYHA class 2–3) and **stage D** is the most advanced stage (NYHA class III-IV), usually eligible for intensive therapy, resynchronization therapy, ventricular assistance device or heart transplant. High blood pressure can be further prognosticator also in low-risk patients

Overall, unstable and risky clinical conditions remain a warning for a safe CR programme in the CHF patient population (Fig. 3). High-risk patients should not undergo CR unless any cause of instability has been resolved. They require to be reclassified onto moderate-risk class before deciding about a CR program. These patients usually need to follow the entire pathway across all rehabilitation services, which include intensive CR program in skilled Medical Centres. Patients with a higher clinical risk need a safer modality of training (Piepoli et al. 2014; Ambrosetti et al. 2017; Karagiannis et al. 2017).

Low-risk stable patients do not deserve particular attention and can be addressed to either a centre-based or home-based CR. Both models have been demonstrated to ensure CV benefit and wellbeing. Services should be commissioned to warrant a smooth transition across all elements of their pathway. Of note, it is likewise important for patients to have easy access to hospital and local healthcare services, possibly choosing the

same one where they have been discharged from. Regular communication between outpatient hospital services and each patient is a requirement for best clinical achievements (de Gregorio et al. 2015; Pulignano et al. 2016; NHS England. 2016).

As aforementioned the recent meta-analysis by Anderson et al. (2017a, b) demonstrated no differences between home- and centre-based CR in terms of clinical outcomes at 1-year follow-up in many patients with ischemic heart disease or overt CHF. The authors also confirmed the continued expansion of evidence-based utility of CR programmes in the community.

Furthermore, no differences between home-based with tele-monitoring guidance and centre-based training were found to reach impressive health-related quality of life. Home-based training, however, was associated with a higher patient satisfaction and, as expected, it was more cost-effective than centre-based programme. Lacking territorial facilities in order to get nursing home-assistance and tele-monitoring were the main limitations of less organized communities (Kraal et al. 2017).

7 How to Assess Functional Capacity

In order to establish exercise capacity in CHF patients before starting a CR programme and during the training period, different protocols have been suggested. Many times, peak exercise values have been investigated using an effort perceived scale during exertion test, as initially proposed by Borg et al. (1984).

A short-time exercise of 8–12 min was suggested by Hansen et al. (1984) for assessing patient's perception of fatigue and/or dyspnoea. The initial 20-point Borg scale has been occasionally used for strength exercise due to its complexity. A 15-point scale was then preferred to support an easy-to-do, reliable, and instrument-independent estimation of exercise intensity. More recently, a modified 10-point scale was demonstrated to be easier to use for evaluating exercise training intensity, rehabilitation and perception, after adequate validation against objective markers of intensity. A ramp protocol on bike or treadmill test with a modified Bruce protocol has been suggested in CHF patients (Noble and Robertson 1996; Day et al. 2004).

However, **cardiopulmonary exercise testing** (CET) has become the most useful method to estimate functional capacity in cardiac patients on treadmill or cycling test. A ramping protocol of 8–12 min is encouraged to the patient performing exercise until symptoms of chest discomfort or dyspnoea become intolerable. Breath-to-breath gas exchange by a covering nose and mount mask is analysed with a metabolimeter. Minute ventilation, instant VO_2 uptake and carbon dioxide (CO_2) production are collected on a regular basis. Peak VO_2 consumption reflects the highest attainable rate of transport and use of O_2 during the incremental ramp protocol. Under normal circumstances, peak VO_2 is expressed as an absolute value (ml/Kg/m) or percent between her/his measured and reference value (Balady et al. 2010; Arena and Sietsema 2011; Schraufnagel and Agostoni 2017).

The ***aerobic threshold***, a concept based on the principle that energy production shifts from aerobic metabolism to a metabolism that combines both anaerobic and aerobic patterns during increasingly workload exercise, can be calculated with CET. Aerobic threshold differs from the ***anaerobic threshold*** on lactate production. Below the aerobic threshold, the muscles are working in optimal aerobic interval, and blood lactate level is <2 mmol/L. Overcoming the aerobic threshold means that the subject is working above 60% of the individual peak VO_2, thus in a borderline condition of O_2 debt, consistent with a moderate lactate production (2–4 mmol/L).

This latter interval still allows a CV benefit, because systemic distribution of blood flow during exercise is homogeneous, according to the rise in HR. However, as exercise intensity or lengthening increases, metabolism becomes totally anaerobic (***anaerobic threshold***) and lactacid (>4 mmol/L). At this step CO_2 production overcomes O_2 uptake, and HR no longer increases (plateau). Also, CHF patients may have uneven distribution of blood flow to muscles

and their O_2 consumption cannot be established easily. Whereas the aerobic-anaerobic time frame shortens with training in athletes, it can be really difficult to establish in patients with depressed myocardial performance (Milani et al. 1996; Lavie et al. 2004; Arena and Sietsema 2011; Schraufnagel and Agostoni 2017).

Even if initially limited to severely compromised patients who should have undergone heart transplant, indication to perform CET has been broadened to other conditions by a recent position paper of the Heart Failure Association of the ESC (Corrà et al. 2017).

In this document, the functional stratification by CET has been extended to the whole CHF population. Peak $VO_2 \leq 10$ ml/kg/min (8 ml/kg/min on beta-blocker therapy) is suggested as a high-risk condition in patients with depressed LV ejection fraction. On the contrary, a low-risk class may be attributed to patients with $VO_2 > 18$ ml/kg/min (12 ml/kg/min on beta-blocker therapy). In the relatively new patient's functional class (CHF with preserved LV ejection fraction), a moderate risk category has been suggested for peak $VO_2 < 50$ ml/kg/min.

It has been suggested that a single MET increment on treadmill test at the peak VO_2 resulted in a 13% reduction in all-cause mortality and 15% cardiovascular death (Kodama et al. 2009).

Conconi test is an alternative way to establish patient's functional capacity based on her/his walking or cycling capacity with just a moderate perception of discomfort or fatigue (based on the Borg scale). It is necessary to register the HR increase approximately every 200 m. As the HR slope does not change anymore (deflection point), this step corresponds to the anaerobic threshold (Grazzi et al. 2005; Arena et al. 2007; Kjertakov et al. 2016).

More recently, the group of Grazzi (Chiaranda et al. 2013) proposed a modified protocol in which the patient was asked to perform a single km at a moderate perceived fatigue (11–13 Borg 15-point scale). The patient began the test by walking on the level at 2.0 km/h, with subsequent increase of 0.3 km/h every 30 s up to the greater walking speed corresponding to 11–13 Borg scale until the end of the km. This study demonstrated an exponential relationship between quartiles all of average walking speed and relative risk of death. Patients with a walking rate below 4.4 km/h had worse prognosis.

Exercise ECG testing is a simple and cost-effective tool capable of providing diagnostic and prognostic evaluation of patients with known or suspected coronary heart disease. It is widely used in daily routine for making diagnosis of active ischemic heart disease, and it can offer further insights by data derived from exercise parameters like effort duration, behaviour of HR, blood pressure and occurrence of arrhythmias (Fletcher et al. 2013).

The **6-min walking test** is the easiest method to assess functional capacity in most patients with CHF, included elderly patients and those being evaluated for cardiac transplantation. It has been often used for staging patients with chronic pulmonic disease. The distance ambulated during the test predicts peak VO_2 and short-term event-free survival (Cahalin et al. 1996; Kervio et al. 2003). However in some patients with disturbed coupling between HR and walking distance, like in those with neuromuscular disease, the HR-adjusted walking distance (walked meters/mean HR) was found to be a stronger prognosticator than the absolute walking distance (Prahm et al. 2014). Particularly in the elderly, the 6-min test has to be considered a submaximal exercise, not greater than 80% of their peak VO_2. Also, to be suitable for clinical use, one or two familiarization attempts are required to bound the learning effect (Kervio et al. 2003).

Echocardiography is a cost-effective technique that provides useful information on cardiac morphology and function both at rest and exertion. Left ventricular function is a crucial marker of the patient's clinical history, and depressed LV ejection fraction has been considered the most important prognosticator. The use of echocardiography in establishing a CR programme has two kinds of indication: the first one is to assess baseline cardiac performance, which is a useful marker of CV risk and also helps to arrange the training pathway adequately (see also Fig. 2). The second and more important application is to check for morphofunctional improvement after

exercise training, beyond the individual mood or wellbeing. However, current guidelines and literature data do not recommend challenging markers to be used as strong clinical prognosticators. Among them, LV ejection fraction remains a commonly used functional index, but its measurement must be provided and verified carefully. Recent studies suggest three-dimensional as a more accurate modality than two-dimensional echocardiography to estimate cardiac chamber size and function (Squeri et al. 2017; Medvedofsky et al. 2017).

In patients with CHF the presence of myocardial tissue fibrosis and abnormal collagen content is a limiting factor for attaining clinical benefit from either medical therapy or exercise. The use of gadolinium-enhanced cardiac magnetic resonance imaging (cMRI) has definitively improved our knowledge on the pathophysiology of several cardiac diseases, especially in patients with inflammatory heart disease and cardiomyopathy (Dickerson et al. 2013; Peterzan et al. 2016).

The good relationship between tissue delay enhancement (accumulation of gadolinium as a consequence of myocardial damage or fibrosis) and ultrasound-derived functional indices confirms the need for "multi-modality" technology to investigate the cardiac function properly.

In this regard, tissue Doppler and deformation (strain) analysis have been demonstrated to be excellent noninvasive tools. For instance, LV global longitudinal strain (GLS, which is a modern marker of myocardial fibres' shortening/deformation) and untwisting (a marker of the whole heart rotation) rates were found to be closely related to cardiopulmonary functional response in CHF patients (Li et al. 2017).

Figure 4 depicts an example of the use of echocardiography for checking cardiac functional benefit out of short-term CR in CHF patients, irrespective of LV ejection fractional changes.

Likewise, peak atrial longitudinal strain can be considered as a novel and more independent marker of left atrial dysfunction in various

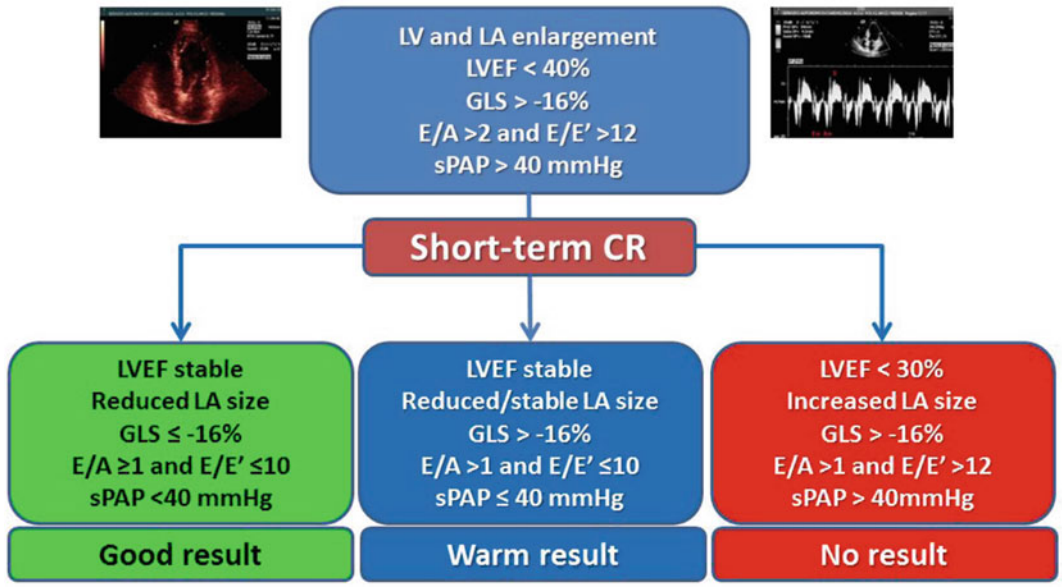

Fig. 4 Example of echocardiography functional marker changes related to short-term CR training efficacy, even in the absence of significant changes (≥10 point percent) in LV ejection fraction. E/A: is the ratio measured from the mitral valve inflow velocity (early/late mitral valve velocity ratio); E/E′: is the ratio between mitral early velocity (E-wave) and the early tissue velocity (E′ wave), measured as a mean value of the lateral mitral annulus and the basal septum; *GLS* global longitudinal strain (is a negative value, thus < is better), *LVEF* left ventricular ejection fraction, *sPAP* systolic pulmonary artery pressure

clinical conditions (de Gregorio 2016; de Gregorio et al. 2016).

Finally, multimodality echocardiography imaging provides strong information on the need for cardiac resynchronization therapy in CHF patients who have been maximized on therapy (Bertini et al. 2016).

8 Clinical Benefit of Physical Training by Meta-Analysis

In a recent meta-analysis Hollings et al. (2017) demonstrate that SET leads to an increase in both lower and upper limbs' dynamism, and improves aerobic fitness as much as aerobic CT alone in coronary heart disease cohorts. In their study, isotonic training was better than isometric and isokinetic modality, with an overall low prevalence of adverse events. Clinical gaps were identified for women and older adults in long-term outcomes. Therefore, safety and effectiveness of high-intensity training remain to be proven through large trials in such clinical settings.

Actually, fewer women than men participate in CR programmes because of a complex array of economical, medical and social challenges experienced. A recent systematic review of 31 studies demonstrated that improvement of participation has been tested through different solutions: automatic and systematic referral methods were seen to improve CR participation by 2–7 times compared to usual care, whereas early access to clinic by 8 times (both had strength of recommendation class I) (Supervía et al. 2017).

Also, liaison intervention increased referral rates as by 3 times than usual care, and other facilities like home visit, nursing phone call, motivational interviewing, gender-tailored intervention, letter, community program, telemedicine support, or smartphone-based program, were demonstrated to be useful as well (Grace et al. 2011; Gravely et al. 2014; Supervía et al. 2017).

Main results from 2 large meta-analyses on CR-related prognosis in both CHF and coronary heart disease (CHD) are displayed in Table 5 (Taylor et al. 2004; Abell et al. 2017).

Kraschnewski et al. (2016) also reported only 20–30% of older adults, with or without cardiac disease, to currently meet criteria of recommendations for strength training to be performed at least twice a week.

These findings likely emphasize the need for additional education campaigns as previously suggested (Naci and Ioannidis 2013).

In addition, generalists, internists, cardiologists, pulmonologists should encourage their patients to maintain physical activity all lifelong, as simply as they can by Table 6.

On the other hand, even if facilities to access training arenas or centres can be unsatisfactory in some Countries, studies support conclusions that home- and centre-based CR programmes are similarly effective in improving health-related quality of life in patients after myocardial infarction or with CHF (Anderson et al. 2017a; b; Kraal et al. 2017).

Older patients with limited opportunities of attending health care services may get benefit from dancing commensurate to their physical

Table 5 Results of large meta-analyses on total (A) and cardiac mortality (B) in CHF patients after CR

[a]Exercise session can be initiated with blood pressure $\leq$150/90 mmHg. Exercise should be stopped as for systolic values $\geq$200 mmHg, or the patient is complaining with chest pain, dizziness, strong fatigue (Borg scale >15)
[b]IT should be performed in a gym, usually in the middle of the week, between CT sessions
[c]After the learning period and 30–45 days of CR training programme

capability, as an alternative way of wellness (Merom et al. 2016).

9 Exercise Training in Particular Clinical Settings

9.1 Cardiac Resynchronization Therapy and Defibrillator

Cardiac resynchronization therapy (CRT) may lead to a significant improvement in functional capacity and quality of life in selected patients (especially women) with dilated CHF and left bundle branch block (Randolph et al. 2017).

Despite initial doubts and uncertainties, exercise training has been demonstrated to ameliorate hemodynamic measures in some out of these patients (Patwala et al. 2009).

Interval training was demonstrated to improve functional capacity, endothelium-dependent vasodilatation and quality of life in 52 CHF male patients with intracardiac implantable defibrillator (ICD) irrespective of cardiac resynchronization therapy (Belardinelli et al. 2006).

However, it should be taken into consideration that ICD uses exercise-independent HR as the primary method of tachycardia detection. Thus, before initiating a CR training program, the cut-off HR of the device should be known

exactly. Exercise intensity should be limited to a maximal HR at least 10–15 beats lower than the threshold discharge rate of the ICD (Fletcher et al. 2013).

Baseline functional status and severity of ventricular dysfunction will have an impact on exercise prescription and grading exercise tolerance before a CR training programme in ICD carries. In general, moderate- or high-intensity competitive athletics are not allowed, especially in activities at risk of chest traumas. Low-intensity sporting activities that do not constitute a significant risk of device damage are permitted, after 6 months since the last arrhythmia requiring an ICD intervention (Lampert et al. 2013; Zipes et al. 2015; de Gregorio and Magaudda 2017).

In a retrospective comparative survey on ICD patients, fewer shocks were registered in rehabilitated patients than in those who did not participate to training programmes (Davids et al. 2005).

Of interest, in the HF-ACTION study, a large assessment of the impact of exercise in 490 ICD patients with stable CHF, only one patient experienced appropriate shock on exertion (O'Connor et al. 2009).

9.2 Heart Transplantation

Patients undergoing cardiac transplantation are almost inactive before surgery and remain deconditioned after the operation. They receive a denervated donor heart with altered physiological response to exercise. Bradycardia is a common condition and the blunted chronotropic and inotropic responses tend to limit their exertional capacity.

However, peripheral resistances, right atrial strain and blood pressure adjustment allow the patient to perform quite good physical activity. These mechanisms support some studies showing exercise training to increase endurance capacity in heart recipients (Hermann et al. 2011; Fletcher et al. 2013).

Generally speaking, patients should enter a medically supervised CR programme as soon as they are discharged from the hospital. However, there is a lengthy delay in time from discharge to CR referral centres. Extended waiting lists are associated with adverse effects on body composition. Once referred, however, patients gain significant benefit in functional capacity (Marzolini et al. 2015).

Though similar to other patients with CVD, prescription of exercise intensity can be challenging in heart transplant recipients because their HR rises more slowly in response to exercise and can remain elevated after the end of exercise. Also, it is difficult to use HR to check for exercise intensity, and then other markers of patient' tolerance (Borg scale, workload, peak VO_2) have to be identified in this clinical setting. Evidence for exercise-based CR to improve functional capacity was recently found, but no effect was observed on quality of life, 1-year after heart transplant. Cardiac rehabilitation appears to be safe, but long-term trials are needed to confirm definite benefits (Marzolini et al. 2015; Anderson et al. 2017b).

9.3 Atrial Fibrillation

There is controversial relationship between exercise and atrial fibrillation (AF) both in apparently healthy individuals ("lone" AF) and in patients with CVD. Light to moderate physical activity, particularly leisure time activity and walking (approximately 600–800 kcal/week, walking distance of 5–10 km per week, pace >2 km/h) showed >40% risk reduction of recurrences in elderly patients with paroxysmal atrial fibrillation (Mozaffarian et al. 2008). On the contrary, another study reported that high-intensity endurance training was associated with increased incidence of AF or flutter in the general population (Mont et al. 2009).

Actually, such discrepancies can be due to inhomogeneous study populations, because aging individuals likely get an arrhythmic risk greater than younger patients when performing mild to moderate exercise.

In a recent retrospective study on 14,094 patients referred for treadmill exercise test at the Mayo Clinic Rochester (MN, USA), a better cardiorespiratory fitness was associated with a lower

risk of incident AF, stroke, and overall mortality. Similarly, the risk of stroke and death was inversely associated with cardiorespiratory fitness (Hussain et al. 2018).

Intense training can lead to a higher incidence of supraventricular arrhythmias in older patients because of the coexistence of multiple risk factors, like hypertension and obesity. These factors may promote (left) atrial chamber enlargement and fibrosis, thus facilitating the occurrence of AF. Nevertheless, in view of potential benefit of exercise in CHF patients, current guidelines do not discourage exercise training in this clinical setting (Fletcher et al. 2013).

Thoughtfulness, however, is needed as the patient enters a training programme. For instance, HR tends to increase as far as in patients with sinus rhythm, but with a challenging trend on warm-up, peak exertion and cool-down. Therefore, HR cannot be considered a suitable marker of the aerobic or anaerobic threshold, nor training effectiveness, also considering the frequent use of beta-blockers and digitalis for HR control.

Finally, recent studies have demonstrated a relationship between obesity and incidence of AF. The pathophysiological mechanisms linking these two entities are highly complex and remain incompletely understood: dysregulation in either hemodynamic, neurohumoral, inflammatory, metabolic and/or autonomics has been demonstrated in a high proportion of such patients (Wong et al. 2016; Lavie et al. 2017).

Among 1415 patients with AF and high body mass index screened for participating to CARDIO-FIT study, 308 patients were selected for a cardiorespiratory fitness training programme. Atrial fibrillation burden, symptom severity, and their functional status improved significantly in the group with a cardiorespiratory fitness gain ≥ 2 METs than in the group <2 METs, and fewer recurrences were registered in symptomatic individuals with paroxysmal AF (Pathak et al. 2015).

In patients with permanent AF, 12-week IT increased skeletal muscle strength (but not mass), exercise capacity and quality of life. It also significantly reduced resting HR. Moreover, such a gain in muscle strength was also relevant for mobility and posture of patients. Conclusions were that regular mild-intensity exercise should be encouraged to majority of patients with AF (Osbak et al. 2012).

Conflict of Interest None to declare.

Advanced Non-invasive Imaging Techniques in Chronic Heart Failure and Cardiomyopathies

Focus on Cardiac Magnetic Resonance Imaging and Computed Tomographic

Gianluca Di Bella, Fausto Pizzino, Rocco Donato, Dalia Di Nunzio, and Cesare de Gregorio

Abstract

Cardiomyopathies (Cs) are a heterogeneous group of myocardial diseases with structural and/or functional abnormalities.

The aetiology is due to genetic-family substrate in most cases, however, the correct and detailed analysis of morphofunctional abnormalities (severity and distribution of hypertrophy, ventricular dilatation, ventricular dysfunction) and tissue characteristics (myocardial fibrosis, myocardial infiltration) are a crucial element for a definite diagnosis.

Among the different diagnostic imaging modalities applied in clinical practice (echocardiography, nuclear medicine), cardiac magnetic resonance (CMR) has emerged as a non-invasive diagnostic tool having high ability to quantify systolic function and tissue abnormalities that represent the substrates of many Cs.

The main added value of CMR is the ability to identify cardiomyopathies with respect to ischemic heart disease and, above all, to discriminate the major types of cardiomyopathies based on morpho-functional presentation patterns and the presence and location of myocardial fibrosis.

Many CMR elements allow increasing diagnostic accuracy but CMR data should be integrated with an appropriate clinical and instrumental context.

Computed Tomographic (CT) scan technology has showed a complementary role in patients having Cs and HF.

In this chapter, the diagnostic, pathophysiologic and prognostic value of CMR and CT in heart failure due to the most common cardiomyopathies will be discussed.

Cardiac magnetic resonance · Cardiomyopathy · Dilated cardiomyopathy · Hypertrophic cardiomyopathy · Myocarditis

1 Introduction

Cardiomyopathies (Cs) are a heterogeneous group of myocardial diseases with structural and/or functional deficiencies unrelated to anomalies of coronary arteries, pericardial diseases, arterial hypertension, valvulopathies and congenital heart disease. Although, a genetic-family substrate is the aetiology in most cases, the correct and detailed analysis of morpho-functional abnormalities (severity and distribution of hypertrophy, ventricular dilatation, ventricular dysfunction) and tissue characteristics (myocardial fibrosis, myocardial infiltration) are a crucial elements for a proper diagnostic and therapeutic work out.

The morpho-functional approach to cardiomyopathy distinguishes myocardial diseases into "hypertrophic," "dilatative," "restrictive", arrhythmogenic dysplasia and non-classified cardiomyopathies.

The most common clinical presentation of Cs is heart failure (HF).

In the last 15 years, cardiac magnetic resonance (CMR) has emerged as a non-invasive diagnostic tool having high ability to quantify systolic function and tissue abnormalities (oedema, fat and fibrosis) that represent the substrates of many Cs (Maron et al. 2006).

The main added value of CMR is the ability to identify cardiomyopathies with respect to ischemic heart disease and, above all, to discriminate the major types of cardiomyopathy based on the biventricular morpho-functional presentation patterns and the presence and location of myocardial fibrosis (Maron 2008).

The CMR with late gadolinium enhancement (LGE) identifies fibrotic tissue as an area of ⁇hyperintensity (hyperenhancement) compared to the healthy myocardium that appears to be hypo-intense. It should be noted that although some CMR elements allow for an increase in diagnostic accuracy, CMR data evaluation should be integrated in the light of an appropriate clinical and instrumental context. (Rovai et al. 2007; Di Bella et al. 2010a, b; Aquaro et al. 2010a, b).

From the practical point of view, the main phenotypic presentations of cardiomyopathies are the following: 1) increase in thickness/hypertrophy (hypertrophic phenotype) and 2) left ventricular dilation/dysfunction ("dilated "phenotype).

2 Hypertrophic Phenotype Cardiomyopathies

Hypertrophic phenotype cardiomyopathies are characterized by an increase in wall thickness in the absence of systolic load conditions that may justify its secondary development such as high blood pressure or valve abnormalities.

These manifestations may depend either on true hypertrophy, that is, by the increase in the mass of the individual myocardial cells, or by a pseudoepertrophy due to the infiltration of extracellular material or the accumulation of intracellular substances. Typically, these conditions occur in hypertrophic cardiomyopathy, infiltrative diseases such as amyloidosis and accumulation diseases such as Anderson-Fabry disease. (Elliott et al. 2008).

Using clinical data, electrocardiogram and ecocardiographic data, it is not easy to obtain a differential diagnosis between these forms, since the phenotypic appearance is extremely similar, especially in the early stages. The CMR 's added value is represented by the ability to obtain morphological images with high spatial resolution and the ability to distinguish peculiar tissue alterations based on signal characteristics in the different sequences (Fig. 1).

3 Hypertrophic Cardiomyopathy

Sarcomeric hypertrophic cardiomyopathy (HCM) is caused by mutations in sarcomeric protein genes. HCM is characterized by an increase in wall thicknesses (15 mm in at least one LV

CMR findings in hypertrophic cardiomyopathies	
Sarcomeric HCM	**Cardiac Amiloidosis**
	• Asymmetric hypertrophy (usually) • Focal LGE in LV junction and septum • Hypertrophy of papillar muscles	• LV Concentric hypertrophy • RV Hypertrophy • Low contrast myocardium-cavity (blood) • Subendocardial circumferential LGE • "zebra" appearance • More focal LGE areas
Anderson-Fabry disease	**Athlete's heart**
	• LV Concentric hypertrophy • Inferolateral mid-wall (epicardial) LGE	• Eccentric hypertrophy • Small wall thickening • Dilated both LV and RV volumes • No LGE

Fig. 1 Late gadolinium enhancement (LGE) patterns in hypertrophic cardiomyopathies that one may encounter in clinical practice. According with LV hypertrophy and LGE localization a suspected diagnosis of sarcomeric HCM, Athlete's heart, Anderson-Fabry disease can be made. Typical CMR findings in CA permit to make an accurate and early diagnosis

segment) in the presence or not of an increased heart mass.

According to hypertrophy localization and systolic movement of the anterior mitral leaflet (SAM) that may lead to obstruction of outflow tract of the left ventricle, HCM can be defined symmetric, asymmetric, obstructive and non-obstructive. (Authors/Task Force members et al. 2014).

CMR can provide detailed information on all aspects of the disease. Using cine CMR (SSFP) sequences, it is possible to accurately measure the parietal thicknesses of all left ventricular segments, including apical, often difficult to evaluate with echocardiography. It is therefore possible to identify the different hypertrophic patterns depending on the localization of the affected segments (apical, mid-ventricular, symmetric, asymmetric). Generally the interventricular septum is the most affected by hypertrophic phenomena, an infero-lateral septum/wall ratio greater than 1.3 identifies asymmetric hypertrophy. (Maron 2012; Wicker et al. 1983).

In the event of left ventricular obstruction, it is often possible to observe a signal void (hypointense line) in the tract of the left ventricle efflux during the systolic phase.

If present, it is often possible to observe the SAM, new CMR flow study methods have proven to be able to detect obstruction and calculate the gradient with high precision. (Allen et al. 2015).

The common CMR findings are reduction of volumes and increased of ejection fraction and left ventricular mass. Other findings that may increase suspicion of HCMs are the findings of myocardial crypts, especially in the inferior and inferior walls, and the presence of hypertrophic papillaries and/or the presence of adjunctive papillaries. In the mid-ventricular forms, frequent identification of apical aneurysms is common. But the real strength of the CMR is tissue characterization; it allows identifying both ischemic-inflammatory phenomena and fibrosis, typical of this cardiomyopathy. The ischemia present in HCM is predominantly microvascular, resulting in inflammatory phenomena leading to tissue oedema and increased interstitial water content. T2 weighed sequences are very sensitive to the presence of free water and allow to detect ooedema. These findings have a strong diagnostic and prognostic value, as the presence of ooedema has been associated with increased arrhythmic risk. (Todiere et al. 2014).

Myocardial fibrosis is another common feature of HCM. The LGE technique allows identifying with great accuracy the fibrotic areas, which almost always exhibit non-ischemic patterns, predominantly intra-myocardial, with frequent localization to septal junctions between right and left ventricles and in the most hypertrophic segments. In the case of apical aneurysm, the walls of the aneurism are often thinned and with transmural fibrosis. The presence of fibrosis has a significant impact on the prognosis, leading to a five-fold greater risk of cardiovascular events than patients who cannot be identified. (Bruder et al. 2010).

A progressive increase in the risk of arrhythmia death has been observed with the increased degree of fibrosis, a percentage increase in fibrosis greater than 15% of the myocardial mass is associated with a risk twice as high as a sudden cardiac death. (Chan et al. 2014).

Some advanced methods such as measuring and mapping the native T1 allow to identify microfibrosis (interstitial fibrosis) by an indirect calculation of the extracellular volume. (Brouwer et al. 2014).

Such alterations are not measurable by the LGE technique that requires a certain percentage of fibrosis in the single voxel to be identified. However, these methods are still applied only in experimental contexts (Hinojar et al. 2015).

4 Cardiac Amyloidosis

Systemic amyloidosis is an accumulation disease due to the presence of an abnormal circulating protein that usually comes from the light chains of immunoglobulins (primitive forms) or transthyretin (genetic and senile forms). These proteins tend to precipitate in different tissues, including myocardium, accumulating in the form of "amyloid" and leading to structural and functional damage. (Di Bella et al. 2014).

Cardiac amyloidosis (CA) is a hypertrophic phenotype cardiomyopathy characterized by an increase in parietal LV thickness and mass that represents the paradigm of restrictive cardiomyopathy.

CMR plays a primary role in diagnosing CA, since this pathology has morphological characteristics and peculiar signal on different CMR sequences. From a morphological point of view, the CMR allows us to appreciate the LV hypertrophy, most frequently symmetrical, with increased of LV myocardial mass. Other often identifiable features are the increase of the interatrial septal and the right ventricle thickness, the increased of the atrio-ventricular valves thickness, dilated atria and the presence of pericardial effusion. (Di Bella et al. 2016a, b; Maceira et al. 2005).

The typical CMR findings of CA after the injection of gadolinium are a low contrast between myocardium and blood (reduced T1 signal strength difference between myocardial blood) at different inversion times, an increased accumulation of contrast on subepicardial and subendocardial area (subendocardial circumferential LGE) or a diffuse LGE localization. Additionally, LGE deposition can be located in the AV valves, right ventricle and atrial wall (Fontana et al. 2015; Syed et al. 2010).

These "typical patterns" are accompanied by alternative patterns, in which the LGE may have a homogeneous focal distribution and locate more frequently in the inferior or inferolateral walls with a mid-wall (non-ischemic pattern) localization as the same observed in other cardiomyopathies such as Fabry's disease.

More advanced techniques allow identification of the alterations of T1 mapping to diagnose CA. Native T1 mapping in CA is almost always increased by amyloid deposition. These techniques also allow to indirectly calculate the volume of myocardial extracellular space, an increase of more than 32% can identify the AC with a sensitivity of 79% and a specificity of 97% (Barison et al. 2015a, b).

Some characteristics allow discriminating which type of amyloid infiltrates the heart. Transthyretin CA show a greater increase in thickness and mass and a greater involvement of the right ventricle compared to those with light chain CA. (Kristen et al. 2015).

5 Fabry Disease

Anderson-Fabry's disease (FD) is an X-linked genetic disease characterized by the deficiency of a lysosomal enzyme, α-galactosidase, which determines the build up of globotriaosylceramide and other sphingolipids. The disease mainly affects the myocardium, the kidney, and the nervous system. Cardiomyopathy is characterized by a hypertrophic phenotype with diastolic dysfunction, valve disorders and conduction defects with progressive evolution towards terminal heart failure (Pieruzzi et al. 2015).

The echocardiographic findings are similar to other forms of hypertrophic cardiomyopathy. The CMR's added value in this pathology includes the possibility of a precise and accurate morphological evaluation (LV mass, thickness, and shape) and functional (volumes, ejection fraction) similar to that already described for HCM. LGE is present in about less than 50% of MAF cases and, in the classical form, is located in the basal and mid segments of infero-lateral wall, with an intramyocardial distribution. Although this finding is common in FD, inferolateral LGE is not specific for this subtype of disease (Madonna et al. 2014).

The variable presence of LGE in this pathology depends on the fact that fibrosis is a late phenomenon. In FD lipid accumulation is intracellular, while gadolinium is an exclusively extracellular contrast media. However, the presence of marked hypertrophy in a young male with familial history associated with LGE intra-myocardial infero-lateral, must induce the suspicion of a FD. Obstruction is rare but a possible finding. The diagnosis of FD is perhaps one of the conditions in which the new experimental analysis and mapping methods of native T1 (pre-contrast) have so far proved to be more useful. Some studies have shown that native T1 is significantly shorter in FD patients than patients with other forms of hypertrophy and healthy controls. T1 shortening is due to sphingolipid accumulation (fat has T1 short). T1 shortening is

proportional to the degree of hypertrophy but may also be present in patients with early-stage FD where hypertrophy has not yet been manifested (Sado et al. 2013). The development of these new methods has therefore opened up new promising perspectives in these patients.

6 Athlete's Heart

The athlete's heart (AH) is a condition that, at times, needs to be differentiated from other cardiomyopathies. Adaptation to intense training develops frequently eccentric hypertrophy in endurance athletes, while power athletes can see concentric hypertrophy (Galderisi et al. 2015). Because athletes are one of the most at risk of sudden cardiac death, distinguishing the AH from other cardiomyopathies having an unfavourable prognosis is of paramount importance (de Gregorio and Andò 2014).

The CMR may be helpful in the exclusion of other cardiomyopathies, although its use is not always consistent. Generally CMR shows increased cardiac mass and parietal thicknesses increased (especially at the septal level), and/or left ventricular dilatation, especially in resistance athletes (cyclists, marathons, etc.). However, dilation is rarely severe, and is associated with a conserved overall systolic function (often at the lower limit of the standard): in addition, usually, there is a balanced dilatation of the right ventricle while the atrial chambers often exhibit normal volumes. A recent study has shown that among the morphological parameters, the ratio between the maximum end-diastolic parietal thickness and indexed end-diastolic volume is the best index to distinguish AH from other forms of pathological hypertrophy (Petersen et al. 2005a, b).

LGE is generally absent in patients with AH. However, small areas of LGE can be identified in these patients or because they are secondary to other pathological processes (myocarditis, ischemia, sarcoidosis, traumas, etc.) or because sometimes it may be possible to detect the least nuanced areas of fibrosis even in healthy subjects (especially septal RV junction). In these cases, instrumental follow-up after appropriate de-training is the most well-known strategy because in most AH cases, there is a partial or total regression of hypertrophy after 3 months (Maron et al. 1993).

For high reproducibility in the estimation of volumes and mass, CMR remains the reference method for the follow up of these patients (Rovai et al. 2007; Di Bella et al. 2010a, b; Aquaro).

7 Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is characterized by LV dilatation and systolic dysfunction in the absence of load conditions (hypertension, valve disease, congenital malformations) or coronary heart disease. The prevalent aetiology is genetic, although in many cases it is not possible to identify the responsible defect (idiopathic forms). CMR can provide valuable information regarding the evaluation of cardiac volume, function and LGE presence and extent.

CMR use may be useful for accurate estimate of the EF when echocardiography documents borderline value in patients who are candidate for cardioverter-defibrillator implant. The left atrium volume evaluation also proved to be an important prognostic factor; patients with a volume greater than 72 ml/m^2 showed high risk of death or transplantation (Gulati et al. 2013).

Fibrosis evaluation by LGE technique is useful in the first instance to exclude other causes potentially determining ventricular dysfunction. In particular, the absence of subendocardial or transmural LGE with a distribution corresponding to one coronary territory excludes ischemic damage. Much more difficult is the distinction between familial DCM respect to other end-stage cardiomyopathies such as hypertrophic cardiomyopathy or myocarditis (Di Bella et al. 2016a, b).

The presence of fibrosis can be found in about 35% of patients with DCM and is associated with greater risk of death, hospitalization and higher incidence of sudden cardiac death and ventricular tachycardia. An increase in extracellular volume measured by T1 mapping can be found in patients with DCM and represents an independent risk

factor for major cardiovascular events (Barison et al. 2015a, b; Aquaro et al. 2010a, b).

DCM phenotype can be found in patients with muscular dystrophies such as Duchenne or Becker. Usually LV dysfunction and dilatation appear at young age and it is slowly progressive. Additionally, myocardial fibrosis is common finding located in the lateral wall with subepicardial distribution, rarely involving the septum. The presence of fibrosis is associated with development of negative remodeling and with higher degree of dysfunction (Silva et al. 2007;Puchalski et al. 2009).

Myocardial fibrosis can also be found in female carriers and even in this population represents a predictor of LV dysfunction (Mavrogeni et al. 2013).

8 Myocarditis

Myocarditis is an inflammatory cardiomyopathy usually due to viral aetiology and characterized by inflammatory infiltrate at myocardial level. Usually, myocarditis is associated with a flue-like syndrome (acute phase). Clinical presentation is very heterogeneous (Yilmaz et al. 2013).

CMR has demonstrated high diagnostic accuracy in patients with infarct like presentation that usually showed preserved EF but impaired LV longitudinal function (Di Bella et al. 2010a, b). However, endomyocardial biopsy remains the standard gold standard method in heart failure and arrhythmic presentation. In addition to morpho-functional evaluation, CMR allows to identify many of the tissue characteristics typical of inflammation (hyperoemia, oedema, and fibrosis).

9 Lake Louise Criteria

Lake Louise criteria is useful for evaluation and accurate diagnosis of oedema, hyperaemia and fibrosis. The diagnosis of myocarditis (78% accuracy) with CMR can be achieved if at least 2 criteria are positive. If there is only one criterion or no criterion exists, but myocardial/clinical suspicion is strong, then the examination can be repeated at 1–2 weeks (Friedrich et al. 2009).

It should be emphasized that the accuracy of the criteria is more relevant in patients with a high clinical suspicion of myocarditis.

Oedema is due to the increased permeability of vascular walls and cell membranes, as a consequence of the release of pro-inflammatory cytokines increasing interstitial and intracellular water content. T2 weighted images show water signal (oedema) as extremely hyperintense in comparison with other tissues. The distribution of the oedema may be diffuse and/or focal (anterior and lateral wall with predominantly subepicardial distribution and septal wall with mid wall distribution). Diffuse oedema is characterized by a > 1.9 ratio between the intensity of the entire myocardial signal and the intensity of the skeletal muscle used as a healthy muscle reference. Although oedema is a distinctive sign of inflammation, it may still be absent or difficult to detect in patients with borderline myocarditis, even for the low signal-to-noise ratio of T2 inversion recovery sequences. Oedema can also be present in other pathologies that come into differential diagnosis with myocarditis, first of all acute coronary syndromes, but in these cases oedema is generally transmural or subendocardial, never subepicardial.

The typical vasodilatation observed in inflammation causes hyperaemia and consequently a greater concentration of gadolinium in the affected areas. This phenomenon (termed "early gadolinium enhancement") occurs within a few minutes of intravenous administration. The gadolinium significantly shortens the T1 of the tissues in which it is located. A 4–5 ratio (depending on the MRI scanner used) between myocardial and healthy skeletal muscle is diagnostic for myocardial hyperaemia. However, the presence of muscular inflammation involvement can affect this method. In addition, an increase of 45% is considered a diagnostic of myocardial hyperaemia. Another hyperaemia method is SSFP sequences after gadolinium.

In the acute myocarditis, LGE is due to the inability of the cells injured to maintain the membrane integrity, allowing the gadolinium to

penetrate the cytoplasm. In late phases, the presence of LGE is due to the increased interstitial space (interstitial fibrosis) due to inflammatory necrosis. The presence of fibrosis allows gadolinium to occupy greater volumes than healthy tissue, resulting in delayed washout. Localization of LGE in myocarditis is characteristic, affecting the sub-epicardium or the mid-ventricular layer. The lateral walls and the interventricular septum are the walls most frequently affected. The amount of LGE detected in acute phase is generally greater than in the following phases. In some cases, you can have restitution with substantial LGE disappearance. The presence of LGE in patients with myocarditis has proven to be a very useful independent predictor of mortality and should always be sought in patients with clinical suspicion.

10 Additional CMR Criteria that Support the Diagnosis of Myocarditis

Although not included in the Lake Louise criteria, the presence of left ventricular dysfunction, pericardial inflammation and/or inflammation are additional information in the diagnosis of acute myocarditis. Another diagnostic element is the temporary increase of the mass and the parietal thicknesses (diffused or localized), which represents the "swelling" and is the macroscopic expression of the oedema.

11 Non-compaction Cardiomyopathy

Non-compaction cardiomyopathy (NCC) is a form of congenital cardiomyopathy with an unknown aetiology that depends on the lack of myocardial compaction of embryonic myocardial trabecules. The ventricular walls appear jagged, with numerous trabeculations and deep recesses extending towards the cavity. These alterations may involve the entire left ventricular endocardial surface but most commonly involve only lateral and apical LV segments. Right ventricle can be involved but because trabeculations are common physiological features, pathological findings are not yet defined. NCC may be a completely asymptomatic condition, so some authors do not consider it a true cardiomyopathy; in other cases, however, progression towards left ventricular dilatation and left ventricular dysfunction may occur, with increased risk of arrhythmia and death. Some forms of NCC may also be associated with hypertrophy and restriction. Some authors consider the NCC not as a cardiomyopathy but as a phenomenon found in other cardiomyopathies such as hypertrophic or dilated (Petersen et al. 2005a, b; Jacquier et al. 2010; Grothoff et al. 2012). Thanks to the high spatial resolution and the ability to effectively analyse all segments, CMR is useful for diagnosing NCC (Fig. 2).

The most commonly used CMR criterion for its simplicity is to evaluate the relationship between myocardial thickness and compact size in the affected segment. A > 2.3 ratio would identify patients with NCC with sensitivity and specificity of 86% and of 99% respectively (Petersen et al. 2005a, b). The most commonly used sequences for measurements are SSFP. Although simple and rapid use this criterion was strongly criticized for having led to an excess of pathology diagnosis.

Other criteria are based on uncompacted myocardial mass. Some authors have suggested that a non-compact bulk percentage of the total mass > 20% would have a sensitivity and specificity of 93.7% 39 (Jacquier et al. 2010). Others Authors have proposed a non-compact index mass of 15 g/m2 and a non-compact mass greater than 25% would be highly specific criteria. Grothoff et al. suggets an index based noncompact/compact ratio > 3 in basal segments at least one segment; this approch would showed a sensitivity and specificity close to 100% (Grothoff et al. 2012).

Mass-based criteria have been shown to be more accurate, however, computational mass calculation is difficult and not entirely reproducible, so there is no unanimous consensus on the parameters to be used to diagnose NC Mass-based criteria have been shown to be more accurate, however, computational mass calculation is undeniable and not entirely reproducible, so there

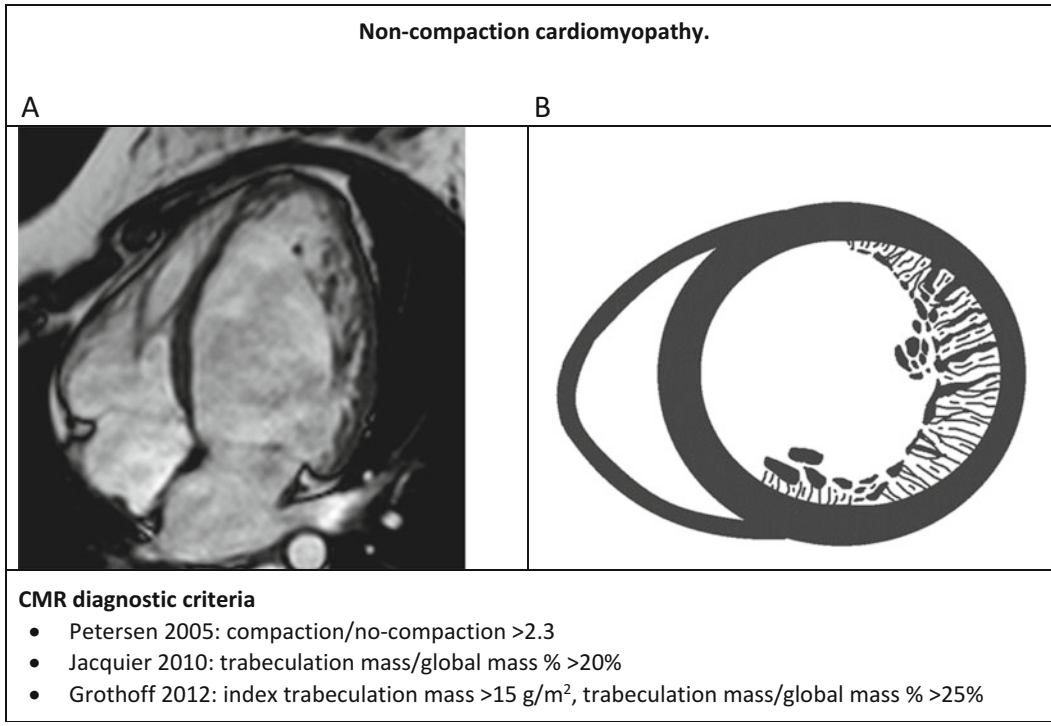

Fig. 2 Cine CMR image on horizontal long axis (panel A) and typical pattern on short axis (panel B) in Non-compaction cardiomyopathy. Lower panel shows the different CMR criteria proposed

is no unanimous consensus on the parameters to be used to diagnose NCC. Some authors would have identified an important prognostic element in the number of segments involved. (Punn and Silverman 2010). Fibrosis can be found in patients with NCC but no specific pattern has been identified and has not proven to be an important predictor of dysfunction or death.

12 Arrhythmogenic Cardiomyopathy

Arrhythmogenic dysplasia is a genetic cardiomyopathy that is characterized by right ventricular involvement and/or involvement of both ventricles (biventricular subtype) or left ventricle (subtype with predominantly left ventricular involvement). Arrhythmogenic cardiomyopathy is a progressive disease that in the initial phase of the right ventricular form is characterized by morphofunctional abnormalities located in specific areas of the right ventricle (sub-tricuspidic right ventricular area, right ventricle apex and right ventricle out-flow, called "triangle dysplasia ") followed by a right ventricular dilatation and dysfunction.

The CMR in addition to allowing the evaluation of the right ventricular size and function can identify fibro-adipose infiltration/replacement areas. In 2010, major and minor diagnostic criteria for the diagnosis of arrhythmia dysplasia were reviewed (Marcus et al. 2010).

From these it can be seen that ventricular kinetics (akinesia/dyskinesia) segmental abnormalities must be associated with right ventricular dilatation or a right ventricular dysfunction (major criterion: ejection < 40%). Although in the 2010 criteria don't have included CMR parameter derived from tissue information (fatty or fibrous infiltration), numerous scientific evidence has demonstrated the additive diagnostic value of both fatty and fibrous infiltration detected using CMR. In particular, various

studies show the negative prognostic impact of the presence of tissue alterations in patients with frequent premature ventricular complexes at right ventricular origin (Aquaro et al. 2010a, b).

In addition to the usual acquisition plans (long horizontal axis, vertical axis, short axis) in SSFP sequences, T-1 weighed, T-1 fat-sat and LGE, and also the acquisition of transaxial or oblique planes oriented to the right ventricular outflow tract are included in CMR protocol.

13 Hemochromatosis

Hemochromatosis is a disease characterized by accumulation of considerable amounts of iron in different tissues including the heart.

Iron causes structural and functional damage to the organs affected mainly by the excessive production of free radicals of oxygen (Gulati et al. 2014). Iron accumulation causes alterations of diastolic function, progressive dilation and left ventricular dysfunction. The CMR plays a decisive role in evaluating hemochromatosis patients. In fact it allows to evaluate the accumulation of myocardial iron by exploiting the effect of metal ferromagnetic properties on relaxation times, particularly on T2. Iron, in fact, results in a T2 shortening proportional to the concentration of metal present in myocardial tissue. The T2 * (T2 star) is the true decay time of the T2 not influenced by 180 ° refund pulses. The most commonly used method is called multi-echo T2 *, which, with the use of dedicated software, allows to obtain the values ⍰⍰of T2 * on both global and segmental LV. Some authors use average septum values ⍰⍰as they have been shown to be more accurate and reproducible. An iron tissue overload is indicated by values < 20 ms while a value <10 ms is a warning of a severe accumulation.The utilization of the T2 * method has allowed better management of iron chelation therapy in hemochromatosis patients without the need for biopsies. Fibrosis may be present in patients with myocardial iron overload and is associated with lower T2 * values and Remodeling negative (Ramazzotti et al. 2009).

14 CT Scan in Cardiomyopathies and Heart Failure

Diagnostic advantage of Computed Tomographic (CT) scan technology in cardiac patients (HF and Cs) is as well as in other clinical settings. High speed of execution, high spatial resolution, good temporal resolution and wide field of view result in high-quality anatomical imaging (Taylor et al. 2010).

Also, the high-field of view allows detecting pulmonary congestion and pleural effusions, inferior cava vein disease and hepatomegaly which can be present in HF patients (Cademartiri et al. 2015).

Of strategic importance, CT can identify all the coronary artery tree, with powered diagnostic value on coronary wall calcifications, intra-coronary plaques, coronary anomalies and intra-myocardial course of coronary branches (Taylor et al. 2010).

Recent studies have demonstrated the chance for a morpho-functional characterization of the myocardial wall like CMR. Cardiac anatomical structures, such as chamber and wall thickness, valves, vessels can be seen in detail, and recent studies confirmed that CT can give strategic information on Cs (Taylor et al. 2010; Cademartiri et al. 2015; Lloyd-Jones et al. 2002).

On the other hand, CT has some disadvantage including the use of ionizing radiation and contrast agents.

In HF patients, CT scan allows a proper diagnosis (or exclusion) of coronary artery disease (CAD, both in acute and chronic clinical settings (Lloyd-Jones et al. 2002).

High sensitivity (98–100%) and good negative predictive value (94–100%) were demonstrated for CT scan when ruling out diagnosis of CAD, and CT became a increasingly used investigation in the general population (Meijboom et al. 2008).

In a recent meta-analysis, CT scan was as accurate as coronary angiography (the gold standard) to rule out CAD as the leading mechanism of heart failure in patients with left ventricular ejection fraction (LVEF) < 35% of unrecognized origin (Bhatti et al. 2011).

The study of the cardiac chambers and the myocardium is not a strong indication for CT

scan. Its use is mainly limited to patients with contraindications to undergo cardiac MRI examination (e.g in patients with metallic devices) or to individuals with poor acoustic window for an echocardiogram, who need important information for their clinical management (Taylor et al. 2010).

A good reliability was confirmed for CT with regard to the most common morpho-functional cardiac parameters (ventricular end-diastolic and end-systolic volumes, ejection fraction, stroke volume, myocardial mass and wall motion abnormalities) in comparison with cardiac MRI, echocardiography or gated SPECT (Schroeder et al. 2008; Fischbach et al. 2007).

A relatively recent clinical application of CT scan is myocardial tissue characterization. Myocardial fibrosis can be recognized with a delay enhancement technique, like that used in gadolinium-enhanced cardiac MRI.

Comparative studies with MRI showed a good correlation between the two methods for the identification of myocardial fibrosis in dilated or hypertrophic cardiomyopathy, cardiac amyloidosis, myocarditis and cardiac sarcoidosis. Moreover, it could be a possible alternative for patients unable to perform cardiac MRI (Lee et al. 2017; Cerny et al. 2017; Takaoka et al. 2017).

Of clinical interest, CT scan can also play a diagnostic role in diagnosis of hypertrophic cardiomyopathy in adult patients, and for a screening of their relatives. In Tako-Tsubo cardiomyopathy, CT scan has been demonstrated to be such an useful tool to exclude CAD, wall motion abnormalities and cardiac complication like apical aneurysm and intra-ventricular thrombosis, (Ugo et al. 2015).

Pathogenesis, Clinical Features and Treatment of Diabetic Cardiomyopathy

Núria Alonso, Pedro Moliner, and Dídac Mauricio

Abstract

Patients with type 1 and type 2 diabetes mellitus (T1D and T2D) show an increased incidence of heart failure (HF) even after adjustment for well established risk factors for HF such as hypertension and ischaemic heart disease. The resulting specific form of cardiomyopathy is known as diabetic cardiomyopathy" (DCM). Pathogenetic mechanisms underlying DCM are likely to be multifactorial, from altered myocardial metabolism (hyperglycaemia, hyperinsulinaemia, increased circulating fatty acids and trglycerides) to microvascular disease, autonomic neuropathy, and altered myocardial structure with fibrosis. Current medical treatment recommendations from scientific societies on HF in patients with diabetes mellitus (DM) do not differ from those for patients without DM. Regarding the effect of different hypoglycaemic drugs on HF in patients with DM, and considering the best available current evidence, the sodium-glucose-co-transporter 2 inhibitors and metformin seem to be especially advantageous regarding the effects in patients with T2D and HF.

patients has improved in recent years, the high prevalence (0.4–2% in the European population) and incidence of this disease has lead to cause significant morbidity and mortality (50% of patients will die in 5 years, and 90% in 10 year), while generating a large number of hospital admissions with the consequent health expenditure. HF affects between 1–2% of the adult population in developed countries, rising to more than 10% in the elderly (Mosterd and Hoes 2007).

Heart Failure is a complex clinical syndrome due to structural and/or functional cardiac alterations whose diagnosis is difficult especially in the initial stages given that symptoms are not specific, and therefore it is difficult to distinguish between HF and other problems (Oudejans et al. 2011). It is widely accepted that individuals may progress through an asymptomatic phase of left ventricular systolic dysfunction (ejection fraction (EF) <50%) before the development of overt HF, even when only mild impairment of EF is present (Wang et al. 2003). In these patients, treatment with an angiotensin-converting enzyme inhibitor has demonstrated to reduce the incidence of HF and the rate of related hospitalizations (SOLVD Investigators et al. 1992). According to the European Society of Cardiology (ESC) guidelines of HF, patients with this condition can be classified into three groups taking according to left ventricular ejection fraction (LVEF): 1) HF with reduced ejection fraction (HFrEF): LEVF <40%; 2) HF with preserved ejection fraction (HFpEF): LEVF >50%; 3) HF with mildly reduced EF (HFmrEF): LEVF 40–49% (Ponikowski et al. 2016). Frequently, patients have both systolic and diastolic HF at the same time, but the term for this condition is still systolic HF. The diagnosis of HF in a non-acute context should be first evaluated on the patient's medical history, symptom presentation (shortness of breath at rest or during exercise, fatigue, tiredness, swelling of ankles), physical examination (tachycardia, tachypnea, pulmonary rales, pleural effusion, elevation of venous jugular pressure, peripheral edema, hepatomegaly) and a resting electrocardiogram. If these elements are normal, the diagnosis of HF is very improbable. If one of the elements is abnormal, the plasma level of natriuretic peptides (NPs) should be determined, with an indication to perform an echocardiogram in those patients with NPs concentrations higher than the exclusion threshold. The diagnosis of HFpEF may be difficult given the absence of obvious signs of central fluid retention. For this reason, the diagnosis should be based on objective measures of cardiac dysfunction which include elevated levels of NPs and an the evidence of cardiac functional and structural alterations underlying HF (Ponikowski et al. 2016). Key structural alterations include a left atrial volume index >34 mL/m^2 or a left ventricular mass index ≥115 g/m^2 in men and ≥95 g/m^2 in women (Caballero et al. 2015). Key functional alterations include an E/e′ ≥13 and a mean e' septal and lateral wall <9 cm/s.

Cardiovascular complications are the leading cause of diabetes-related morbidity and mortality. Further, diabetes is associated with an increased risk of HF after adjustment for well-known HF risk factors as observed in several population-based studies (Vaur et al. 2003). The Framingham Heart Study showed, after correcting for cardiovascular risk factors and coronary artery disease (CAD), that the frequency of HF was twice and five times higher in men and women with diabetes, respectively, than in age-matched non-diabetic subjects (Kannel and McGee 1979). Indeed, HF is one of the most common initial manifestations of cardiovascular disease in patients with type 2 diabetes mellitus (T2D). The risk of HF is also increased in patients with type 1 diabetes mellitus (T1D). These patients have been described as having a four-fold increase in the risk of being admitted to the hospital with HF, compared with population-based controls

(Rosengren et al. 2015). In both type 1 (Rosengren et al. 2015) and T2D (Lind et al. 2012), poor glycaemic control has been described to be associated with an increased incidence of HF. Moreover, as shown in both observational and clinical studies, diabetes is associated with a poor subsequent prognosis in subjects with HF (Gustafsson et al. 2004). In fact, in patients with T2D, mortality is increased ≈10-fold in patients with versus those without HF (Standl et al. 2016).

2 Diabetic Cardiomyopathy: Definition, Prevalence and Characteristics

The presence of left ventricular dysfunction in diabetic subjects without CAD or hypertension led to the use of the term diabetic cardiomyopathy (DCM). The usual definition of DCM includes the presence of structural and functional abnormalities of the myocardium in subjects with diabetes without coronary artery disease, hypertension or significant valvular disease. The existence of this specific form of cardiomiopathy was first proposed in 1972 after postmortem studies (Rubler et al. 1972), based on the findings of HF in diabetic individuals free of detectable CAD. Subsequent studies provided more definitive evidence for DCM in diabetic subjects without CAD (Regan et al. 1977).

Functionally, DCM is characterized by cardiac hypertrophy, loss of cardiomyocytes, interstitial fibrosis and diastolic dysfunction followed by systolic dysfunction (Boudina and Abel 2007). The disease course consists of a silent asymptomatic subclinical, and usually long, period during which cellular structural damage initially leads to diastolic dysfunction, thereafter to systolic dysfunction, and eventually to HF (Velez et al. 2014). A relevant characteristic of the myocardium in diabetes is cardiac hypertrophy. The evidence from 2 large studies (Strong Heart study and the Cardiovascular Health study) showed that there is an association between diabetes and cardiac hypertrophy (increased left ventricular mass and wall thickness), together with deranged systolic and diastolic functions (Devereux et al. 2000). These myocardial structural changes were later confirmed independently in the Framingham study, in which independently of blood pressure, there was a correlation between glycaemic control and cardiac hypertrophy (Kannel and McGee 1979). Diastolic dysfunction, an early functional alteration in the diabetic myocardium described as correlated with diabetes duration, could be the first sign of DCM (From et al. 2009). The presence of subclinical diastolic dysfunction in these subjects is associated with the development of heart failure, and also with mortality, independent of the presence of hypertension and CAD. Additionally, in population-based cohorts, diastolic dysfunction has been associated with development of HF after a 6-year follow-up period (Kane et al. 2011).

Using conventional ultrasound imaging and Doppler imaging, diastolic dysfunction is detected in 25–60% of subjects with diabetes (Boyer et al. 2004). According to the recommendations of the 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic HF, in at risk individuals for HF, a transthoracic echocardiography protocol with the assessment of tissue Doppler velocities and deformation indices should be considered to identify myocardial dysfunction at the preclinical stage. The available evidence indicates that in diabetic subjects left ventricular (LV) diastolic dysfunction might precede LV systolic dysfunction (From et al. 2009; Poirier et al. 2001). Studies that have used tissue Doppler imaging in patients with T2D have demonstrated impairment of diastolic function, even in patients with short duration of the disease (Di Bonito et al. 2005). In these patients, duration of DM of over 4 yr is correlated with significant LV diastolic dysfunction (From et al. 2009). The fact that systolic dysfunction may develop at a later stage of the disease is a challenge for the diagnosis using conventional echocardiography. Moreover, it must be noted that, although echocardiographic abnormalities are very common in outpatients with T2D, it has recently been reported that neither cardiac symptoms nor

clinical characteristics are effective for identifying patients with echocardiographic abnormalities (Jørgensen et al. 2016). The use of cardiac ultrasound screening by application of age-and sex-adjusted normal myocardial velocity ranges has demonstrated that 36% of diabetic patients without coronary artery disease or left ventricular hypertrophy have significant subclinical left ventricular dysfunction (Fang et al. 2005). Diastolic dysfunction is considered the first marker of DCM. However, the evaluation of myocardial dysfunction by echocardiography with speckle-tracking imaging has demonstrated that systolic strain alteration may exist in the presence of normal diastolic function, suggesting that diastolic dysfunction might not be regarded as the first marker of a preclinical stage of diabetic cardiomyopathy (Ernande et al. 2011). In patients with T1D, the prevalence described for myocardial dysfunction in a recent study performed in 1093 T1D patients was 15.5% (1.7% with LVEF <45%, and 14.4% with evidence of diastolic dysfunction) (Jensen et al. 2014). Whether screening and aggressive management of diabetic patients with preclinical diastolic dysfunction might delay the progression to HF with improved outcomes is not yet known.

Because treatment for HF improves survival and quality of life, clinicians should be observant of signs of HF in the management of patients with diabetes, starting at early stages. Echocardiography might be warranted, especially in the presence of poor glycaemic control, long duration of diabetes, an adverse risk factor profile or micro/macro albuminuria.

3 Mechanisms Involved in the Pathophysiology of Diabetic Cardiomyopathy

The metabolic milieu associated with diabetes is characterized by alterations in multiple molecular pathways in the cardiomyocytes, leading to an impairment of cardiac contractility and promoting myocyte dysfunction, injury and eventually death. Thus, the pathogenetic mechanisms underlying diabetic heart disease are likely to be multifactorial, ranging from altered myocardial metabolism (hyperglycaemia, hyperinsulinaemia, increased circulating fatty acids and triacyclglycerols) to endothelial dysfunction, microvascular disease, autonomic neuropathy, and altered myocardial structure with fibrosis. The main potential pathophysiological factors that drive the development of DCM are shown in Fig. 1.

3.1 Cardiac Lipotoxicity

In the normal heart, a constant energy supply is primarily met by the β-oxidation of long-chain fatty acids (FAs). β-oxidation accounts for

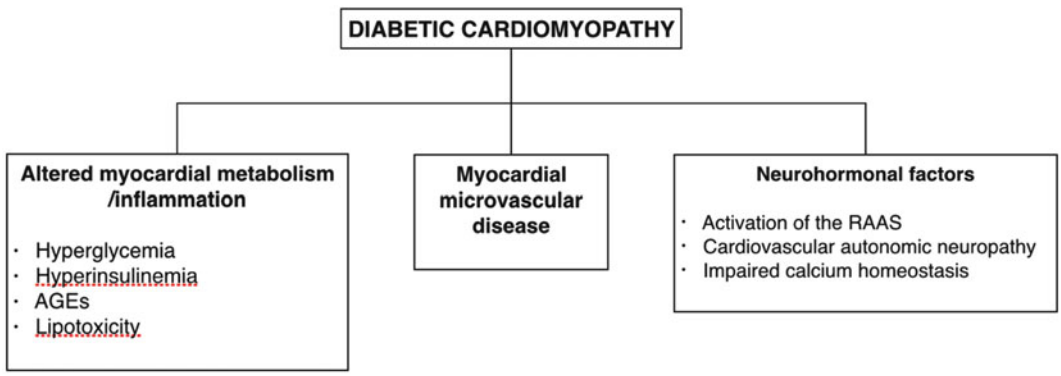

Fig. 1 Schematic depiction of the potential pathophysiological pathways that have been implicated in diabetic cardiomyopathy. These can be divided into: (1) altered myocardial metabolism/inflammation, (2) myocardial microvascular disease and (3) neurohormonal factors

approximately 50–70% of the energy production of the heart, with the remainder primarily accounted for by carbohydrate (glucose and lactate) oxidation and the oxidation of ketone bodies (Asrih et al. 2012). Fatty acids are delivered to the heart from two sources: (a) FAs esterified as triglycerides (TGs) contained in circulating TG-rich lipoproteins (chylomicrons and very-low density lipoproteins (VLDL)) and liberated by lipoprotein lipase (LpL)-mediated lipolysis associated with proteoglycans and glycosylphosphatidylinositol-anchored high density lipoprotein–binding protein 1 (GPIHBP1) on the luminal surface of endothelial cells; and b) non-esterified FAs, referred to as free FAs (FFAs), bound to serum albumin. Fatty acids can be taken up passively by cardiomyocytes via diffusion across the cell membrane (20%), or by a protein-mediated mechanism involving fatty acid binding proteins (FABPs) and CD36 (80%) on the cell membrane. Ectopic fat accumulation (cardiac steatosis) within (intramyocardial) or around (epicardial/pericardial) the heart has been described to be greater in obesity and in patients with T2D. In patients with T2D, myocardial TG content has been described to be associated with impaired left ventricular diastolic dysfunction, independent of age, body mass index, visceral fat, and diastolic blood pressure (Levelt et al. 2016). In some studies, it has been reported that intramyocardial TG content was correlated with left ventricular diastolic dysfunction (Ng et al. 2010). In addition, it has been shown in cardiac imaging studies performed with different metabolites that patients with T2D have lower uptake of glucose and greater uptake and oxidation of FAs (Rijzewijk et al. 2009). Epicardial fat depots have also been reported to be increased in patients with diabetes (From et al. 2009). Interestingly, the Framingham Heart Study and the Multi-Ethnic Study of Atherosclerosis revealed that the size of fat depots around the heart are risk predictors for CV dysfunction and coronary disease (Mahabadi et al. 2009). Remarkably, studies have also shown that patients with T1D have higher epicardial fat thickness than individuals without diabetes, independent of body mass index, age or level of glycated haemoglobin. In recent years, ectopic fat deposition in another organ different from the heart (i.e., the liver) has been described to be associated with both myocardial steatosis and dysfunction (Bonapace et al. 2012).

There are two possible scenarios to explain the accumulation of intramyocardial TGs described in patients with diabetes: (1) oversupply of FA and (2) impaired FA oxidation. A number of factors, including elevated levels of insulin, contribute to high concentrations of FFAs. Insulin accelerates TG synthesis and inhibits lipolysis in adipocytes. In the setting of insulin resistance, such as in T2D, lipolysis in the adipose tissue and hydrolysis of TGs are increased and lead to elevated concentrations of circulating FFAs. Cardiac insulin resistance is accompanied by a persistent relocation of the fatty acid transporters CD36 and FABP from the cytosol to the cell membrane, leading to chronic elevation of FAs uptake and oxidation (Goldberg et al. 2012), and internalization to an intracellular location of the glucose transporter GLUT4. The preferential use of FAs for myocardial metabolism, instead of glucose, is an important contributing factor to the development of DCM. CD36 is a transmembrane protein that transports long-chain FAs, and it is highly expressed in the heart, adipose tissue and skeletal muscle (Pepino et al. 2014). In both heart and skeletal muscle, FA uptake rates have been found to run in parallel to the expression level of CD36. Thus, CD36 overexpression results in elevated rates of FA uptake (Steinbusch et al. 2011), whereas CD36 knockout (KO) or knockdown impairs the transport of FA across the plasma membrane (Angin et al. 2012). The results obtained in aged CD36-deficient mice have provided evidence that CD36 mediates age-induced cardiomyopathy in these mice (Koonen et al. 2007). After the uptake of FAs by target tissues, these may have 3 major different fates in the cell. They can be converted into sphingolipids, such as ceramide; alternatively, they can be esterified into TGs, diglycerides, or phospholipids; or they can undergo oxidation to obtain energy. When the balance between FA uptake and oxidation is altered, excess FAs are

directed towards the synthesis of complex lipids, such as TG, diacylglycerols (DAGs) and phospholipids. An alternative route to use fatty acid surplus is via the ceramide biosynthetic pathway. DAGs and ceramides are signalling lipids believed to be toxic when their intracellular concentrations are increased. Animal experiments have implicated ceramide in the pathogenesis of cardiac dysfunction associated with obesity and diabetes (Park and Goldberg 2012). However, whether ceramide is relevant to cardiac failure in humans is still unclear. Finally, it should be noted that saturated long-chain FAs, most notably palmitate, are associated with toxicity in cells, either because of their direct actions or their incorporation into phospholipids.

3.1.1 Lipid Abnormalities in Patients with T2D

Patients with T2D often present with atherogenic dyslipidaemia, which is characterized by hypertriglyceridaemia, low high-density lipoprotein (HDL) cholesterol, an increase in small and dense LDL particles and hyper-apolipoprotein B (apoB). These patients show elevated plasma concentrations of both fasting and postprandial triglyceride-rich lipoproteins (TRLs), a mixture of lipoproteins derived either from the intestine (chylomicrons) or the liver (VLDL). Patients with T2D also show an increase in the concentration of modified forms of LDL particles (oxidized LDL (ox LDL), glycosylated LDL (glLDL) and electronegative LDL, the last generated by mechanisms such as lipolysis and non-esterified fatty acid loading). This modified forms of LDL are mainly increased in patients with T2D who have a predominance of small dense LDL (sdLDL) particles (phenotype B) (Sánchez-Quesada et al. 2013). Regarding the effect of modified LDL on cardiomyocytes it has been described that under hypoxic conditions the supply of FFAs from LDL-negative to the cardiomyocyte is increased. This increase of FFAs favours intracellular TG synthesis that is accompanied by inefficient sequestering of FFAs into lipid droplets and promotes the production of reactive oxygen species (Revuelta-López et al. 2015). Given that TG accumulation in the myocardium has been described to cause deleterious lipotoxicity, a potential pathogenic pathway of electronegative LDL particles on cardiomyocyte function should further be explored.

3.1.2 Lipid Abnormalities in Patients with T1D

In patients with T1D, an altered lipid pattern has been described, especially in women with poor glycaemic control, consisting of increased triglyceride levels and decreased HDL concentrations, which except for HDL-c are normalized by the optimization of glycaemic control (Pérez et al. 2000). Regarding the quality of lipoproteins, intensive diabetes therapy has recently been reported to be associated with potentially favourable changes in circulating LDL and HDL subclasses in T1D (Vinagre et al. 2014).

3.2 Microvascular Disease

The alterations of myocardial composition and the consequent diastolic properties and left ventricular filling pressure might be mediated by changes in coronary microcirculation. Although heart disease due to diabetes is mainly associated with complications in large vessels, microvascular abnormalities are also believed to be involved in altering cardiac structure and function. Three major defects, endothelial dysfunction, alteration in the production/release of hormones, and shifts in the metabolism of smooth muscle cells, have been suggested to produce damage to the small arteries and capillaries (microangiopathy) due to hyperglycaemia and to promote the development of DCM. These factors might either act alone or in combination to oxidative stress as well as changes in cellular signalling and gene transcription, in turn causing vasoconstriction and structural remodelling of the coronary vessels (Adameova and Dhalla 2014). In fact,

histological examination of human diabetic post-mortem hearts has shown the presence of microangiopathy in this organ (Bloch et al. 1980). Among the possible mechanisms promoting microangiopathy in DCM are hyperglycaemia, hyperlipidaemia, and activation of the neurohumoural system (Adameova and Dhalla 2014). As a consequence, alterations in the function and permeability of the endothelium, increased reactivity of the smooth muscle cells and adhesion of monocytes, as well as thrombocytes, might induce vasoconstriction and stimulation of the signalling pathways that promote fibrosis. In patients with T2D, coronary microvascular dysfunction has been described to be associated with concomitant albuminuria (von Scholten et al. 2016). In the Strong Heart Study (Liu et al. 2003), after adjustment for multiple known contributing factors, including CAD, the degree of diastolic dysfunction was shown to be proportional to the level of microalbuminuria. Also in patients with T1D without known heart disease, micro- and macroalbuminuria have been described to be associated with subclinical myocardial dysfunction (Jensen et al. 2014). Thus, these results suggest a common lesion occurring in multiple microvascular beds. Moreover, in patients with T2D coronary flow reserve, which reflects coronary microvascular function, left ventricular dysfunction has been described (Kawata et al. 2015).

3.3 Hyperglycaemia and Advanced Glycation End Products (AGEs)

During long standing hyperglycemic state in diabetes mellitus, glycation is the non-enzymatic process through which glucose forms covalent adducts with proteins (Du et al. 2003). This results in stable compounds that slowly accumulate during life; these glycated proteins induce structural and physiologic changes in the CV system: increased myocardial and vascular, atherosclerotic plaque formation, endothelial dysfunction, and altered responses to vascular injury. The enhanced generation and accumulation of advanced glycation end-products (AGEs) have been linked to increased risk for macrovascular and microvascular complications associated with diabetes mellitus. A correlation has also been reported between AGEs levels and isovolumetric relaxation time and diastolic left ventricular diameter (Kilhovd et al. 1999). The influence of glycaemic optimization on the risk of cardiovascular events in diabetic subjects with heart failure has not been clearly established. A meta-analysis that included 8 randomized trials showed that more intensive glycaemic control in patients with T2D did not reduce the occurrence of HF events (Castagno et al. 2011). In contrast, the results regarding optimization of glycaemic control and its effects on diastolic dysfunction in patients with T2D have been conflicting. In T2D patients with mild diastolic function and good glycaemic control (mean HbA1c of 6%) without confounding comorbidities, the Diabetes mellitus and Diastolic Dysfunction (DADD) investigators reported, in a controlled clinical trial, that glycaemic control did not result in improvement in either diastolic LV function or myocardial perfusion reserve (Jarnert et al. 2009). Conversely, in an earlier small, observational study, von Bibra et al. described in a small group of T2D with comorbidities that the intensification of glycaemic control was associated with an improvement in myocardial diastolic function (von Bibra et al. 2004).

3.4 Cardiovascular Autonomic Neuropathy

Cardiovascular autonomic neuropathy in patients with diabetes is caused by an alteration of the autonomic system. The prevalence of this form of neuropathy varies between 20 and 65% depending on the duration of DM and the study methods for its assessment (Debono and Cachia 2007). Cardiovascular autonomic neuropathy is associated with rest tachycardia, exercise intolerance, orthostatic hypotension and silent

myocardial ischemia. In patients with T2D, cardiovascular autonomic neuropathy diagnosed by autonomic function tests, has been described to be associated with left ventricular diastolic dysfunction (LVDD) suggesting that patients with LVDD have cardiovascular autonomic neuropathy and hence are at increased risk of mortality due to sudden cardiac death (Mythri and Rajeev 2015). However, it should be noted that this is an area of knowledge that is largely unexplored.

3.5 Inflammation

Diabetes mellitus is considered as a pro-inflammatory state (Diamant et al. 2005). In this sense, several groups have reported increased circulating levels of inflammatory biomarkers such as cytokine IL-6 and C-reactive protein in patients with T2D. Expression of inflammatory cytokines is also markedly increased in experimental models of diabetes. These inflammatory markers are influenced by a wide range of clinical and pathologic conditions such as metabolic syndrome and the presence of DM, and thus might not specifically reflect alterations in myocardial inflammatory processes (Frangogiannis 2014). Animal models of T1D and T2D have revealed increased myocardial inflammation driven in part by increased activation of M1 macrophages (Jadhav et al. 2013). In the Zucker diabetic fatty rats, the polarization of macrophages toward anti-inflammatory macrophage M2 phenotype in cardiac tissue is described to be associated with an improvement of cardiac hemodynamic parameters such as ventricular contractility (Jadhav et al. 2013). Even though it is difficult to distinguish between ischemic/non-ischemic causes of cardiomyopathy, in the presence of a myocardial infarction, certain cell types involved in the inflammatory response can migrate across the vascular wall, and promote cytotoxic effects on cardiomyocytes, thereby potentially extending ischemic/non ischemic injury. To our knowledge, in humans, there is not yet any evidence of myocardial inflammation. These results point to the necessity of conducting further studies on myocardial inflammation and the potential utility of the role of anti-inflammatory strategies to prevent cardiac dysfunction in subjects with diabetes.

3.6 Activation of the Renin-Angiotensin-Aldosterone System (RAAS)

In the diabetic heart, there is an increased density and expression of the angiotensin II receptor (Khatter et al. 1996). Activation of RAAS in the myocardium promotes remodelling processes. In patients with preserved ejection fraction, it has been described that treatment with a mineralcorticoid receptor antagonist is associated with a reduced risk of hospitalization for HF and that this treatment also reverses cardiac remodelling (Orea-Tejeda et al. 2007). In animal models of diabetes, aldosterone antagonism (spironolactone) attenuated the increased content of myocardial content of connective tissue in diabetic mice (Westermann et al. 2007). This treatment has also been described to attenuate cardiac failure by decreasing cardiac inflammation and normalizing metalloproteinase activity in streptozotocin-induced diabetic cardiomyopathy (Westermann et al. 2007).

3.7 Impaired Calcium Homeostasis

It is known that calcium and other ion homeostasis is altered in diabetic cardiomyocytes (Cesario et al. 2006). Failing heart muscle generally exhibits distinct changes in intracelular Ca^{2+} handling, including impaired removal of cytosolic Ca^{2+}, reduced calcium loading of the cardiac sarcoplasmic reticulum, and defects in this sarcoplasmic reticulum Ca^{2+} release accompanied by an impairment of cardiac relaxation and systolic function. In streptozotocin-induced diabetic rats, decreased activity of the

sarcoplasmic reticulum Ca^{2+}ATP ase has been reported; this reduced enzymatic activity contributes to the pathogenesis of cardiac dysfunction in this animal model of diabetes (Zhao et al. 2006; Lopaschuk et al. 1983).

4 Medical Therapy for Heart Failure in Patients with Diabetes

Current guidelines from the European (Ponikowski et al. 2016) as well as the American (WRITING COMMITTEE MEMBERS and ACC/AHA TASK FORCE MEMBERS 2016) cardiology societies do not recommend specific treatment approaches in patients with diabetes. In this section, our approach takes into consideration treatments according to LVEF and is divided into: (1) treatment in patients with reduced EF (HFrEF), and treatment in patients preserved EF (HFpEF) or mild-range EF (HFmEF). Likewise, treatment in patients with HFrEF is divided into the first line medical treatment and other treatments.

4.1 Pharmacological Treatment of Heart Failure with Reduced Ejection Fraction (HFrEF)

The main aims of the medical treatment for patients with HF include the improvement of quality of life and clinical status, and the avoidance of hospitalizations and reduction of mortality. Several clinical trials have provided the evidence base for the medical treatment of chronic heart failure. Regarding HFrEF, neurohormonal antagonists (such as angiotensin-converting enzyme inhibitors (ACEIs), mineralcorticoid receptor antagonists (MRAs) and β-blockers) proved to reduce morbidity and mortality. Thus, these groups of drugs are the main medical treatment. Furthermore, ivabradine and more recently sacubitril/valsartan have demonstrated benefit in terms of mortality and hospitalizations in subjects with EF < 35% in clinical trials (McMurray et al. 2014; Swedberg et al. 2010; Shekelle et al. 2003).

However, no pharmacological treatment has been shown to reduce mortality in patients with HFpEF, and the existing evidence to improve morbidity or prevent hospitalizations is poor. For this reason, current clinical guidelines just recommend the control of congestion, symptoms and comorbidities in this group of patients.

Because diabetes confers a poorer prognosis in terms of morbidity and mortality in subjects with HF, the implementation of evidence-based treatment is imperative. Below, we include the mains details of the current recommendations about medical treatment in chronic HF according to European Society of Cardiology (Ponikowski et al. 2016).

4.1.1 First Line Medical Treatment in HFrEF

Angiotensin Converting Enzyme Inhibitors (ACEIs) /Angiotensin II Receptor Blockers ACEIs significantly reduce the number of hospitalizations for HF, myocardial infarction and CV mortality in subjects with asymptomatic or symptomatic left ventricular systolic dysfunction (Ponikowski et al. 2016). For this reason, they are strongly recommended in the absence of contraindications in all patients with HF. The dose of ACEIs ought to be increased to the maximum tolerated dose to achieve optimal inhibition of the RAAS (Masoudi and Inzucchi 2007). In patients who cannot tolerate ACEIs, angiostensin receptor blockers (ARBs) are recommended (Ponikowski et al. 2016).

In patients with symptomatic chronic HF and intolerance to ACEIs, treatment with the ARB candesartan reduced CV mortality and morbidity (Granger et al. 2003). Treatment with valsartan, another angiotensin-receptor blocker, was reported to reduce the combined end-point of mortality and morbidity and to improve clinical signs and symptoms in patients with HFrEF when added to prescribed therapy which included ACEIs (Masoudi and Inzucchi 2007; Granger et al. 2003; Cohn and Tognoni 2001). The benefits of ACEIs in subjects with diabetes

and HFrEF are similar to those of subjects without DM (McMurray et al. 2014). Thus, ACEIs should be used in all subjects with diabetes and HFrEF.

Beta-Blockers The results obtained in clinical trials performed in more than 20,000 patients with HFrEF have demonstrated that β-blockers significantly decrease the risk of death and hospitalization due to HF and improves symptoms despite treatment with an ACEIs (Packer et al. 2001). β-blockers and ACEIs are complementary, and both are strongly recommended in patients with HFrEF. Beta-blockers should be initiated in clinically stable patients. It is recommended that treatment is started at low doses and the dose should be increased according to the tolerance of the patient until the maximum tolerated dose. Current guidelines recommend the use of β-blockers in patients with coronary heart disease given its effectiveness in patients with myocardial infarction. Thus, they are also recommended in subjects with previous myocardial infarction and asymptomatic left ventricular systolic dysfunction (LVSD) (Ponikowski et al. 2016).

Recent studies have shown that the benefit of treatment with β-blockers in HFrEF is mainly in patients in sinus rhythm (Kotecha et al. 2014). However, current guidelines maintain the recommendation for the use of β-blockers in all patients with depressed EF in sinus rhythm, and even in atrial fibrillation. The use of β-blockers in patients with diabetes and HFrEF, as in patients without diabetes, is associated with a decreased risk of all-cause, cardiovascular and cardiac mortality. Thus, this treatment should be considered, in addition to ACEIs, in all diabetic subjects with HFrEF and stable symptoms of HF.

Mineralcorticoid Receptor Antagonists (MRAs) In two clinical trials (the RALES study and the EPHESUS study) (Pitt et al. 1999, 2003), MRAs on top of standard therapy in subjects with HFrEF were reported to improve symptoms, decrease the risk of hospitalization and reduce mortality. Therefore, MRAs are recommended in all symptomatic patients with HFrEF and LV ejection fraction below 35% (Ponikowski et al. 2016). Heart failure guidelines recommend routine surveillance of serum potassium and renal function in patients treated with MRAs. This is especially important in diabetic subjects. These patients have a higher prevalence of chronic kidney disease, and some of them might also have type IV renal tubular acidosis; these two factors clearly increase the risk of hyperkalaemia, particularly if they are already receiving treatment with ACEIs.

4.1.2 Second Line Medical Treatment in HFrEF

Sacubitril/Valsartan This is a first-in-class drug that contains an angiotensin II receptor blocker (valsartan) and a neprilysin inhibitor (sacubitril). In the cardiovascular system, neprilysin cleaves numerous vasoactive peptides. Some of these peptides have vasodilatory effects (including natriuretic peptides, adrenomedullin and bradykinin), and others exert vasocontricting effects (angiotensin I and II and endothelin-1, among others). The inhibition of neprilysin leads to a slower degradation of NPs. High circulating NPs inhibits the secretion of renin and aldosterone. Additionally, NPs increase natriuresis, diuresis, and myocardial relaxation.
In the PARADIGM-HF trial, in symptomatic patients with HFrEF, LVEF below 35–40%, elevated NPs and glomerular filtration rate over 30 mL/min/1.73 m^2, received either sacubitril/valsartan or enalapril (Zhao et al. 2006). Sacubitril/valsartan was superior to enalapril in terms of hospitalizations for HF, and cardiovascular and overall mortality. Moreover, this treatment resulted in a greater long-term reduction of HbA1c than in patients receiving enalapril (Seferovic et al. 2017).

Sacubitril/valsartan is therefore indicated in patients with HFrEF and EF $<$ 35% who are symptomatic despite standard treatment (Ponikowski et al. 2016). Combined treatment

with an ACEIs (or ARB) and sacubitril/valsartan is contraindicated. To avoid the occurrence of angioedema, ACEIs should be stopped 36 h before starting treatment with sacubitril/valsartan.

Ivabradine Increased resting heart rate is a well-established risk factor for adverse events. Ivabradine decreases the heart rate by inhibiting of the I_f channel in the sinus node. In the Systolic Heart failure Treatment with the I_f inhibitor Ivabradine Trial (SHIFT), treatment with ivabradine versus placebo in patients with symptomatic HFrEF, LVEF $\leq$35% and heart rate over 70, was associated with an improvement of clinical outcomes that included admissions for worsening HF (Swedberg et al. 2010; Shekelle et al. 2003). Therefore, ivabradine is recommended in patients with HFrEF that fit these criteria and are symptomatic despite standard treatment (Ponikowski et al. 2016).

Table 1 Summarizes the results obtained from clinical trials assessing the effect of drug therapy on HF mortality and morbidity in patients with reduced LVEF

4.1.3 Other Medical Treatments in HFrEF

A. **Diuretics:** The main clinical manifestations of HF are due to the retention of fluids; thus, treatments aimed at improving congestive symptoms play a central role in this treatment approach. Thus, diuretics are one of the cornerstones of HF treatment, to reduce symptoms of congestion although they have not shown reduction in mortality (Ponikowski et al. 2016). The proper use of these agents requires adequate knowledge of their pharmacodynamics and pharmacokinetics, their interactions and possible causes of inefficiency, as well as their potential dangers. To avoid the latter, basic rules should be maintained, including the use of the lowest possible doses that can keep the patient free from oedema and periodic monitoring of renal function and serum electrolytes. In comparison with thiazides, loop diuretics induce a more intense and shorter diuresis, although they may act synergistically; for the treatment of resistant oedema, this combination may be used.

B. **Hydralazine and isosorbide dinitrate** may be used in combination in symptomatic subjects with HFrEF, in whom ACEIs or ARB are contraindicated or are not well tolerated, although this recommendation is based on old studies in which the standard treatment did not include ACEIs, β-blockers or ARMs (Cohn et al. 1986).

C. **Digoxin** may be used in subjects who keep sinus rhythm with symptomatic HFrEF despite all the other medical treatment described, to reduce the risk of hospitalization (all-cause and heart failure hospitalizations) (Digitalis Investigation

Table 1 Clinical trials evaluating drug benefit in patients with reduced ejection fraction

	Mortality	Morbidity
ACEi (Ponikowski et al. 2016)	↓	↓
ARBs (Masoudi and Inzucchi 2007; ranger et al. 2003; Cohn and Tognoni 2001)	↓	↓
B-receptor blockade (acker et al. 2001)	↓	↓
Mineralcorticoid/aldosterone receptor antagonists (Kotecha et al. 2014; Pitt et al. 1999)	↓	↓
I_f –channel inhibitors (Ivabradine) (Swedberg et al. 2010; Shekelle et al. 2003)	↓	–
Angiotensin receptor neprilysin inhibitor (Zhao et al. 2006)	↓	↓

ACEi (Angiotensin-converting enzyme inhibitor): captopril, enalapril, lisinopril, ramipril, trandolapril; **ARBs** (Angiotensin receptor blockers): candesartan, valsartan; **β-receptor blockade:** bisoprolol, carvedilol, metroprolol succinate; **Mineralcorticoid/aldosterone receptor antagonists:** eplerenone, spironolactone; **Ivabradine:** in symptomatic HF patients with LVEF $\leq$35%, sinus rhythm and heart rate $\geq$ 70 beats $\times$ minute; **Angiotensin receptor neprilysin inhibitor:** in symptomatic HF patients with LVEF $\leq$35–40%, elevated natriuretic peptides and glomerular filtration rate $>$ 30 ml/min

Group 1997), although its effect on top of β-blockers has never been assessed. In subjects with symptomatic HF and atrial fibrillation, digoxin is a useful resource to slow a rapid ventricular rate when other therapeutic options cannot be pursued.

Finally, there are few studies that have examined the effect of statin treatment on vascular markers of inflammation and echocardiographic findings in patients with non-ischemic forms of HF. These studies have shown that treatment with statins (atorvastatin) in patients with reduced LVEF improves LVEF and attenuates adverse LV remodelling (Sola et al. 2006; Yamada et al. 2007).

4.2 Current Therapies for Treatment of Heart Failure with Preserved (HFpEF) or Mid-Range Ejection Fraction (HFmEF)

Until now, patients with EF between 40–49% (HFmrEF) had been excluded from HF clinical trials or, alternatively, they were included in the HFpEF group (EF $\geq$ 50%); therefore, the evidence regarding treatment response of patients in this "grey area" is poor (McMurray et al. 2003; Smith et al. 2003). Although the pathophysiology is heterogeneous, for the time being, current HF guidelines recommend the same medical treatment for HFmrEF and HFpEF patients.

Treatment with ACEIs, ARBs, β-blockers, MRAs or ivabradine in patients with HFpEF or HFmrEF was not shown to decrease mortality in any of the trials in which it has been evaluated, and evidence to improve morbidity or prevent hospitalizations is poor.

Patients with HFpEF or HFmrEF are usually elderly subjects, highly symptomatic and with low quality of life. A main aim of medical therapy in these patients is to improve clinical symptoms. In the SENIORS study, 2128 patients over 70 years of age with previous HF were randomized to the β-blocker nebivolol or placebo. Treatment with nebivolol reduced the combined endpoint of death or cardiovascular hospitalization (Flather et al. 2005).

The different studies that have analysed the cause of death in subjects with HF have suggested that the proportion of non-cardiovascular deaths is higher in subjects with HFpEF compared to HFrEF. This is consistent with the belief that comorbidities may play an important role in outcomes in patients with HFpEF compared with HFrEF. This was confirmed in a national ambulatory cohort of Veterans with HF (Ather et al. 2012), in which it was shown that those patients with HFpEF had a higher non-cardiac morbidity burden associated with higher non-HF hospitalizations compare to HFrEF suggesting that comorbidities should be treated aggressively in patients with HFpEF (Ponikowski et al. 2016).

5 Treatment of Diabetes in Patients with HF

Given the associations of cardiac dysfunction with glucose metabolism, cardiac energy reserve, and steatosis, metabolic interventions aiming to improve glucose metabolism might have beneficial impacts on cardiac function. Nevertheless, the best treatment strategy in diabetic patients with HF remains controversial, and only some glucose-lowering medications have specifically been studied in patients with HF. Although intensive glycaemic control does not seem to impact the outcomes of HF, the choice of the glucose-lowering drug may have a major impact on the development of HF and other cardiovascular outcomes.

(a) Metformin: Currently, the main clinical practice guidelines unanimously recommend the use of metformin as the initial therapy of choice in the vast majority of patients with T2D. There are no data from randomized trials specifically designed to evaluate the effects of metformin on HF, either on incident HF or on safety and efficacy in patients with established HF. Until now, there are data that support the

evidence that metformin is at least as safe as other hypoglycemic agents in patients with DM and HF, even in those cases with decreased ejection fraction (Eurich et al. 2013). In a systemic review of observational studies, metformin was reported to be associated with a 20% lower adjusted death rate compared with other antihyperglycaemic medications, mainly sulfonylureas (Eurich et al. 2013). Moreover, data from observational studies showed that metformin leads to a reduction in all-cause mortality in patients with T2D with congestive HF and appears to reduce the admissions from congestive HF in patients with congestive HF or with moderate chronic nephropathy (Eurich et al. 2013). Furthermore, metformin has not been reported to be associated with an increased risk of lactic acidosis in patients with chronic HF or with mild chronic kidney disease (Inzucchi et al. 2014). Hence, these data have prompted regulatory authorities to remove HF from the earlier list of product-label contraindications for metformin therapy (Inzucchi et al. 2007). The Food and Drug Administration withdrew congestive HF as a contraindication for the use of metformin in 2006. Also, in April 2016, the agency reviewed its warning regarding chronic nephropathy to restrict the use of metformin only in patients with severe disease (glomerular filtration rate < 30 ml/min/1.73m^2), thus allowing its administration in subjects with moderate chronic nephropathy (30–60 ml/min/1.73 m2). For this reason, in the absence of severe ventricular dysfunction, metformin is currently recommended as first-line therapy in clinically stable subjects with HF.

(b) Sulfonylureas and insulin: As with metformin, clinical trial data are scarce concerning the impact on HF in subjects with established cardiovascular disease treated with either sulfonylureas or insulin. No difference in HF events was recorded in the UK Prospective Diabetes Study (UKPDS) comparing sulfonylureas or insulin treatment with dietary intervention in 3867 newly diagnosed patients with diabetes (Intensive blood-glucose control with sulphonylureas or insulin compared with conventional treatment and risk of complications in patients with type 2 diabetes (UKPDS 33) 1998). Regarding sulfonylureas, population-based observational studies have provided discordant results (McAlister et al. 2008; Tzoulaki et al. 2009). Conversely, no increase in HF hospitalization or cardiovascular events was observed in the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial (ORIGIN Trial Investigators et al. 2012). In summary, based on this limited evidence, the presence of HF is not a contraindication for the use of sulfonylurea therapy, but an alternative option of using metformin seems preferable. Moreover, as with insulin therapy, severe hypoglycaemia is common with sulfonylurea therapy with potential adverse cardiac effects; thus, sulfonylurea therapy should be reconsidered in patients with HF if hypoglycaemia occurs.

(c) Thiazolidinediones: The thiazolidinedione (TZD) family of Peroxisome proliferator-activated receptor gamma (γ) (PPARγ) agonists initially provided a promising therapeutic option in T2DM owing to antidiabetic efficacy combined with pleiotropic beneficial cardiovascular effects. However, the utility of TZDs in T2D has declined in the past decade, largely due to concomitant adverse effects of fluid retention and edema formation attributed to salt-retaining effects of proliferator-activated receptor γ activation on the nephron. The two major cardiovascular outcome trials with these drugs, Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycaemia and Diabetes (RECORD) and PROspective pioglitAzone Clinical Trial In macroVascular Events (PROactive), identified a substantial increase in risk of

HF, although HF was not a pre-specified adjudicated endpoint in PROACTIVE (Dormandy et al. 2005). In this latter study, a significant reduction in the secondary outcome (cardiovascular death, and non-fatal myocardial infarction or stroke) occurred (HR 0.84), although there was no significant reduction in the primary endpoint, that included also re-vascularization procedures. More recently, treatment with pioglitazone showed superiority for major cardiovascular events in a population of 3895 patients with recent stroke and insulin resistance (although not T2D) randomized to pioglitazone versus placebo in the Insulin Resistance Intervention After Stroke trial, with no significant increase in HF outcomes (Kernan et al. 2016). However, thiazolidinediones have a fluid retention potential, leading to increased heart failure events. Already in 2003, the American Diabetes Association and the American Heart Association recommended that TZDs should be used with caution in subjects with class I-II of the New York Heart Association, while they should be avoided in subjects with class III and IV (Nesto et al. 2003). The European Society of Cardiology stated in their 2016 guidelines that thiazolidinediones are not recommended in any patient with HF (Ponikowski et al. 2016).

(d) dipeptidyl peptidase IV (DPP-4) Inhibitors: DPP4 is a serine peptidase that is widely distributed and may be found as a membrane-anchored surface protein or in a soluble form. Studies in different experimental models suggest that these drugs may have renoprotective and cardioprotective effects. However, conflicting findings have been described in other preclinical animal models and also in clinical studies. The cardiovascular effects of DPP-4 inhibitors remain controversial. While these drugs did not reduce or increase the risk of primary, pre-specified composite cardiovascular outcomes, one DPP-4 inhibitor (sitagliptin) demonstrated no effect on HF (Green et al. 2015), another (saxagliptin) increased the ~~increased the~~ risk of hospitalization for HF in the overall population (Scirica et al. 2013), and a third (alogliptin) demonstrated inconsistent effects on heart failure hospitalization across subgroups of patients (Zannad et al. 2015). The mechanisms related to the increased HF risk with saxagliptin and the evident heterogeneity with regard to HF effects within the DPP4 inhibitor class require further elucidation.

(e) GLP-1 receptor agonists (GLP-1RA): No increased risk of hospitalization for HF has been reported with GLP-1RAs in meta-analyses of phase-II/III trials (exenatide, albiglutide, dulaglutide, liraglutide) (Li et al. 2016), demonstrating the safety of this pharmacological class, and these findings have been confirmed in three large prospective cardiovascular outcome trials (Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) with lixisenatide, Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Results (LEADER) with liraglutide and the Trial to Evaluate Cardiovascular and other long-term outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN-6) with semaglutide). In particular, the LEADER trial reported a trend towards a reduction in HF hospitalization (−13%, $P = 0.14$), together with a significant reduction in cardiovascular and all-cause mortality in patients with T2D at risk for cardiovascular disease. These results are reassuring in the face of the somewhat negative results of the Functional Impact of GLP-1 for Heart Failure Treatment (FIGHT) trial, which evaluated the effects of liraglutide in patients with advanced HF and low LVEF, such that further studies and caution are now required when using this agent to treat these patients in clinical practice.

(f) Sodium-glucose transporter type 2 (SGLT2) inhibitors: The first prospective, randomized, controlled trial assessing CV safety in patients with T2D was the Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus patients (EMPA-REG OUTCOME) trial, which was also the first clinical trial to demonstrate that an antidiabetic agent, empagliflozin, could reduce cardiovascular events (Zinman et al. 2015). Empagliflozin is a highly selective inhibitor of the sodium glucose contransporter 2 (SGLT2) in the kidney. Results obtained in the EMPA-REG trial showed that treatment with empagliflozin versus placebo, in addition to standard of care in subjects with T2D and high cardiovascular risk, is associated with significant reductions in the primary 3-point major adverse CV events outcome (a composite of CV death, non-fatal myocardial infarction and non-fatal stroke) (14% risk reduction), a 38% relative risk reduction in CV death, a 32% relative risk reduction in all-cause mortality and a 35% risk reduction in hospitalization for HF.

Empagliflozin has been shown to delay the progression of kidney disease and to reduce clinical renal events, including dialysis. Importantly, empagliflozin decreased the number of hospitalizations for HF and mortality by one-third. However, the mechanisms by which empagliflozin exerts CV protection are currently unknown. The early impact of empagliflozin on CV and hospitalization for HF suggest early haemodynamic effects of the drug. Furthermore, SGLT2 inhibition has been found to increase the concentration of circulating ketone bodies, which might provide an alternative energy source for the diabetic heart in the presence of insulin resistance. In addition, other potential mechanisms, such as weight loss, reduced blood pressure, sodium depletion, reduced oxidative stress, and arterial stiffness, as well as a reduction in sympathetic nerve activation, are currently being discussed (Neal et al. 2017). Recently, a large multinational study using real-world clinical practice databases from different countries compared hospitalization for HF and death in patients newly initiated on any SGLT-2 inhibitors (empagliflozin, dapagliflozin, canagliflozin) versus other glucose-lowering drugs. The results obtained showed that treatment with SGLT-2-inhibitors was associated with a lower risk of HF and death, suggesting that the benefits seen with empagliflozin in a randomized trial might be a class effect applicable to a broad population of T2D patients in real-world practice(CVD-REAL). According to 2016 ESC guidelines, empagliflozin should be considered in patients with T2D to prevent or delay HF and to prolong life (Ponikowski et al. 2016).

To date, prospective CV outcome trials are ongoing with other SGLT2 inhibitors (dapagliflozin in the DECLARE-TIMI) to determine whether the beneficial cardiovascular outcome effects reported from the EMPA-REG OUTCOME trial are a class effect or unique to empagliflozin. Recently, combined results from the Canagliflozin Cardiovascular Assessment Study (CANVAS) and the CANVAS renal end-points trial (CANVAS-R) have been reported. In these studies, patients with T2D, 65.6% with a history of cardiovascular disease, were randomized to canagliflozin (300 mg daily or 100 mg daily) or placebo. Results obtained show that the rate of the primary outcome, a composite of CV death, and non-fatal myocardial infarction or stroke, was lower in the group of patients treated with canagliflozin than in the placebo group (occurring in 26.9 vs. 31.5 participants per 1000 patient-years; hazard ratio, 0.86; $P < 0.001$ for noninferiority; $P = 0.02$ for superiority). However, the CANVAS data also revealed a significant doubling in the risk for amputations, primarily on the toe or metatarsal (6.3 vs 3.4 cases per 1000 patient-years, hazard ratio, 1.97) (Zannad et al. 2015). Additionally, the effects of various agents, including empagliflozin, on cardiovascular morbidity and mortality in patients with HFpEF will be determined by future trials in heart failure (e.g., EMPagliflozin outcomE tRial in Patients With chrOnic heaRt Failure With Preserved

Ejection Fraction [EMPEROR-Preserved; NCT03057951]; and Dapagliflozin in Type 2 Diabetes or Pre-diabetes, and PRESERVED Ejection Fraction Heart Failure [PRESERVED-HF; NCT03030235]); however, thus far, symptom control is the major therapeutic goal (Lehrke and Marx 2017).

In conclusion, the choice of a glucose-lowering drug in subjects with diabetes should be individualized. The American Diabetes Association and European Association for the Study of Diabetes emphasize the importance of personalized treatment in patients with DM and list different conditions to be taken into consideration when choosing a drug: risk of hypoglycaemia, effect on body weight, side effects and costs among the different factors. Moreover, it will also have to be taken into account if the patient has a history of cardiovascular disease or HF (Fitchett et al. 2017).

Take Home Messages

1. The risk of HF in patients with DM is significantly increased, and it is one of the most common initial manifestations of CVD in patients with T2D.
2. Diabetes is associated with worse outcomes in patients with HF.
3. In diabetic cardiomyopathy, the disease course consists of a silent asymptomatic subclinical, and usually long period, during which cellular structural damage initially leads to diastolic dysfunction, thereafter to systolic dysfunction, and eventually to HF.
4. The pathogenic mechanisms underlying DCM are likely to be multifactorial, ranging from altered myocardial metabolism to endothelial dysfunction, microvascular disease, autonomic neuropathy, and altered myocardial structure with fibrosis.
5. The presence of subclinical diastolic dysfunction in patients with T2D is associated with the subsequent development of HF and mortality, independent of hypertension and coronary disease.
6. The presence of albuminuria in a patient with diabetes is associated with an increased risk of having subclinical abnormal myocardial function.
7. Current guidelines from the European, as well as the American, cardiology societies do not recommend specific therapeutic approaches in subjects with diabetes compared with those without the disease.
8. Considering the best available current evidence, the sodium-glucose-co-transporter 2-inhibitors and metformin seem to be especially advantageous with regard to HF effects, with their use associated with reduced HF events and improved mortality.

Heart Failure and Kidney Disease

Dario Grande, Margherita Ilaria Gioia, Paola Terlizzese, and Massimo Iacoviello

Abstract

Kidney disease is commonly found in heart failure (HF) patients. They share many risk factors and common pathophysiological pathways which often lead to mutual dysfunction. Both haemodynamic and non-haemodynamic mechanisms are involved in the development of renal impairment in heart failure patients. Moreover, the presence of a chronic kidney disease is a significant independent predictor of worse outcome in chronic as well as in acute decompensated HF. As a consequence, an accurate evaluation of renal function plays a key role in the management of HF patients. Serum creatinine levels and glomerular filtration rate (GFR) estimates are the corner stones of renal function evaluation in clinical practice. However, to overcome their limits, several emerging glomerular and tubular biomarkers have been proposed over the last years. Alongside the renal biomarkers, imaging techniques could complement the laboratory data exploring different pathophysiological pathways. In particular, Doppler evaluation of renal circulation is a highly feasible technique that can effectively identify HF patients prone to develop renal dysfunction and with a worse outcome. Finally, some classes of drugs currently used in heart failure treatment can affect renal function and their use can be influenced by the presence of chronic kidney disease.

chronic clinical setting, because of the close relationship between heart and kidney function (Chong et al. 2015). Renal and heart diseases share common risk factors and pathophysiological pathways which can lead to an acute or chronic mutual dysfunction, termed cardiorenal syndrome (Table 1). Cardiorenal syndrome has been classified in five subtypes: type 1 refers to acute heart failure as the cause of acute kidney disease; type 2 refers to chronic heart failure as the cause of chronic kidney disease; in type 3 the acute worsening of kidney function causes heart dysfunction; in type 4, chronic kidney disease (CKD) leads to heart failure; in type 5 there is a simultaneous injury of heart and kidneys caused by systemic diseases (Ronco et al. 2008). About half of the patients with heart failure suffers from at least moderate chronic kidney disease, defined as a glomerular filtration rate (GFR) <60 ml/min/1.73 m2, compared to the 10.6% of the general population (Damman et al. 2014a; Hill et al. 2016). The prevalence of CKD is higher among the patients with acute decompensated heart failure (ADHF), ranging from 30 to 60%, depending on the definition used (Adams et al. 2005). Similarly, in-hospital worsening renal function (WRF) is observed in 23% of HF patients, even if the optimal definition for WRF is still debated, leading to some heterogeneity in the results from the various cohorts (Damman et al. 2014a; Smith et al. 2006; Metra et al. 2008). Among patients with chronic heart failure (CHF), up to 42% have CKD (Damman et al. 2014a). Renal impairment is an independent risk factor for adverse outcome in subjects with ADHF and CHF (Smith et al. 2006; Hillege et al. 2000; Damman et al. 2009a; Chang et al. 2010).

2 Pathophysiology

Heart and kidney are two organs tightly linked in physiological and pathological conditions, because they both contribute to preserve the homeostasis of water and electrolytes and the cardio-circulatory function. Heart is greatly dependent on fluid homeostasis regulated by the kidney and renal function is subordinated to perfusion pressure through hemodynamic, neurohormonal, inflammatory and local mechanisms (Damman and Testani 2015). Moreover, heart and kidney diseases frequently coexist because they share pathophysiological pathways and risk factors (such as hypertension, diabetes and atherosclerosis). In heart failure several mechanisms are involved in the pathogenesis of renal impairment, e.g. haemodynamic alterations due to reduced cardiac output and renal venous congestion, neurohormonal deregulations, systemic and local inflammation (Colombo et al. 2012), high-dose of diuretics.

Renal haemodynamic factors are main determinants of renal impairment (and GFR reduction) in HF patients (Damman and Testani 2015). GFR is dependent on renal blood flow and filtration fraction and it is maintained in a normal range by autoregulation despite significant reduction of cardiac output. When these mechanisms are exhausted, as in HF, GFR declines with cardiac output (Braam et al. 2012). Renal hypoperfusion with "forward" underfilling triggers renin–angiotensin–aldosterone system (RAAS) and sympathetic nervous system activation which causes arteriolar vasoconstriction both at glomerular and tubular level. Especially in the acute setting, relevant drop of cardiac output can lead to tubular hypoxia and acute tubular necrosis (Schefold et al. 2016).

Table 1 Consensus Conference of Acute Dialysis Quality Initiative Group classification of cardiorenal syndromes

Type	Primary dysfunction	Consequences
Type 1	Acute worsening of heart function	Kidney injury and/or dysfunction
Type 2	Chronic abnormalities in heart function	Kidney injury and/or dysfunction
Type 3	Acute worsening of kidney function or AKI	Heart injury and/or dysfunction
Type 4	CKD	Heart injury and/or dysfunction
Type 5	Systemic conditions	Simultaneous heart and kidney injury and/or dysfunction

However, the haemodynamic interaction between heart and kidney is even more complex and other mechanisms are involved, considering the modest association between renal impairment and left ventricular systolic function in a large registry of HF patients (Heywood et al. 2007). Emerging data on the interaction between venous congestion and renal dysfunction in HF have lead to a reappraisal of this relationship (Nohria et al. 2008). High central venous pressure and renal venous hypertension can impair GFR through an increase in interstitial pressure and a reduction of artero-venous gradient (Mullens et al. 2009).

Among the non-haemodynamic factors, the hyperactivation of RAAS and sympathetic nervous system has an important role in HF. In addition to the direct effect on the arteriolar tone, at renal level RAAS increases in the long term the secretion of proinflammatory molecules, promotes fibrosis and leads to reduced response to natriuretic peptides (Ruiz-Ortega et al. 2002; Charloux et al. 2003). Moreover, the sympathetic hypertone provokes renin release from juxtaglomerular cells and RAAS activation, oxidative stress and endothelial dysfunction (together with RAAS) (Damman and Testani 2015; Goldsmith et al. 2010).

On the other hand, chronic kidney disease is an established and increasingly recognized risk factor for cardiovascular disease, particularly heart failure. The risk of cardiac impairment increases gradually with kidney dysfunction. In particular, a 15 times higher cardiovascular mortality has been observed in end-stage renal disease (ESRD) patients compared to general population (Granata et al. 2016). In this group of patients, the myocardial structural changes are mainly characterized by left ventricular hypertrophy and fibrosis responsible for diastolic dysfunction; however also dilatation of the left ventricle and impairment of systolic function can occur (Alhaj et al. 2013). Among the several mechanisms involved in the development of heart failure in ESRD patients, an increased preload, caused by fluid overload and a high flow state, related to arterio-venous fistulas, can promote the eccentric remodeling of the left ventricle. On the other hand, an increased afterload, due to high arterial systemic resistances (systolic and diastolic hypertension) and a reduced arterial compliance (vascular calcification), can promote a ventricular concentric remodeling. In addition to the changes in preload and afterload, myocardial fibrosis can be enhanced by a number of non-haemodynamic factors as uremic toxins, oxidative stress, inflammatory status, hyperparathyroidism, hypovitaminosis D and hyperphosphatemia (Alhaj et al. 2013; Tumlin et al. 2013).

3 Markers of Glomerular Function

Taking into account its relevant prognostic role, the evaluation of kidney function in subjects with heart failure is extremely important. A number of laboratory examinations are available to assess renal function and, in particular, the filtration ability of the kidney (Table 2).

3.1 Serum Creatinine and Glomerular Filtration Rate

Serum creatinine levels and GFR estimation are the corner stone for renal function evaluation and are routinely recommended in HF patients management for assessing renal dysfunction and filtration impairment (Ponikowski et al. 2016). Serum creatinine is the product of creatine phosphate breakdown at muscular level. It is produced at relatively constant rate and eliminated by the kidney through glomerular filtration and partially by active secretion in the tubules (Levey et al. 2006). Empirical formulas can be used to easily estimate GFR based on serum creatinine levels, age, gender and weight. The most commonly used formulas are Cockroft-Gault, simplified Modification of Diet in renal disease (MDRD) and, recently, Chronic Kidney Disease Epidemiology Collaboration (CKD EPI) (Stevens et al. 2006). These equations have been validated in CKD populations with good results. Among these formulas, CKD EPI has been shown to be less biased in GFR estimation, especially within the population with preserved

Table 2 Advantages and limitations of renal biomarkers and imaging techniques

Technique	Advantages	Limitations
Serum creatinine	Easy to interpret; cheap	Biased due to age, diet, gender and muscle wasting
BUN	Cheap; strong prognostic value	Less reliable marker of filtration function
Cystatin C	Unbiased; reliable in GFR estimation	Relatively expensive
Microalbuminuria	Easy; early marker of renal impairment; prognostic value independent of GFR	Low specificity
Tubular markers	Early markers of renal impairment; strong markers of AKI; prognostic value independent of GFR	Costs; low specificity
Bidimensional ultrasonography	Feasible; it excludes obstructive uropathy and some parenchymal alterations	Low specificity; no hemodynamic information
Renal resistance index	Feasible; prognostic value independent of GFR	Influenced by renal obstructive arterial disease; lower accuracy with irregular rhythms
Venous Doppler	Feasible; prognostic value independent of GFR	Lack of standardization
Computed tomography	High spatial resolution	Nephrotoxicity of constrast medium; exposure to radiations; no indications in clinical practice
Nuclear imaging	Low radiation dose	Exposure to radiations
MRI	No radiation exposure; unique functional information	Expensive; time consuming; lack of standardization; no indications in clinical practice

renal function (Stevens et al. 2010). In the setting of CHF patients, it leads to a more accurate classification of renal functional stages and a better risk stratification, particularly in those patients with normal or near normal renal function (McAlister et al. 2012; Valente et al. 2014). For this reason, it has recently become the most used estimate of GFR in clinical practice. Serum creatinine levels can also be used to identify patients with WRF, who are at higher risk for events (Smith et al. 2006; Metra et al. 2008). In HF patients, it is generally defined as an absolute increase of >0.3 mg/dl and/or a relative increase of >25% in serum creatinine levels within two-time points (Damman et al. 2009a). In the KDIGO (Kidney Disease: Improving Global Outcomes) guidelines, CKD progression has been defined as a decline in the stage of CKD accompanied by a 25% or greater drop in eGFR from baseline (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group 2013).

Creatinine concentration and GFR estimation are currently recommended to assess renal impairment in HF and to classify renal dysfunction based on GFR category (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group 2013). However, some limitations in the use of serum creatinine exist, as its levels are biased due to age, diet, gender and body mass. A decrease in creatinine levels (with overestimation of GFR) is observed in muscle wasting, a common condition seen in advanced HF. Additionally, GFR estimation can be hampered when filtration function decreases as the relative effect of active secretion is more pronounced, leading to an overestimation of GFR (Damman et al. 2012). On the basis of these limitations, new biomarkers have been proposed to better evaluate glomerular function.

3.2 Blood Urea Nitrogen (BUN)

Urea is produced by protein catabolism, filtered at glomerular level and reabsorbed in the collecting ducts by an AVP-mediated system. In conditions of low cardiac output, the increased RAAS and adrenergic stimulation lead to enhanced fluid and sodium retention.

Consequently, distal flow is reduced and urea reabsorption increases. Urea has been shown to be a strong prognostic marker in both acute and chronic HF populations, being an important predictor of morbidity and mortality (Damman et al. 2012; Aronson et al. 2004; Cauthen et al. 2008). In the acute setting, blood urea nitrogen, together with blood pressure and serum creatinine, has been used to estimate in-hospital mortality with a tree algorithm in the ADHERE registry (Fonarow et al. 2005). The prognostic value of urea could also be greater than serum creatinine (Klein et al. 2008), probably because urea levels take into account other factors than glomerular filtration, as protein intake (and thus nutritional status), catabolic state and reabsorption coupled with sodium at tubular level as a marker of low flow (Schrier 2008). Urea levels are therefore dependent both on glomerular function and on a number of factors related to HF severity. This could explain its strong prognostic role, but it cannot be considered a reliable marker of filtration function. The ratio between urea and creatinine has been extensively used for the differentiation of prerenal renal dysfunction from intrinsic renal parenchymal disease. In prerenal renal dysfunction significant renal neurohormonal activation causes a disproportionate reabsorption of urea compared to creatinine, leading to an urea/creatinine ratio $>$ 100 (or a BUN/creatinine ratio $>$ 20). In patients with HF and renal dysfunction, an elevated urea/creatinine ratio could differentiate a renal impairment due to hypoperfusion from CKD. Furthermore, high urea/creatinine ratio has been associated with congestion and long-term mortality in HF patients (Parrinello et al. 2015).

3.3 Cystatin C

Cystatin C belongs to cysteine proteinase inhibitor family and is secreted by all nucleated cells. It is filtered freely through the glomerulus and then reabsorbed but not secreted by tubular cells, where it is catabolised. As opposed to creatinine, it is relatively independent from age, body mass, nutritional status and cachexia (Newman et al. 1995). The only concerns are inflammation and thyroid dysfunction which could influence Cystatin C levels (Fricker et al. 2003; Singh et al. 2007). Empirical formulas have been proposed to estimate GFR, with better results compared to serum creatinine in different clinical settings and particularly in normal and near normal renal function (Damman et al. 2012; Dharnidharka et al. 2002). Cystatin C has also shown to be accurate in stratifying the risk in the elderly, in diabetic patients and in patients affected by coronary artery disease (Shlipak et al. 2005a; Ix et al. 2006; de Boer et al. 2009). Limited data exist on the role of Cystatin C in HF; however, it appears to be a promising prognostic marker both in acute and chronic HF (Arimoto et al. 2005; Shlipak et al. 2005b; Lassus et al. 2007). Despite these interesting proprieties, Cystatin C is not widely used in clinical practice, perhaps because of its relative high cost compared to creatinine. However, current KDIGO guidelines for CKD state that Cystatin C could be used as a confirmatory test in circumstances when GFR estimation based on creatinine alone is less accurate (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group 2013)

3.4 Albuminuria

Albumin is the most abundant protein in blood. Because of its size, its negative electric charge (the same as the glomerular basement membrane) and the tubular absorption, it is normally present at very low level in the urine. The urinary excretion of albumin is generally evaluated by the ratio between urinary albumin and creatinine (UACR). Albuminuria is present when UACR is $>$30 mg/g, an UACR between 30 and 300 mg/g is termed microalbuminuria, an UACR $>$300 mg/g is defined macroalbuminuria (Miller et al. 2009). Albuminuria is the effect of glomerular membrane damage due to endothelial dysfunction, inflammation, increased glomerular pressure and atherosclerosis (Comper et al. 2008). For this reason, it should be considered a marker of glomerular permeability rather than an

estimate of filtration. Microalbuminuria is highly prevalent in CHF (van de Wal et al. 2005). In this setting other mechanisms could be involved, i.e. renal venous congestion and reduced renal perfusion (Damman et al. 2009b). It has been shown to be associated mortality and HF related hospitalization, independently from creatinine levels and GFR. This association remains significant even in CHF patients with normal GFR, suggesting that microalbuminuria could be an early sign of renal impairment (Jackson et al. 2009; Masson et al. 2010). In the management of patients with renal dysfunction, albuminuria classification, together with GFR category, is recommended as a marker of kidney damage in CKD definition and risk stratification (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group 2013).

4 Markers of Tubular Damage

Another component of acute kidney injury is tubular cell damage, which may be damaged earlier than the glomerulus. Therefore, different markers of tubular damage are being studied to better evaluate and predict renal impairment.

4.1 Neutrophil Gelatinase Associated Lipocalin (NGAL)

NGAL is a small protein produced by the kidney and other organs. It is freely filtered through the glomerulus and completely reabsorbed in the proximal part of the tubule. In normal conditions very low urinary and blood concentrations are observed (Schmidt-Ott et al. 2007). When tubular damage occurs, NGAL cannot be completely reabsorbed, leading to increased urinary levels. In renal diseases, higher plasma levels are also common but relatively less specific, being also found in sepsis, inflammation and cancer (Schmidt-Ott et al. 2007). In case of acute kidney injury, NGAL precedes the rise of serum creatinine by at least 24 h, as the other tubular markers (Mishra et al. 2005). In the acute decompensated heart failure setting, it is associated with the occurrence of WRF and with adverse clinical outcome (Collins et al. 2012; Alvelos et al. 2013). In CHF patients, NGAL levels are markedly increased compared to controls, but they were not able to predict adverse events. Thus, NGAL should be considered as a marker of tubular damage in the acute rather than in the chronic setting (Damman et al. 2010).

4.2 N-Acetyl Beta Glucosaminidase (NAG)

NAG is a lysosomal protein of the proximal tubule, excreted into urine in case of tubular damage (Bazzi et al. 2002). NAG levels are associated with tubular injury in acute kidney disease where it predicts worse prognosis (Liangos et al. 2007). In the intensive care setting, NAG is related to the risk of acute kidney injury (Westhuyzen et al. 2003). In patients with CHF it showed to predict an increased risk of death or HF-related hospitalizations, independently from GFR (Damman et al. 2010). These results were also confirmed in the large cohort of CHF patients of the GISSI HF trial, where it was the only tubular marker related to prognosis and risk of WRF (Damman et al. 2011). Few data are available on the prognostic role of NAG in acute decompensated heart failure.

4.3 Kidney Injury Molecule (KIM1)

KIM1 is a transmembrane glycoprotein which is expressed in proximal tubule cells after hypoxic tubular injury almost 1 day before the increase in serum creatinine (Han et al. 2002). KIM1 urinary levels have high sensitivity for early detection of acute kidney injury. CHF patients have higher KIM1 levels compared to controls. In these setting, urinary KIM1 predicts poor prognosis independently from GFR (Damman et al. 2010).

4.4 Fatty Acid-Binding Proteins (FABPs)

FABPs are proteins that bind free fatty acids. Different tissue-specific FABs have been identified (Veerkamp et al. 1990). In the kidney, liver specific FABP (FABP-1) and heart specific FABP (FABP-3) have been respectively expressed in the proximal and in the distal tubule (Maatman et al. 1991). Urinary FABP-1 and FABP-3 levels have been associated with ischemic tubular injury and risk for AKI (Noiri et al. 2009). In CHF patients persistently high FABP-3 levels are associated with cardiovascular events (Niizeki et al. 2008).

4.5 TIMP-2 and IGFBP7

Tissue inhibitor of metalloproteinase 2 (TIMP-2) and insulin-like growth factor–binding protein 7 (IGFBP7) are cell-cycle arrest biomarkers found to be elevated in renal tubule damage (Niizeki et al. 2008). The product of the urinary concentrations of these two biomarkers, [TIMP-2] × [IGFBP7], has been demonstrated to predict short term acute kidney injury in acute decompensated heart failure with good sensitivity and specificity (Schanz et al. 2017). Furthermore, patients with AKI and elevated [TIMP-2] × [IGFBP7] show a trend toward reduced survival within 1 year (Schanz et al. 2017).

5 Imaging

Several different imaging techniques can explore renal function in terms of anatomy and haemodynamics (Table 2). Ultrasound and Doppler examinations represent an easy and widespread technique used to evaluate parenchymal abnormalities and estimate perfusion pressures with parameters correlated with prognosis in the setting of HF patients. On the other hand, there are several promising second level techniques, especially involving nuclear and magnetic resonance imaging (MRI), which are confined only to an experimental role, so far.

5.1 Renal Ultrasonography

Bidimensional renal ultrasound is a low cost and easy to perform technique which allows an anatomical examination of renal parenchyma. Unfortunately, there are no morphological abnormalities specifically related to heart failure. The observed renal anatomy is greatly dependent on the stage of heart failure and on the severity of the concurrent kidney disease, so the bidimensional examination mostly differentiate an acute from a chronic renal impairment and can exclude an obstructive uropathy as a cause for renal dysfunction. Renal dimensions are related to body surface area, and are generally between 10 and 12 cm in length (Emamian et al. 1993).

In case of renal dysfunction associated with chronic heart failure, there is a non-specific sonographic appearance, common with other causes of CKD: kidneys are smaller, with reduced cortical thickness and cortex-medulla ratio (Moghazi et al. 2005). The parenchyma appears relatively echogenic compared to the liver, due to interstitial fibrosis related to chronic disease (Page et al. 1994). During de novo acute decompensated heart failure renal anatomy is frequently preserved, provided no prior CKD is present. Kidneys have normal dimension and cortex-medulla ratio, with a fairly echolucent appearance of the parenchyma compared to the liver. An echogenic appearance can be rarely observed in case of long-standing renal hypoperfusion (Di Lullo et al. 2012). Both in the acute and in the chronic setting signs of urinary obstruction are generally absent, unless urologic co-morbidities occur.

5.2 Vascular Renal Doppler

The Doppler study of renal arterial flow allows a more comprehensive evaluation of the complex mechanisms involved in the relationship between

renal dysfunction and HF, considering renal haemodynamics and, in particular, arterial resistances. Renal resistances are determined by a number of factors: arteriolar tone, parenchymal anatomy and renal venous congestion.

Glomerular filtration is strictly related to glomerular (blood) hydrostatic pressure and, in turn, to renal blood flow, together with capsular hydrostatic pressure and colloid osmotic pressure. In normal conditions, glomerular filtration and renal perfusion are in parallel stabilized by intrinsic and extrinsic regulation mechanisms with low changes despite wide fluctuations of systemic blood pressure between 70 and 180 mmHg. Out of this range filtration is highly dependent on blood pressure. Renal blood flow is mainly regulated by intrinsic autoregulation (namely myogenic reflex and tubulo-glomerular feedback) and neurohormonal factors as opposed to perfusion of other organs, which are primarily dependent on oxygen demand (Braam et al. 2012; Smilde et al. 2009). Renal blood flow, in theory, is dependent on perfusion pressure (and therefore on cardiac output) and on arterial resistances. In case of a normal autoregulatory system, a reduced cardiac output will not affect net filtration because autoregulation will determine a decrease of arterial resistances ensuring a normal renal blood flow. However, in the setting of heart failure, autoregulatory mechanisms could be altered, being depleted or overruled by sympathetic activation and leading to high renal resistances. Therefore, a reduced cardiac output may cause a disproportional fall of glomerular filtration (Braam et al. 2012). A long-standing increase of renal resistances due to hyperstimulation of arteriolar tone can lead to a functional and then to a structural vascular rarefaction. The former is caused by a prolonged vasoconstriction which causes a reduced number of perfused vessels without anatomical vascular abnormalities. A sustained vasoconstriction may lead to local ischemia, endothelial dysfunction, release of both growth factors and enzymes and, finally, to fibrosis and vascular remodeling. This condition, labeled as "structural rarefaction", refers to an actual reduction in the number of anatomical vessels embedded in the tissue. The vascular remodeling could be considered a cause of persistent increase of renal resistances (Prewitt et al. 1982; Chade 2013). Whatever the mechanism involved, functional rarefaction due to neurohormonal activation or anatomical rarefaction due to remodeling, it is clear that high resistances are associated with reduced renal blood flow and could eventually identify a subset of HF patients prone to renal dysfunction.

Renal arterial haemodynamics could be quantitatively evaluated through renal resistive index (RRI) of Doppler arterial waveform. RRI is derived from Pourcelot's formula: (peak systolic velocity – end diastolic velocity) / peak systolic velocity. The relationship between RRI and arterial resistances is not completely linear. A number of other variables are involved in this interaction, such as vascular stiffness and rhythm disturbances (Mostbeck et al. 1990; Bude and Rubin 1999; Tublin et al. 1999; Murphy and Tublin 2000). Moreover, central venous pressure (CVP) has shown to be positively correlated with RRI: an increase in central venous and intra-abdominal pressure could be transmitted to the renal parenchyma by the stiff capsule leading to an increase in renal interstitial pressure and consequently in arterial resistances (Ciccone et al. 2014). Doppler evaluation of arterial circulation is performed with an anterior approach and a convex probe or with a posterior approach in sitting position and an echocardiographic phased-array probe. Renal arteries are sampled at the level of segmental arteries with a good feasibility. The median value of RRI in healthy adults is 0.60, with slight variations between right and left kidneys (Darmon et al. 2010). RRI evaluation is generally reproducible, with low intraobserver and interobserver variability (Lubas et al. 2014). RRI values above 0.70 are considered abnormal.

The prognostic role of RRI has been evaluated first in patients with chronic nephropathy, where higher values have been shown to correlate with greater degree of parenchymal fibrosis, an increased risk for progression of kidney disease and a generally poor outcome (Platt et al. 1990; Parolini et al. 2009; Hanamura et al. 2012). In the population of patients with HF, RRI has proven

to be useful in risk stratifying patients with both preserved (HFpEF) and reduced (HFrEF) ejection fraction. In the HFpEF population, it has been correlated with poor prognosis, i.e. a greater risk for death and HF related hospitalization (Ennezat et al. 2011). Later on, RRI has been also evaluated in the cohort of outpatients with HFrEF. In this setting, it was associated with a number of endpoints related to progression of heart failure. Patients with higher RRI values are considered at higher risk for HF related hospitalization, all cause death, death due to HF and urgent heart transplantation (Ciccone et al. 2014). RRI could also identify CHF patients prone to poorer renal prognosis, such as those at risk for diuretic resistance (considered as the need for higher diuretic doses) and WRF, during a mid and long-term follow up (Iacoviello et al. 2015; Iacoviello et al. 2016). The prognostic role of RRI in HF has been demonstrated to be independent and incremental, when compared to renal function evaluated with serum creatinine and GFR (Ciccone et al. 2014). RRI could be used together with established laboratory renal markers to better characterize renal function of HF patients, thus integrating information provided by estimated GFR and microalbuminuria (Leone et al. 2016). However, further studies are needed to confirm clinical usefulness of this imaging approach.

In a similar way, scientific efforts should be made to clarify the possible role of renal venous Doppler pattern, which has been recently proposed as a tool to better evaluate renal congestion. Indeed, the renal venous congestion plays a key role in kidney physiology. This has been already demonstrated in the first decades of the last century in an experimental ex-vivo model. High renal venous pressure more than low renal perfusion pressure was associated with a reduction of glomerular filtration rate (Winton 1931). This has been recently observed also in acute as well as in chronic heart failure (Mullens et al. 2009; van de Wal et al. 2005). Renal congestion can lead to a fall in glomerular filtration in two ways. High venous pressure can be transmitted upstream to capillaries at glomerular and tubular level, causing in turn a reduced artero-venous gradient through renal circulation. Moreover, because of the tight renal capsule, high pressure can be transmitted to renal interstitial and then to tubular space. Tubular hypertension can affect upstream capsular hydrostatic pressure, one of the driving forces of glomerular filtration (Tublin et al. 2003). According to this pathophysiological background, the evaluation of renal venous flow could provide information about the presence of increased renal pressure due to peripheral congestion (Jeong et al. 2011). Venous impedance index (VII) has been used as a measure of venous pulsatility. It is calculated as peak maximum flow velocity minus maximum flow velocity at nadir, divided by peak maximum flow velocity (Ishimura et al. 1997). However, as minimum velocity is considered, VII is useful unless intermittent flow is observed. On the other hand, intrarenal venous flow pattern has been shown to be significantly associated with central venous pressure. In the setting of HF patients, venous flow has been classified as continuous or discontinuous, and among those as monophasic or biphasic discontinuous. Discontinuous patterns identify the subset of patients with worse renal function and high central venous pressure. Finally, they were associated with poor prognosis, considered as cardiovascular death and HF hospitalization (Iida et al. 2016). In other series of patients, venous flow has been divided into five groups: continuous with a normal velocity decrease in diastole, continuous with reduced modulation, monophasic with short presystolic interruption or reversal (corresponding to atrial systole), polyphasic intermittent and monophasic intermittent flow. Even in this cohort of patients, the last two intermittent flow patterns are observed in more compromised patients who show worse outcome. Interestingly, the pattern with short presystolic interruption represents a group at intermediate risk, with mild increase in central venous pressure and probably an early renal involvement (Puzzovivo et al. 2016).

5.3 Other Imaging Techniques

Other imaging techniques have been explored for the functional evaluation of the kidneys. Nuclear imaging is based on the use of radioisotopes bound to non-metabolized molecules with known pharmacokinetics. Among the different radioisotopes, Technetium (^{99m}Tc) is the molecule of choice because of its short half-life and low radiation exposure. For assessment of GFR, ^{99m}Tc–DTPA (diethylenetriaminepentaacetic acid) is used. DTPA is eliminated by filtration without entering the cells, and being neither secreted nor reabsorbed by the tubules. GFR values obtained with ^{99m}Tc–DTPA are slightly lower compared to inulin (Haufe et al. 2006). ^{99m}Tc–MAC3 (mercaptoacetyltriglycine) is used for renal blood flow estimation. In the setting of pre-renal azotemia (as in HF), ^{99m}Tc–MAC3 uptake is generally normal in the first 1–2 min, whereas it is reduced in vascular and parenchymal causes and in acute tubular necrosis. After 20 min, MAC3 uptake is increased in pre-renal azotemia, vascular causes and acute tubular necrosis, while it is reduced in parenchymal and obstructive diseases (Kalantarinia 2009). Positron emission tomography (PET), especially combined with CT to enhance spatial resolution, allows a functional and molecular evaluation of the kidney. It could be useful to determine GFR, renal blood flow and to assess the tissue activity of transporters, enzymes and receptors. However, this technology is not widely available for clinical purposes and at the moment it is limited only to the experimental setting (Haufe et al. 2006; Kalantarinia 2009).

Computed tomography (CT) is considered the gold standard for the diagnosis of nephrolithiasis, renal masses and parenchymal diseases. Triphasic helical CT after contrast injection can be used to evaluate functional parameters, as GFR and renal blood flow (Hackstein et al. 2004). However, in the clinical setting of HF, especially in patients with renal impairment, it has limited feasibility and scarce literature because of the high risk of contrast induced nephrotoxicity.

Magnetic resonance imaging (MRI) is a fast growing field in the setting of kidney disease especially because it combines anatomical and functional evaluation of the kidney. The main limitations to its widespread use is the lack of standardized sequences and postprocessing softwares, and for this reason it is confined, so far, to the research field (Michaely et al. 2007). MRI could be used to estimate classical parameters such as GFR and renal blood flow. GFR quantification is based on the kinetics of a gadolinium-containing contrast medium which is eliminated only through glomerular filtration, being not reabsorbed nor secreted by the tubules (Hackstein et al. 2003; Boss et al. 2007). On the other hand, renal blood flow can be evaluated with phase-contrast MRI of the renal artery. This method relies on magnetically excited arterial water molecules used as endogenous tracer for perfusion imaging (Roberts et al. 1995). Together with these approaches, used to assess these conventional parameters, some other techniques are under development for further functional evaluations. With this regard, BOLD (blood oxygenation level dependent) MRI seems to be a promising tool; it works by exploiting the magnetic properties of haemoglobin in order to evaluate the degree of tissue oxygenation of renal parenchyma. Deoxygenated haemoglobin has paramagnetic activity as opposed to oxygenated haemoglobin which is diamagnetic. The increase in tissue deoxygenated haemoglobin during oxygen extraction leads to a decrease in T2* signal, corresponding to the degree of tissue oxygenation. Since renal parenchyma shows a physiological heterogeneous oxygenation with the medulla working at lower oxygen levels, in the setting of HF, BOLD MRI of this region could be especially sensitive to early prerenal kidney injury (Simon-Zoula et al. 2006; Artunc et al. 2011).

6 Renal Dysfunction and HF Treatment

Current recommended therapies for HF patients have been shown to improve functional status

and survival but, in some cases, they could negatively interact with renal function. Patients with HF and renal dysfunction are usually underrepresented in randomized controlled trials on cardiovascular diseases and there are relatively limited data on the baseline renal function and on the effects of treatment on renal disease (Coca et al. 2006). The subgroup of patients with severely decreased renal function (GFR <30 mL/min/1.73m^2) has been generally excluded from clinical trials and therefore there is lack of evidence-based therapies in this population (Ponikowski et al. 2016).

6.1 ACE Inhibitors and Angiotensin II Receptor Blockers

The favourable effect of Angiotensin-converting enzyme inhibitors (ACE-I) and Angiotensin II receptor blockers (ARB) on cardiac function and survival in patients with HF has been well established (Ponikowski et al. 2016). They have shown to improve symptoms and exercise capacity, reduce the risk of hospitalization and mortality (Chang et al. 2010; Garg and Yusuf 1995). ACE-I are recommended, unless contraindicated, in all symptomatic HF patients, while ARB are recommended in patients who are ACE-I intolerant (Chang et al. 2010). In the last European guidelines, ACE-I are also recommended in patients with asymptomatic LV systolic dysfunction to reduce the risk of symptoms development, hospitalization and death (Ponikowski et al. 2016). In the subgroup of patients with HF and moderate renal dysfunction (GFR 30–59 ml/min/1.73 m^2) there is evidence of favorable outcome with ACE-I therapy (Bowling et al. 2012; Massie et al. 2001; Tokmakova et al. 2004). ACE-I might also be beneficial and considered in patients with severe renal dysfunction (GFR <30 ml/min/1.73 m^2), however there are no conclusive data (Bowling et al. 2012). Analogously, there is moderate evidence for the use of ARB in the population of patients with HF and moderate renal dysfunction, whereas there are no data available on the effect of ARB in severe renal disease (Granger et al. 2003). ACE-I and ARB are contraindicated in pregnancy, history of angioedema, bilateral renal artery stenosis and previous allergy to ACE-I/ARB. Recommended dose of ACE-I/ARB should be adjustment according to GFR (Table 3) (Damman et al. 2014b). Caution is advised in patients who experience hyperkalemia (>5 mmol/l) and/or severe renal dysfunction. An early increase in serum creatinine is relatively common during initiation and uptitration of ACE-I/ARB therapy (10–35% of patients). This deterioration in renal function is usually small and does not have the same adverse prognostic implications as other kind of WRF in HF natural history (Testani et al. 2011). However, an extreme decrease in renal filtration function is dangerous. In patients with severe renal dysfunction, the renin-angiotensin system blockade is known to impair the autoregulatory mechanisms and make glomerular filtration critically dependent on renal blood flow (Metra et al. 2012). The degree of creatinine increase that should warrant therapy discontinuation is uncertain. The European guidelines suggest that an increase in creatinine of up to 50% above baseline or an increase in potassium to $\leq$5.5 mmol/L is acceptable (Ponikowski et al. 2016). If greater rises in creatinine or potassium are observed, the dose of ACE-I/ARB should be reduced. If creatinine increases by $>100\%$ or to >3.5 mg/dl and/or GFR <20 ml/min/1.73 m^2, therapy should be discontinuated. Renal function and electrolytes should be checked before initiation of ACE-I/ARB therapy, 1–2 weeks after initiation and final uptitration, and every 4 months after the final dosage is achieved. Blood chemistry should be also checked after dose reduction in case of WRF.

6.2 Mineralcorticoid Receptor Antagonists

Mineralcorticoid receptor antagonists (MRA) act by blocking the receptor that binds aldosterone. Two MRAs, spironolactone and eplerenone, have been demonstrated to reduce mortality and hospitalization in HF with reduced ejection

Table 3 Dose adjustment of treatments in patients with impaired renal function (Tokmakova et al. 2004)

Drug	Dose Adjustment
ACE-I	
Captopril	GFR >40: no adjustment
	GFR 20–40: 1/2 dose
	GFR 10–20: 1/4 dose
	Dialysis: 1/8 dose
Enalapril	GFR 30–80: no adjustment
	GFR 10–30: 1/2 dose
	Dialysis: only dose on dialysis days
Lisinopril	GFR 30–80: no adjustment
	GFR 10–30: 1/2 dose
	Dialysis: only dose on dialysis days
Ramipril	GFR 30–60: no adjustment
	GFR 10–30: 1/2 dose
	Dialysis: only dose on dialysis days
ARB	
Candesartan	GFR >15: Starting dose 4 mg/die than dose uptitration based on response
	GFR <15 or dialysis: no experience
Valsartan	GFR >10: no adjustment
	GFR <10 or dialysis: no experience
Losartan	No adjustment
MRA	
Spironolactone	GFR >60: no adjustment
	GFR 30–60: every other day regimen
Eplerenone	GFR >60: no adjustment
	GFR 30–60: every other day regimen

fraction (Pitt et al. 1999, 2003; Zannad et al. 2011). Therefore, MRA are recommended in all symptomatic patients with HF and reduced ejection fraction (LVEF $\leq$35%) despite treatment with an ACE-I/ARB and beta-blockers (Ponikowski et al. 2016). The beneficial effects of spironolactone and eplerenone have shown to be consistent irrespective of baseline renal function. There is convincing evidence for the use of MRA in patients with HF and moderate renal dysfunction. However, no data are available the setting of severe renal dysfunction because these patients were excluded from the randomized clinical trials (Vardeny et al. 2012). Therefore, MRA are contraindicated in patients with baseline GFR <30 ml/min/1.73 m^2 and/or potassium >5.0 mmol/l and in patients with previous allergic reaction. Spironolactone and eplerenone should be initiated at a dose of 25 mg daily, increasing to 50 mg daily. For patients with moderate renal dysfunction or concerns of hyperkalemia an initial regimen of every-other-day dosing is advised (Table 3). As for ACE-I/ARB, MRA can determine an initial increase in serum creatinine. In the RALES trial, an increase in creatinine was more common in the spironolactone group compared to placebo. However, WRF was not associated with worse outcome in this group, in contrast to WRF of the placebo group (Vardeny et al. 2012). The main concern associated with use of MRA is hyperkalemia, which is relatively common in the clinical practice (25% of patients) and occurs mostly in patients with reduced baseline GFR. The development of potassium >5.5 mmol/l and/or creatinine >2.5 mg/dl and/or GFR <30 ml/min/1.73 m^2 should trigger dose reduction of MRA. In case of potassium levels

>6.0 mmol/l and/or creatinine >3.5 mg/dl and/or GFR <30 ml/min/1.73 m^2, MRA should be discontinuated. Renal function and electrolytes should be checked at 1 and 4 weeks after initiation/uptitration, monthly for the first 3 months and every 3–4 months thereafter.

6.3 Angiotensin Receptor Neprilysin Inhibitors

Angiotensin receptor neprilysin inhibitors (ARNI) is a new class of drugs recently developed. LCZ696 is the first agent of this class and combines the neprilysin inhibitor prodrug sacubitril and the ARB valsartan. The active metabolite of sacubitril inhibits neprilysin, leading to a slowed degradation of natriuretic peptides and bradikinin. Higher blood levels of vasoactive peptides are responsible for the favourable cardiovascular effects, such as increased diuresis and natriuresis, vasodilatation and myocardial anti-remodeling effect (McCormack 2016). In the recent PARADIGM-HF trial, sacubitril/valsartan has demonstrated to be superior over enalapril in reducing mortality and hospitalization in a population of ambulatory HFrEF patients with LVEF <40% (later amended to <35%) and high BNP levels (McMurray et al. 2014a). Sacubitril/valsartan is therefore recommended as a replacement for ACE-I in patients with these characteristics who remained symptomatic despite optimal medical treatment (Ponikowski et al. 2016). In the PARADIGM-HF, 37% of enrolled patients had a baseline GFR <60 ml/min/1.73 m^2 (McMurray et al. 2014b). Reduced GFR at the enrolment did not modify the effect of sacubitril/valsartan on mortality and morbidity, as shown in a subgroup analysis (McMurray et al. 2014a). Up to now, there is very limited clinical experience in patients with severe renal dysfunction, as those patients were excluded from the previous studies. Sacubitril/valsartan is contraindicated with concomitant use of an ACE inhibitor. Other contraindications related to valsartan should also be considered. The initial recommended dose of sacubitril/valsartan is 49/51 mg twice daily, increased to 97/103 mg after 2–4 weeks. An initial dose of 24/26 mg twice daily should be considered in patients with moderate renal dysfunction. The effect of sacubitril on renal dysfunction is of interest because neprilysin inhibition is expected to have favourable effect on kidney function (Judge et al. 2015). This renoprotective effect is probably related to the slower degradation of natriuretic peptides and it has been observed in both the studies on sacubitril/valsartan. In the PARAMOUNT trial, GFR decreased to a greater extent in the valsartan group compared to the sacubitril/valsartan group (Solomon et al. 2012). In the PARADIGM-HF, significant increase in creatinine levels (>2.5 mg/dl) and discontinuation of the treatment because of renal impairment were less frequent in the sacubitril arm in comparison to the enalapril group (McMurray et al. 2014a). Further data on the renoprotective role of sacubitril/valsartan will come from the ongoing Heart and Renal Protection III (UK HARP-III) trial, which will compare sacubitril/valsartan with irbesartan in a population of CKD patients with proteinuria and GFR between 20 and 60 ml/min/1.73m^2.

6.4 Hydralazine and Nitrates

In CHF hydralazine is generally used in combination with high doses of oral nitrates, as isosorbide dinitrate (ISDN). Both these molecules are vasodilator drugs with a complementary "nitroprusside-like" hemodynamic effect, caused by the predominant venodilatory action of ISDN and the arterial-dilatory effect of hydralazine (Bauer and Fung 1991). The first data on the clinical effects of the association of hydralazine and isosorbide dinitrate (H-ISDN) come from a small RCT on 642 men treated with digoxin and diuretics. In this population, H-ISDN was associated with a trend towards mortality reduction compared to placebo (Cohn et al. 1986). In a subsequent study, the African-American Heart Failure Trial (A-HeFT), the

addition of H-ISDN to conventional therapy significantly reduced mortality and HF hospitalizations in African-American patients affected by HF (Taylor et al. 2004). The results of A-HeFT are difficult to translate to non-African-American patients, therefore in this population the mortality benefit remains uncertain. In the HF European guidelines, H-ISDN is recommended in self-identified African-American patients with HFrEF, symptomatic despite standard treatment. H-ISDN may also be considered in symptomatic patients intolerant or with contraindications to RAAS blockers (Ponikowski et al. 2016). In patients with advanced HF, the acute treatment with intravenous hydralazine showed positive changes on the renal hemodynamics. Hydralazine decreased total renal resistance and significantly increased renal blood flow, with preservation of GFR (Cogan et al. 1980). Similar results were observed after oral hydralazine therapy. The favorable hemodynamic effect was associated with a significant increase in creatinine clearance (Pierpont et al. 1980). Data from a post-hoc analysis of the A-HeFT, demonstrate that the beneficial effects of H-ISDN on event-free survival were consistent across subgroups, in particular in patients with and without history of chronic heart failure (Taylor et al. 2007). Because of its neutral effect in kidney disease, H-ISDN is frequently prescribed, in clinical practice, to patients with HF and renal failure or hyperkalemia, in whom ACE-I/ARB use could be complicated or contraindicated (Ziaeian et al. 2017; Giamouzis et al. 2011).

6.5 Diuretics

Despite the beneficial effects on renal haemodynamics due to the RAAS inhibition, the sodium excretion capacity of kidneys remains often poor, leading to sodium retention and fluid overload. The goal of diuretic therapy in HF is to relieve signs and symptoms of congestion by stimulating diuresis and natriuresis. Diuretics act by inhibiting the reabsorption of sodium at tubular level. The loop diuretics (furosemide, bumetanide and torasemide) operate at the level of the ascending limb of the loop of Henle and are the cornerstone of symptoms management in HF patients. On the other hand, thiazide diuretics act in the distal convoluted tubule and are mainly used as antihypertensive agents. Diuretic treatment is generally initiated with the minimum effective dose and then adjusted according to the therapeutic response. The symptomatic benefit of diuretics is universally accepted; nevertheless, no randomized controlled trial has prospectively evaluated their effects on morbidity and mortality. A small meta-analysis on loop and thiazide diuretics showed a possible favorable effect on mortality and hospitalization in the HF general population (Faris et al. 2012), but no prognostic data are available in the specific setting of HF and renal dysfunction (Damman et al. 2014b).

However, diuretics may have detrimental effects of renal function. Because of their mechanism of action, a prolonged use has been shown to worsen renal function in patients with both normal and reduced filtration capacity (Bayliss et al. 1987). The mechanisms involved are hypovolemia with renal hypoperfusion which, in turn, causes a reduction of glomerular perfusion pressure and renal arteriolar constriction mediated by neurohormonal upregulation (Bayliss et al. 1987). The degree of renal dysfunction has been shown to influence the variability of diuretic response among HF patients. Indeed, renal impairment is associated with a downward and right shift of the dose-response curve, leading to higher doses required to achieve the same level of sodium excretion (Ellison 2001). An altered dose-response relationship could lead to a self-perpetuating vicious circle with higher loop diuretic dosages needed for symptoms relief, which have been demonstrated to be independently associated with mortality (Eshaghian et al. 2006).

Furthermore, renal disease is one of the main causes of diuretic resistance, i.e. the lack of treatment response and the inability to achieve a negative fluid balance. In patients with impaired renal function, poor kidney perfusion as well as low protein levels are responsible for the reduced

concentration of loop diuretics that reach peritubular capillaries. Moreover, high levels of urate and other endogenous organic anions compete with loop diuretics for the organic anion transporter. Finally, filtered albumin can bind loop diuretics in the tubular lumen, preventing their effect at their site of action (Verbrugge et al. 2016). Diuretic resistance frequently requires an adequate fluid and/or sodium restriction and increasing loop diuretic dose is often a solution to the problem. Furthermore, adding either thiazides or metolazone, and eventually MRA, on top of loop diuretic therapy could be of further help in case of severely impaired renal function. Indeed, the sequential nephron blockade may be useful in order to overcome the upregulation of thiazide-sensitive sodium transporter and the renal adaptation of distal tubules that increase the capacity to reabsorb sodium (Verbrugge et al. 2016). Unfortunately, the combined diuretic therapy is associated with enhanced risk of electrolytes disturbances (hypokalemia, hypomagnesemia, hyponatremia), hypovolemia and renal impairment. Blood chemistry and volume status should be periodically checked in order to adjust the diuretic dose and maintain euvolemia. In case of significant hypokalemia (<2.5 mmol/l) and/or severe renal dysfunction a dose reduction or the discontinuation of thiazide diuretics should be considered.

7 Conclusion

Kidney disease is highly prevalent in subjects affected by heart failure and has a negative prognostic value independently of the degree of cardiac dysfunction. Therefore, an accurate renal function evaluation is relevant to identify patients prone to worse outcome. GFR estimation based on serum creatinine levels is considered the easiest way to assess overall kidney function in clinical practice and it is routinely used in HF patients management. However, several limitations in the use of serum creatinine exist. To overcome some of the caveats related to creatinine, several new glomerular and tubular markers have been studied. Emerging renal biomarkers have demonstrated to carry incremental diagnostic and prognostic information in renal diseases and identify renal impairment at an earlier stage. In addition to laboratory data, imaging techniques have shown to give complementary information in HF-related renal dysfunction. In particular, Doppler evaluation can explore renal arterial and venous haemodynamics, giving independent and incremental prognostic information. Finally, the management of patients with significant renal impairment and concomitant heart failure is still a major challenge. Unfortunately, because of the underrepresentation of patients with renal dysfunction in HF clinical trials, limited data are available for this specific subgroup. With this regard, current evidences support the use of HF drugs in patients with moderate renal dysfunction, but data on the population with severe and end-stage renal dysfunction are still lacking. Lastly, the new ARNI class showed a promising renoprotective effect in recent clinical trials, but further data are expected about its safety in patients with severe renal dysfunction.
